Preface

Part I. General Physiology

Section 1. General Physiology

Introduction

1.1. Functional organization, composition and internal environment of human body

Functional organization of the human body

Body composition

Internal environment and homeostasis

1.2. The cell physiology

Cell structure

The cell membrane

Intercellular junctions

1.3. Transport through cell membrane

Passive transport

Active transport

Vesicular transport

Other transport processes

1.4. Membrane potential

Introduction

Genesis of membrane potential

Recording of membrane potential

1.5. Genetics: An overview

Structural and functional characteristics of substrate for genetics

Applied genetics

Part II. Systemic Physiology

Section 2. Nerve Muscle Physiology

Introduction

2.1. The nerve

Functional anatomy

Biological activities

Electrical properties of nerve fibre

Physiological properties of nerve fibres

Nerve fibre types

Degeneration and regeneration of neurons

Factors promoting neuronal growth

2.2. Neuromuscular junction

Structure of neuromuscular junction

Neuromuscular transmission

Drugs affecting and disorders of neuromuscular junction

2.3. Skeletal muscle

Introduction

Functional anatomy and organization

Process of muscle excitability and contractility

Characteristics of muscle excitability and contractility

Some characteristics of the skeletal muscles in the intact body

Electromyography and common disorders of muscles

Source of energy and metabolic phenomenon during muscle contraction

2.4. Smooth muscle and cardiac muscle

Smooth muscle

Cardiac muscle

Comparison of skeletal, smooth and cardiac muscles

Section 3. Blood and Immune System

Introduction

Functions of blood

Immune system

3.1. Plasma and plasma proteins

Plasma

Plasma proteins

3.2. Red blood cells and anaemias

Characteristic features of red blood cells

Formation of red blood cells

Haemoglobin

Red cell fragility

Lifespan and fate of red blood cells

Bilirubin and jaundice

Anaemias

3.3. White blood cells

White blood cells types and their counts

Formation of white blood cells

Morphology, functions, lifespan and variations in counts of WBCs

Applied aspects

3.4. Immune mechanisms

Introduction

Architecture (components) of immune system

Immunity

Antigens

Antibodies

Development of immune response

Other immune mechanism-related aspects

3.5. Platelets, haemostasis and blood coagulation

Platelets

Haemostasis

Blood coagulation

Clotting factors

Mechanism of coagulation

Antithrombotic mechanisms

Bleeding disorders

3.6. Blood groups and blood transfusion

Blood groups

Blood transfusion

Blood components

Section 4. Cardiovascular System

Introduction

Functions of CVS

Physiology of CVS

4.1. Functional anatomy of heart and physiology of cardiac muscle

Functional anatomy of heart

Physiology of cardiac muscle

4.2. Origin and spread of cardiac impulse and electrocardiography

Origin and spread of cardiac impulse

Electrocardiography

4.3. Heart as a pump: Cardiac cycle, cardiac output, and venous return

Cardiac cycle

Cardiac output and venous return

4.4. Dynamics of circulation: Pressure and flow of blood and lymph

Introduction

Functional organization and structure of vascular system

Haemodynamics

Pressure and flow in various functional segments of systemic vascular tree

Blood pressure

4.5. Cardiovascular regulation

Introduction

Neural control mechanism

Humoral control mechanisms

Local control mechanisms

4.6. Regional circulation

Introduction

Coronary circulation

Cerebral circulation

Cutaneous circulation

Skeletal muscle circulation

Splanchnic circulation

4.7. Cardiovascular homeostasis in health and disease

Cardiovascular homeostasis in health

Cardiovascular homeostasis in diseases

Section 5. Respiratory System

Introduction

5.1. Respiratory tract: Structure and functions

Functional anatomy

Functions of the respiratory system

5.2. Pulmonary ventilation

Introduction

Mechanics of pulmonary ventilation

Lung volumes and capacities

Pulmonary elastance and compliance

Work of breathing

5.3. Pulmonary circulation

Functional anatomy

Characteristic features of pulmonary circulation

Functions of pulmonary circulation

Regulation of pulmonary blood flow

5.4. Pulmonary diffusion

Introduction

Physics of gas diffusion and gas partial pressures

Alveolar ventilation

Alveolar ventilation–perfusion ratio

Alveolar air

Diffusion of gases through the respiratory membrane

5.5. Transport of gases

Introduction

Transport of oxygen

Transport of carbon dioxide

5.6. Regulation of respiration

Introduction

Neural regulation of respiration

5.7. Respiration: Applied aspects

Introduction

Respiratory adjustments to stresses in health

Disturbances of respiration

Artificial respiration and cardiopulmonary resuscitation

Pulmonary function tests

Section 6. Excretory System

Introduction

Functions of excretory organs

Overview of excretory system

6.1. Kidneys: Functional anatomy and blood flow

Functional anatomy of kidneys

Renal blood flow

6.2. Mechanism of urine formation: Glomerular filtration and tubular transport

Introduction

Glomerular filtration

Tubular reabsorption and secretion

6.3. Concentration, dilution and acidification of urine

Concentration and dilution of urine: A mechanism to regulate urine volume and osmolality

Acidification of urine

6.4. Regulation of body fluid osmolality, composition and volume

Introduction

Body fluid compartments

Control of body fluid osmolality

Regulation of extracellular fluid volume and composition

Defence of specific ion composition

Disturbances of volume and concentration of body fluid

6.5. Applied renal physiology including renal function tests

Pathophysiology of common renal disorders

Diuretics

Renal function tests

Dialysis and renal transplantation

6.6. Physiology of micturition

Urinary bladder and urethra

Physiology of micturition

Abnormalities of micturition

Section 7. Gastrointestinal System

Introduction

Functions of gastrointestinal system

Physiology of gastrointestinal tract

7.1. Functional anatomy and general principles of functions of gastrointestinal system

Functional anatomy

General principles of gastrointestinal functions

7.2. Physiological activities in mouth, pharynx and oesophagus

Introduction

Mastication

Lubrication of food by saliva

Deglutition (swallowing)

7.3. Physiological activities in stomach

Functional anatomy

Physiology of gastric secretion

Physiology of gastric motility

Functions of stomach

Applied aspects

7.4. Pancreas, liver and gallbladder

Pancreas

Liver and gallbladder

7.5. Physiological activities in small intestine

Functional anatomy

Small intestinal secretions

Motility of small intestine

Functions of small intestine

Applied aspects

7.6. Physiological activities in large intestine

Functional anatomy

Large intestinal secretions and bacterial activity

Motility of large intestine

Defaecation

Functions of large intestine

Applied aspects

7.7. Digestion and absorption

Digestion and absorption of carbohydrates

Digestion and absorption of proteins

Digestion and absorption of fats

Absorption of water, electrolytes, minerals and vitamins

Applied aspects

Section 8. Endocrinal System

Introduction

Relationship between endocrine and neural physiology

Organization of endocrine system

8.1. General principles of endocrinal system

Hormones: Definition and classification

Hormones: General considerations

Hormone: Receptors and mechanism of action

Measurement of hormones

8.2. Endocrinal functions of hypothalamus and pituitary gland

Introduction and functional anatomy

Endocrinal aspects of hypothalamus

Anterior pituitary hormones

Posterior pituitary hormones

8.3. Thyroid gland

Functional anatomy

Thyroid hormones

Applied aspects of thyroid hormones

8.4. Endocrinal control of calcium metabolism and bone physiology

Introduction

Calcium, phosphorus and magnesium metabolism

Bone physiology

Calcitropic hormones

Applied aspects

8.5. Adrenal glands

Functional anatomy

Hormones of adrenal cortex

Applied aspects

Hormones of adrenal medulla

8.6. Pancreatic and gastrointestinal hormones

Endocrine pancreas

Applied aspects

Gastrointestinal hormones

8.7. Endocrinal functions of other organs and local hormones

Hormones of the heart

Hormones of the kidney

Pineal gland

Thymus

Local hormones

Section 9. Reproductive System

Introduction

9.1. Sexual growth and development

Prepubertal sexual growth and development

Puberty and adolescence

9.2. Male reproductive physiology

An overview of male reproductive system

Functional anatomy of testes

Functions of testes

Control of androgen secretion

Applied aspects

9.3. Female reproductive physiology

An overview of female reproductive system

Ovaries

Female sexual cycle

9.4. Physiology of coitus, pregnancy and parturition

Physiology of coitus

Physiology of pregnancy

Physiology of parturition

Applied aspects

9.5. Physiology of lactation

Development and functional anatomy of breast

Physiology of lactation

9.6. Physiology of contraception

Introduction

Contraceptive methods in females

Contraceptive methods in males

Section 10. Nervous System

Introduction

Organization of nervous system

Anatomical divisions of the nervous system

Functional divisions of the nervous system

Understanding the nervous system

10.1. Physiological anatomy, functions and lesions of spinal cord and brainstem

Physiological anatomy and functions of spinal cord

Physiological anatomy and functions of brainstem

Tracts of spinal cord and brainstem

Lesions of spinal cord and brainstem

10.2. Physiological anatomy, functions and lesions of cerebellum and basal ganglia

Cerebellum

Basal ganglia

10.3. Physiological anatomy, functions and lesions of thalamus and hypothalamus

Thalamus

Hypothalamus

10.4. Physiological anatomy and functions of cerebral cortex and white matter of cerebrum

Cerebral cortex

White matter of cerebrum

10.5. Autonomic nervous system

Anatomical considerations

Physiological considerations

Applied aspects

10.6. Meninges, cerebrospinal fluid, blood–brain barrier and cerebral blood flow

Meninges of the brain

Cerebrospinal fluid

Blood–brain barrier and blood–CSF barrier

Cerebral blood flow

10.7. Synaptic transmission

Synapse: Definition and types

Chemical synapse

Neurotransmitters

10.8. Somatosensory system

General sensory mechanism

Somatosensory system

10.9. Somatic motor system

Introduction

Components of somatic motor control system

Skeletal muscles: The effector organ of somatic motor system

Reflex activity

Regulation of posture

Vestibular apparatus and equilibrium

10.10. Limbic system and physiology of emotional, behavioural and motivational mechanisms

Limbic system

Physiology of emotions

Physiology of motivation

Monoaminergic neuronal tracts and physiological basis of psychotic disorders

Physiological basis of psychotic disorders

10.11. Reticular formation, electrical activity of the brain, and alert behaviour and sleep

Reticular formation and reticular activating system

Electrical activity of the brain

Wakefulness and sleep

10.12. Some higher functions of nervous system

Language and speech

Learning and memory

Higher intellectual functions of the prefrontal association cortex

Section 11. Special Senses

Introduction

11.1. Sense of vision

Introduction and functional anatomy

Maintenance of clear refractive media of the eye

The image forming mechanism

Physiology of vision

Field of vision and binocular vision

Physiology of ocular motility

Aqueous humour and intraocular pressure

Physiology of pupil

11.2. Sense of hearing

Functional anatomy

Physiology of hearing

Applied aspects

11.3. Chemical senses: Smell and taste

The sense of smell

Sense of taste

Part III. Specialized Integrative Physiology

Section 12. Specialized Integrative Physiology

Introduction

12.1. Physiology of exercise and sports

Introduction

Responses to exercise

Effects of training

12.2. Environmental physiology

High-altitude physiology

Physiology of high atmospheric pressure

12.3. Physiology of acid–base balance

General considerations

Maintenance of blood pH

Acid–base disorders

Analysis and clinical evaluation of acid–base disorders

12.4. Physiology of body temperature regulation

Body temperature

Heat balance

Regulation of body temperature

Abnormalities of body temperature regulation

12.5. Physiology of growth and behavioural development

Growth and development

Behavioural development

12.6. Physiology of fetus, neonate and childhood

Introduction

Role of placenta in fetal physiology

Systemic physiology of fetus, newborn and childhood

12.7. Geriatric physiology

Introduction

Age-related changes in different organ systems

Theories of ageing

Modulating the process of ageing

Dedication

To the teachers and residents in physiology for their endeavour to dissipate and acquire knowledge. My parents and teachers for their blessings my children, Aruj, Bhawna and Arushi, for their patience and tolerance shown to loss of many precious moments and finally to my husband, Dr AK Khurana, for his understanding, encouragement and invaluable guidance

Preface

Indu Khurana

First edition of this book, published in 2006, was primarily aimed for the needs of undergraduate students. Undoubtedly, the text in some parts was a bit detailed, and this very fact was duly mentioned in the preface. However, it was never anticipated that it will become the book of choice for postgraduates in physiology. The undergraduate students also appreciated the text, but always demanded its reduced version. Such a feedback inspired the author to bring out another volume entitled “Medical Physiology for Undergraduate Students” in 2012. In view of the fast changing concepts in physiology and to cater to the needs of postgraduates, the second edition of “Textbook of Medical Physiology” has been thoroughly revised and updated. However, even undergraduates will find it as a useful resource for in-depth understanding of the subject and also for preparing for various postgraduate entrance tests.

Salient features of the second edition

- Thoroughly revised and updated second edition retains its well accepted unique style of organization of the text in three parts and twelve sections.
- Presentation of the text with various levels of headings, subheadings, boldface and italics has been maintained to help the students easily understand, retain and reproduce.
- Text has been updated incorporating the recent advances in each

section including more aspects of molecular physiology.

- Applied physiology has been updated with recent concepts on pathophysiology, and recent advances in the basic investigations and therapeutic principles.
- The book has been transformed into a fully four colored text enhancing lucidity and understanding of the figures and text.
- To further upgrade the book, many new figures, tables and flowcharts have been added.

Second edition of the book has been possible as a result of active criticism, suggestions and generous help of many teachers and students. Surely I owe sincere thanks to them all. Having Arushi Khurana, MD, from the Department of Internal Medicine, University of Connecticut, USA as a co-author has been very useful in updating the text, especially the applied and molecular aspects. I bow with reverence to my teachers: Prof B K Maini, Prof R K Marya, Prof P I Singh and Prof K K Mahajan for grooming me for this task. I wish to express by indebtedness to my husband, Sr. Prof A K Khurana, my son Dr Aruj K Khurana and daughter-in-law Dr Bhawna Piplani Khurana, who have not only helped me during each and every step but also have contributed the updated chapter on 'Sense of Vision'. Sr Prof Sushma Sood, HOD, Physiology has always encouraged and helped me by her academic discussions with a friendly approach. I am thankful to all the faculty members and residents of my department for their co-operation. Of incalculable help to me in updating this edition have been Dr Itika Singh and Dr Harminder. Dr Itika Singh has also contributed as co-author of the chapter on 'Physiology of Body Temperature Regulation'. I am also thankful to Dr Rakesh Gupta, who is just my younger brother and now elevated as Director of PGIMS, Rohtak, Prof Sarla Hooda, a sisterly friend and Registrar UHS and Prof V K Jain, Pro Vice Chancellor UHS, Rohtak. It is my special pleasure to thank Prof O P Kalra, Vice Chancellor, Pt. B D Sharma, UHS, Rohtak for infusing academic atmosphere. The encouragement received from the friends and stalwarts in Physiology especially, Prof Rashmi Mathur, AIIMS, New Delhi, Prof Asha Gandhi, Lady Hardinge Medical College, New Delhi, Prof Rashmi Babbar & Prof A K Jain, Maulana Azad Medical College, New Delhi, Dr Latika Mohan, Dean AIIMS, Rishikesh, Prof K D Singh, Principal GMC, Patiala, Prof Raj

Kapoor, HOD, VMMC, New Delhi, Prof D K Aggarwal, JLN Medical College, AMU, Aligarh, Prof Nilima Shankar & Prof Neelam Vaney, UCMS, New Delhi, Dr Nandini Kapoor, HOD, GMC, Chandigarh, needs special mention.

Lastly, it is my special pleasure to acknowledge with gratitude the most assured co-operation and skill of the staff of Elsevier, India especially Ms Shabina Nasim, Mr Shravan.

Dr Saurabh, Dr Ashima and Mr Majumdar deserve a special mention in this Preface for their artistic touch, which I feel provided a considerable beauty to this book.

Sincere efforts have been made to verify the correctness of the text, however in spite of best efforts some inaccuracies, ambiguities and typographical mistakes likely to be noticed by the readers. Therefore, feedback and suggestions from the teachers and students are invited for improving future edition. Feedbacks received shall be highly appreciated and duly acknowledged.

PART I

General Physiology

OUTLINE

Section 1. General Physiology

SECTION 1

General Physiology

OUTLINE

Introduction

- 1.1. Functional organization, composition and internal environment of human body
- 1.2. The cell physiology
- 1.3. Transport through cell membrane
- 1.4. Membrane potential
- 1.5. Genetics: An overview

Introduction

Physiology, in simple terms, refers to the study of normal functioning of the living structures. The *human physiology* is concerned with the way the various systems of the human body function, and the way each contributes to the functions of the body as a whole. In other words, the human physiology is concerned with specific characteristics and mechanisms of the human body that make it a living being, and the mechanisms which help in adaptation and homeostasis, which are the two fundamental features of life.

The *general physiology* envisages the general concepts and principles that are basic to the functions of all the systems. As we know, the fundamental unit of human body is a cell; therefore, this section includes a short review of fundamental aspect of the cell physiology. Before studying the general biophysiological processes and the cell physiology, it will be worthwhile to have a brief knowledge about the functional organization, composition and internal environment of the human body.

CHAPTER

1.1

Functional organization, composition and internal environment of human body

FUNCTIONAL ORGANIZATION OF THE HUMAN BODY

- Skin and its appendages
- Skeletal system
- Muscle system
- Nervous system
- Cardiovascular system
- Respiratory system
- Digestive system
- Excretory system
- Reproductive system
- Endocrine system
- Blood and immune system

BODY COMPOSITION

- Total body water
- Body electrolytes

INTERNAL ENVIRONMENT AND HOMEOSTASIS

- Internal environment
- Homeostasis
- Role of different systems
- Modes of action of homeostasis control systems

Functional organization of the human body

The human body is actually a social order of about 100 trillion cells organized into different functional structures, some of which are called organs, some organs combinedly form a system. For convenience of description, the human body can be considered to be functionally organized into various systems.

1. Skin and its appendages

Skin is the outermost covering of the human body. Its appendages include hairs, nails, sebaceous glands and sweat glands. In addition to providing mechanical protection to the underlying tissues, the skin performs following important functions:

- It acts as a physical barrier against entry of micro-organisms and other substances.
- It prevents loss of water from the body.
- It is a very important sensory organ, containing receptors for touch and related sensations.
- It plays an important role in regulating body temperature.

2. Skeletal system

The basic framework of the body is provided by a large number of bones

that collectively form the *skeleton*. At joints, the bones are united to each other by fibrous bands called *ligaments*. In addition to the bones and joints, the skeletal system also includes the *cartilages* present in the body.

3. Muscle system

Overlying and usually attached to the bones are various muscles. Muscles are composed of many elongated cells called *muscle fibres* which are able to contract and relax. Three distinct types of muscles can be identified, and they are skeletal muscles, smooth muscles and cardiac muscles.

4. Nervous system

The nervous system is made up, predominantly, of tissue that has the special property of being able to conduct impulses rapidly from one part of the body to another. The specialized cells that constitute the functional units of the nervous system are called *neurons*. The nervous system may be divided into: (i) the *central nervous system*, made up of brain and spinal cord, and (ii) the *peripheral nervous system*, consisting of the peripheral nerves and the ganglia associated with them. The nerves supplying the body wall and limbs are often called *cerebrospinal nerves*. The nerves supplying the viscera, along with the parts of the brain and spinal cord related to them, constitute the *autonomic nervous system*. The autonomic nervous system is subdivided into two major parts: the *sympathetic* and the *parasympathetic* nervous system.

5. Cardiovascular system

The cardiovascular system consists of the *heart* and the *blood vessels*. The blood vessels that take blood from the heart to various tissues are called *arteries*. The smallest arteries are called *arterioles*. Arterioles open into a network of *capillaries* that perfuse the tissues. Exchange of various substances between the blood and the tissues take place through the walls of capillaries. In some situations, capillaries are replaced by slightly different vessels called *sinusoids*. Blood from capillaries (or from sinusoids) is collected by small *venules* which join to form *veins*. The veins return blood to the heart.

6. Respiratory system

The respiratory system consists of the lungs and the passages through which air reaches them. The passages are nasal cavities, the pharynx, the trachea, the bronchi and their intrapulmonary continuations.

7. Digestive system

The digestive or the so-called alimentary system includes all those structures that are concerned with eating, and with the digestion and absorption of food. The system consists of an alimentary canal which starts at the mouth and ends at the anus. The alimentary canal includes the oral cavity, pharynx, oesophagus, stomach, small intestine and large intestine. Other structures included in the digestive system are the liver, the gall bladder and the pancreas.

8. Excretory system

Excretion is the removal of waste products of metabolism from the body. *Egestion* (or defaecation) is the removal of undigested food from the gut and is not regarded as excretion because the material taken into the gut through the mouth is not made by the body itself. The organs forming the excretory system are the kidney, the ureters, the bladder and the urethra.

9. Reproductive system

Reproduction is the production of a new generation of individuals of the same species. It involves the transmission of genetic material from one generation to the next. The *male reproductive organs* are the testis, the epididymis, the ductus deferens, and the seminal vesicles (which are paired), and the prostate, the male urethra and the penis (which are unpaired). The *female reproductive organs* are the right and left ovaries and uterine tubes, the uterus, the vagina, the external genitalia and the mammary glands.

10. Endocrine system

Endocrine tissue is made up essentially of cells that produce secretions which are poured directly into blood. The secretions of the endocrine cells are called *hormones*. Some organs are entirely endocrine in function. They are referred to as *endocrine glands* (or *ductless glands*). Those traditionally included under this heading are the hypophysis cerebral (pituitary gland), the pineal gland, the thyroid gland, the parathyroid glands, and the suprarenal (adrenal) glands. Groups of endocrine cells may be present in the organs that have other functions. These include the *islets of Langerhans* of pancreas, the interstitial cells of the testis, the follicles and corpora lutea of the ovaries. Hormones are also produced by some cells in the kidney, the thymus and the placenta. Some workers describe the liver as being partly an endocrine gland.

11. Blood and immune system

Blood is regarded as a modified connective tissue because the cellular elements in it are separated by a considerable amount of 'intercellular substance' and because some of the cells in it have close affinities to cells in general connective tissue.

Circulating blood normally contains three main types of cells which perform their respective physiologic functions: (i) the red cells (*erythrocytes*) are largely concerned with oxygen transport, (ii) the white cells (*leucocytes*) play various roles in the body defence against infection and tissue injury, and (iii) platelets (*thrombocytes*) which are primarily involved in maintaining integrity of blood vessels and in preventing blood loss. Detailed physiology of each organ system is considered in the relevant chapters.

Body composition

The normal body in an average adult male is composed of *water* (60%), *minerals* (7%), *protein* and related substances (18%), and *fat* (15%). The water, denoted by the term total body water (TBW), and the electrolytes need special emphasis.

Total body water

Water is the principal and essential constituent of the human body. The total body water is about 10% less in a normal young adult female (average 50%) than that in average adult male (60%) due to relatively greater amount of adipose tissue in the females. In both sexes, the value tends to decrease with age (Table 1.1-1).

TABLE 1.1-1

Total Body Water (% of Body Weight in Relation to Age and Sex)

Age (years)	Percent (%) of TBW	
	<i>Male</i>	<i>Female</i>
10-18	59	57
18-40	61	51
40-60	55	47
Above 60	52	46

The body fluid compartments

The total body water is distributed into two main compartments of the

body fluids separated from each other by membranes freely permeable to water (Fig. 1.1-1, Table 1.1-2):

FIGURE 1.1-1 Distribution of total body water in different compartments. Arrows indicate fluid movement.

TABLE 1.1-2

Distribution of Total Body Water in a Normal 70 kg Person

Compartment	Volume (L)	Percent (%)	
		Body weight	Body water
Total body water (TBW)	42	60	100
• Intracellular fluid (ICF)	28	40	67
• Extracellular fluid (ECF)	14	20	33
• Plasma (25% of ECF)	3.5	05	08
• Interstitial fluid, transcellular fluid and mesenchymal tissue fluid (75% of ECF)	10.5	15	25

1. Intracellular fluid compartment

The intracellular fluid (ICF) compartment comprises about 40% of the body weight, the bulk of which is contained in the muscles.

2. Extracellular fluid compartment

The extracellular fluid (ECF) compartment constitutes about 20% of the body weight. The ECF compartment comprises following:

i. Plasma

It is the fluid portion of the blood (*intravascular fluid*) and comprises about 5% of the body weight (i.e. 25% of the ECF). On an average out of 5 L of total blood volume, 3.5 L is plasma.

ii. Interstitial fluid including lymph

It constitutes the major portion (about 3/4) of the ECF. The composition of interstitial fluid is the same as that of plasma except it has little protein. Thus, interstitial fluid is an ultrafiltrate of plasma.

iii. Transcellular fluid

It is the fluid contained in the secretions of the secretory cells and cavities of the body, e.g. saliva, sweat, cerebrospinal fluid (CSF), intraocular fluids (aqueous humour and vitreous humour), pericardial fluid, bile, present between the layers (pleura, peritoneum and synovial membrane), lacrimal fluid and luminal fluids of the gut, thyroid and cochlea.

Transcellular fluid volume is relatively small, about 1.5% of the body weight, i.e. 15 ml/kg body weight (about 1 L in a person of 70 kg).

iv. Mesenchymal tissue fluid

The mesenchymal tissues such as dense connective tissue, cartilage and bones contain about 6% of the body water.

The interstitial fluid, transcellular fluid and mesenchymal tissue fluid combine to form 75% of ECF.

The normal distribution of total body water in the fluid compartments is kept constant by two opposing sets of forces: osmotic and hydrostatic pressure.

Measurement of body fluid volumes

Theoretically, it is possible to measure the volume of each fluid component by injecting a substance (indicator) that will stay in only one

compartment (provided the concentration of the substance in the body fluid and the amount removed by excretion and metabolism can be accurately measured) as:

$$V = \frac{A_1 - A_2}{C} \text{ where:}$$

V = Volume of fluid compartment,

A_1 = Amount of indicator injected in the fluid,

A_2 = Amount of indicator removed by excretion and metabolism and

C = Concentration of the indicator in the fluid.

For example, if 150 mg of sucrose (A_1) is injected into a 70 kg man, 10 mg sucrose (A_2) has been excreted or metabolized and the concentration of plasma sucrose (C) measured is 0.01 mg/ml; then the volume distribution of sucrose is:

$$\frac{150 \text{ mg} - 10 \text{ mg}}{0.01 \text{ mg/ml}} = 14,000 \text{ ml}$$

Prerequisites for accurate body fluid measurement.

Though the formula described above for measuring the body fluid volume appears simple, the material injected (indicator) should have following characteristics:

- It should be nontoxic.
- It must mix evenly throughout the compartment being measured.
- It should be relatively easy to measure its concentration.
- It must have no effect of its own on the distribution of water or other substances in the body.

- Either it must be unchanged by the body during the mixing period or the amount changed (excreted and/or metabolized) must be known.

This method of measuring body fluids is called '*indicator dilution method*' and can be used to measure the volume of different compartments of the body fluid by using suitable indicators/markers which will get distributed in that particular compartment as follows:

1. Measurement of total body water (TBW) volume

The volume of TBW can be measured by injecting a marker which will be evenly distributed in all the compartments of body fluid. Such markers include:

- Deuterium oxide (D_2O),
- Tritium oxide and
- Aminopyrine.

The volume of the TBW can be calculated from the values of the concentration of the marker in the plasma.

2. Measurement of extracellular fluid (ECF) volume

The volume of ECF can be measured by injecting those marker substances which cannot enter the cells but can freely pass through the capillary membrane, and thus can distribute evenly in all the compartments of ECF. Such substances include:

- *Radioactive substances* like sodium, chloride ($^{36}Cl^-$ and $^{38}Cl^-$), bromide ($^{82}Br^-$), sulphate and thiosulphate; and
- *Nonmetabolizable saccharides* like inulin, mannitol and sucrose.

The most accurate method of measuring the volume of ECF is by using *inulin* (polysaccharide, MW 5200). The values of ECF volume are calculated from the values of concentration of *inulin* in the plasma since it makes an important component of the ECF.

3. Measurement of plasma volume

The plasma volume can be measured by injecting those markers which bind strongly with the plasma protein and either do not diffuse or diffuse

only in small quantities into the interstitium. These substances are:

- Radioactive iodine— ^{131}I and
- The dye Evan's blue—T-1824.

The plasma volume can also be calculated from the values of the RBCs which can be measured using radioactive isotopes of chromium (^{51}Cr).

4. Measurement of intracellular fluid (ICF) volume

The volume of ICF cannot be measured directly, since there is no substance which can be confined exclusively to this compartment after intravenous injection. Therefore, values of ICF volume are calculated from the values of TBW and ECF as:

$$\text{ICF volume} = \text{TBW volume} - \text{ECF volume}$$

5. Measurement of interstitial fluid volume

Like ICF volume, the volume of interstitial fluid also cannot be measured directly for the same reasons. Its values can be roughly calculated from the values of ECF volume and plasma volume as:

$$\text{Interstitial fluid volume} = \text{ECF volume} - \text{plasma volume.}$$

The ECF volume/intracellular fluid volume ratio is larger in infants and children as compared to adults, but absolute volume of ECF in children is smaller than in adults. Therefore, dehydration develops rapidly, more frequently and severely in children than in adults.

Body electrolytes

The electrolytes constitute about 7% of the total body weight and they perform many major functions in the body. The distribution of electrolytes in various compartments differs markedly. [Table 1.1-3](#) shows the distribution of electrolytes in two major compartments of body fluid: the extracellular fluid (ECF) and the intracellular fluid (ICF).

TABLE 1.1-3

Distribution of Ions in the ECF and ICF (Values Are in mEq/L of H₂O)

Ion	Extracellular fluid	Intracellular fluid
<i>Cations</i>		
Na ⁺	142	14
K ⁺	5.5	150
Ca ²⁺	5	<1
Mg ²⁺	3	58
<i>Anions</i>		
Cl ⁻	103	4
HCO ₃ ⁻	28	10
PO ₄ ³⁻	4	75
Proteins	1 g/dL	5 g/dL

From [Table 1.1-3](#), it may be noted that in the ICF the main cations are K⁺ and Mg²⁺, and the main anions are PO₄³⁻ and proteins. It has low concentration of Na⁺ and Cl⁻. While in ECF, the predominant cation is Na⁺ and the principal anions are Cl⁻ and HCO₃⁻. Besides these, a small proportion of nondiffusible proteins and some diffusible nutrients and metabolites such as glucose and urea are also present in ECF. These differences are of great importance for the survival of tissues.

The essential difference between the two main subdivisions of ECF is the higher protein content in plasma than in the interstitial fluid which plays important role in maintaining fluid balance.

It is important to note that:

- Essentially all of the body K⁺ is in the exchangeable pool.
- Only 65–70% of the body Na⁺ is exchangeable.
- Almost all of the body Ca²⁺ and Mg²⁺ are nonexchangeable.
- Only the exchangeable solutes are osmotically active.

Functions of electrolytes

1. Electrolytes are the main solutes in the body fluids for maintenance of acid–base balance.
2. Electrolytes maintain the proper osmolality and volume of body fluids.
3. The concentration of certain electrolytes determines their specific physiologic functions, e.g. the effect of calcium ions on neuromuscular excitability.

Internal environment and homeostasis

Internal environment

Claude Bernarde (1949), the great French physiologist, introduced the term *internal environment* of the body or the *milieu interieur* for the extracellular fluid (ECF) of the body. He said so since all the body cells essentially depend upon the ECF for maintenance of cellular life. Cells are capable of living, growing and performing their special functions so long as the proper concentration of oxygen, glucose, different ions, amino acids, fatty substances and other constituents are available in the internal environment.

The composition of extracellular fluid vis-a-vis intracellular fluid has been discussed in the just preceding pages.

Homeostasis

Homeostasis, a term introduced by WB Cannon, refers to the mechanism by which the constancy of the internal environment is maintained and ensured. For this purpose, living membranes with varying permeabilities such as vascular endothelium and cell membrane play important roles in the exchange of fluids, electrolytes, nutrients and metabolites across the compartments of body fluids.

The factors involved in the maintenance of internal environment can be summarized as:

- Maintenance of pH of ECF (acid–base balance),
- Regulation of temperature,
- Maintenance of water and electrolyte balance,
- Supply of nutrients, oxygen, enzymes and hormones and
- Removal of metabolic and other waste products.

Role of different systems of the body in homeostasis

Almost all the systems of the human body play vital roles in the maintenance of the internal environment. The details of the role played by each system are described in the relevant chapters. The outlines of the contributions to different mechanisms of homeostasis made by different

functional systems of the body are summarized.

1. Transport of extracellular fluid

The circulatory system plays the most vital role in the transport of extracellular fluid (ECF) in the body. In this way, the ECF everywhere in the body, both the plasma and interstitial fluid, is continually being mixed, thereby maintaining almost complete homogeneity throughout the body.

2. Supply of oxygen and nutrients to ECF

The nutrients and oxygen are must to provide energy for various cell activities for the growth of the tissue. The respiratory system, digestive system, circulatory system and the musculoskeletal system play major roles in the supply of adequate amount of oxygen and nutrients. Hormones play an essential role in the metabolism of nutrients and other substances necessary for the cells.

3. Removal of metabolic end products and waste

Kidneys and other excretory organs are involved in the excretion of end products of metabolism and other waste products. Respiratory system plays a role in the removal of carbon dioxide from the body.

4. Water and electrolyte balance

in the body is maintained by a combined effort of kidneys, skin, lungs, salivary secretion and digestive system.

5. The pH of blood and acid–base balance

are maintained by the respiratory system, kidneys, blood and the various buffer systems in the body.

6. The temperature of the body

is maintained affirmably by a combined effort of the skin, cardiovascular system, respiratory system, digestive system, excretory system, skeletal muscle system and the nervous system.

7. Regulation of body functions

is very important for homeostasis. The nervous system and the hormonal system of regulation play key roles. The autonomic nervous system regulates all the vegetative functions of the body essential for homeostasis.

8. Reproduction

Reproduction is not considered a homeostatic function. However, it does help to maintain static conditions by generating new beings to take the place of those that are dying. This perhaps sounds like a permissive usage of the term homeostasis, but it does illustrate that, essentially all body structures are so organized that they help to maintain the automaticity and continuity of life.

Mode of action of homeostatic control system

The homeostasis is a complex phenomenon. The above-mentioned examples of homeostatic control mechanisms are only a few of the many hundreds to thousands in the body, all of which have certain characteristics in common. The mode of operation of all the systems, which are involved in the homeostasis, is through 'feedback' mechanism, and the adaptive control system. Feedback mechanism is of two types: the negative feedback mechanism and the positive feedback mechanism.

Negative feedback mechanism

Most control systems of the body act by negative feedback. That is, in general if the activity of a particular system is increased or decreased, a control system initiates a negative feedback, which consists of a series of changes that return the activity toward normal.

The degree of effectiveness with which a control system maintains constant conditions is determined by the gain of the negative feedback.

Examples of a feedback mechanism

1. When the blood pressure suddenly rises or lowers, it initiates a series of reactions that try to bring the blood pressure to normal levels.
2. When thyroxine secretion is in excess, it inhibits the secretion of thyroid stimulating hormone (TSH) from pituitary so that, thyroxine is not secreted from the thyroid gland.

Positive feedback mechanism

Positive feedback is better known as a vicious circle. Usually, it is harmful and in some instances even death can occur due to positive feedback. For example, as shown in [Fig. 1.1-2](#), when a person has suddenly bled 2 L of blood, a vicious circle of progressively weakening of the heart is set in motion, which ultimately causes death.

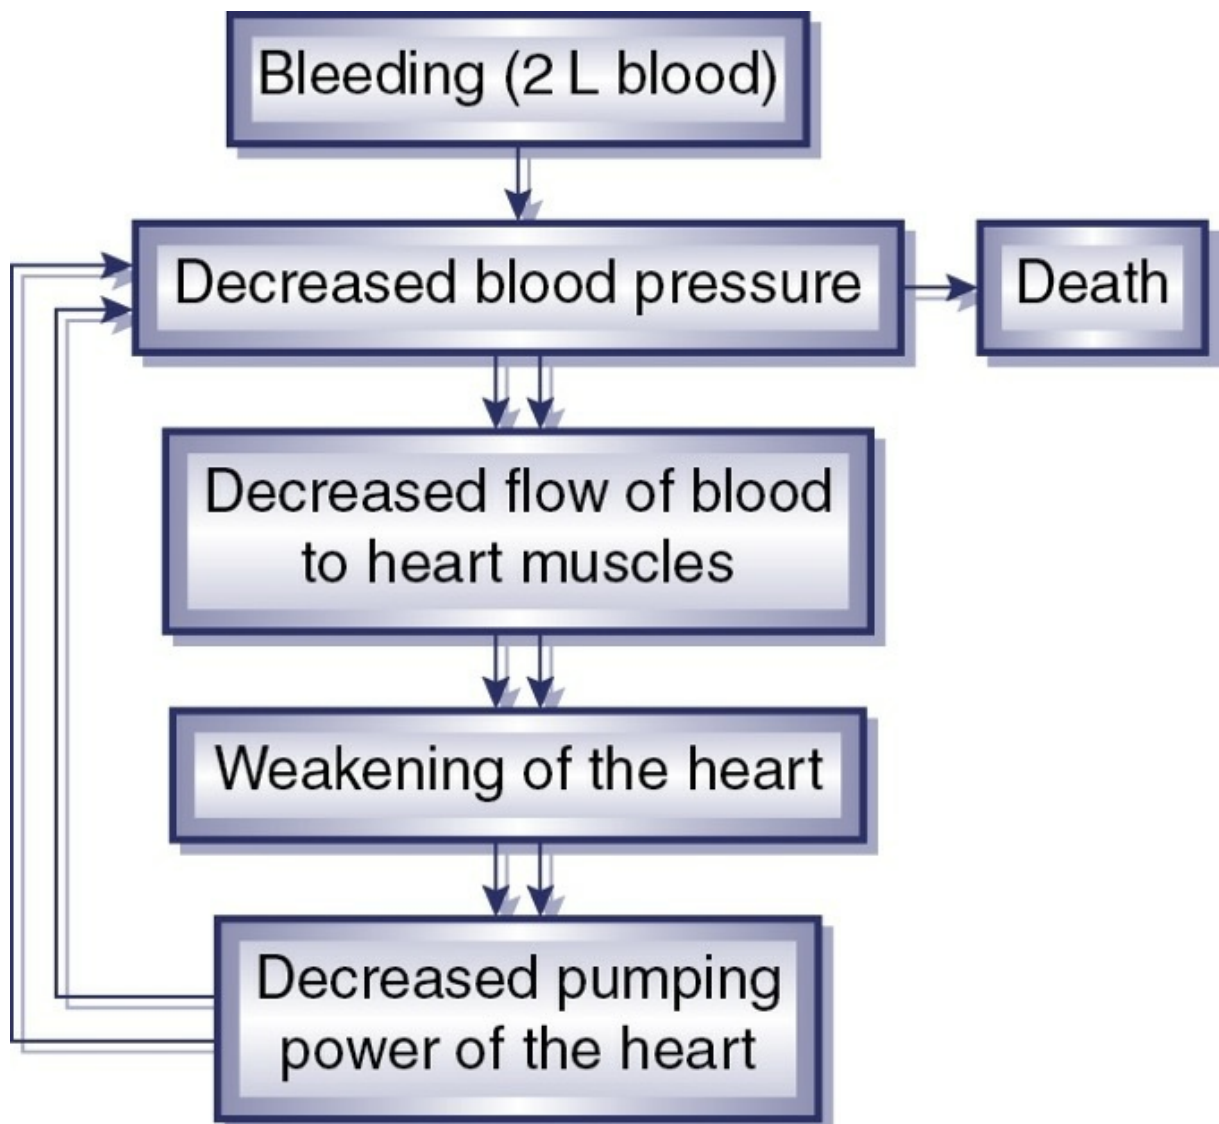

FIGURE 1.1-2 Showing how a positive feedback mechanism can cause death.

A mild degree of feedback can be overcome by the negative feedback control mechanisms of the body, and a vicious cycle fails to develop. For example, when a patient bleeds 1 L of blood instead of 2 L, the negative feedback mechanisms of controlling the blood pressure may overcome the positive feedback, and the blood pressure will return to normal, as shown in [Fig. 1.1-2](#).

Further, sometimes positive feedback can serve useful purposes, e.g. under following circumstances:

- *Clot formation* following rupture of vessels is accelerated by a vicious cycle of thrombin formation (for details see page 212). This stops the bleeding.
- *Child birth* during labour is facilitated by progressively increasing

uterine contractions due to positive feedback from stretching of cervix by head of the baby (for details see page 878).

- *Generation of nerve signals* by the vicious cycle of progressive leakage of Na^+ ions from the channels set up following stimulation of membrane of nerve fibre is due to the positive feedback.

Adaptive control system

Adaptive control system refers to a delayed type of negative feedback mechanism. This is seen in nervous system (for details see page 930). For example, when some movements of the body occur very rapidly, there is not enough time for nerve signals to travel from the peripheral parts of the body all the way to the brain and then back to the periphery again in time to control the movements. Under such circumstances, the brain uses a principle called *feed-forward control* to cause the required muscle contraction, which retrospectively is conveyed to the brain by the sensory nerve signals from the moving part. If the movement performed is found incorrect, then the brain corrects the *feed-forward signals* that it sends to the muscle the next time the movement is required. Such a correction made by successive retrospective feedback mechanism is called *adaptive control*.

CHAPTER

1.2

The cell physiology

CELL STRUCTURE

- Cell membrane
- Cytoplasm
- Nucleus

CELL MEMBRANE

- Fluid mosaic model
- Arrangement of different molecules in cell membrane

INTERCELLULAR JUNCTIONS

- Tight junction
- Adherens junction
- Gap junction

Cell structure

The cell is the smallest structural and functional unit of the body. The human body contains about 100 trillion cells. Different types of cells of the body possess features which distinguish one type from the other, and are specially adapted to perform one or few particular functions, e.g., the red blood cells transport oxygen from lungs to the tissues, the muscle cell is specialized for the function of contraction, the intestinal mucosal cells are specialized for absorption of foodstuffs and so on. However, most mammalian cells have an overall common structure and certain basic characteristics which are described.

Under normal conditions, cells are dynamic structures existing in fluid

environment. A typical cell, as seen by the light microscope, consists of three basic components:

- Cell membrane,
- Cytoplasm and
- Nucleus.

Cell membrane

Cell membrane or the plasma membrane is the protective sheath enveloping the cell body. It separates the contents of the cell from the external environment and controls exchange of materials between the fluid outside the cell (extracellular fluid) and the fluid inside the cell (intracellular fluid). A detailed knowledge of its structure ([Fig. 1.2-1](#)) is essential for the understanding of cell functions. Therefore, it will be discussed separately (see page 16).

FIGURE 1.2-1 Structure of a typical cell (in the centre) showing various organelles: **A**, mitochondrion; **B**, endoplasmic reticulum (rough and smooth); **C**, Golgi apparatus; **D**, centrosome; **E**, nucleus; and **F**, secretory granules.

Cytoplasm

Cytoplasm is an aqueous substance (cytosol) containing a variety of cell organelles and other structures. In eukaryotic cells, the nucleus and cytoplasm together form the protoplasm. The structures dispersed in the cytoplasm can be broadly divided into three groups: organelles, inclusion bodies and cytoskeleton.

A. Organelles

The organelles are the permanent components of the cells that are bounded by limiting membrane and contain enzymes, hence

participating in the cellular metabolic activity. These include the mitochondria, the endoplasmic reticulum, ribosomes, the Golgi apparatus, peroxisomes, centrosomes and centrioles.

1. Mitochondria

Mitochondria are the major sites for aerobic respiration. These are oval structures about 5–12 μm in length and 0.5–1 μm in diameter, and more numerous in metabolically active cells.

Structure

The mitochondria consist of:

- **Membranes.** There are two layers of the membrane: the outer smooth and inner folded into incomplete septa called cristae (Fig. 1.2-1A). Chemically and structurally, the membranes of mitochondria are similar to the cell membrane. The inner membrane in addition, contains lollipop-shaped globular structures present between the layers of membrane.
- **Matrix** of the mitochondria contains enzymes required in Krebs cycle by which products of carbohydrate, fat and protein metabolism are oxidized to produce energy, which is stored in the form of ATP in the lollipop-like globular structures.

Functions

In addition to their role as power-generating units, the mitochondria may have a role in synthesizing membrane-bound proteins, since they also possess DNA and ribosomes. The mitochondria have their own genome; however, the DNA of mitochondrial genome is much less than the nuclear genome. Mitochondrial DNA encodes 13 protein subunits which are associated with proteins and are coded by nuclear genes to form enzyme complexes and ribosomal transfer RNA (needed by intramitochondrial ribosomes for protein synthesis). The enzyme complexes responsible for oxidative phosphorylation include:

- Complex I—reduced nicotinamide adenine dinucleotide dehydrogenase (NADH)
- Complex II—succinate dehydrogenase ubiquinone oxidoreductase
- Complex III—ubiquinone-cytochrome C oxidoreductase

- Complex IV—cytochrome C oxidase

The complexes I, III and IV pump protons (H^+) into intermembranous spaces during electron transfer, and complex II along with complexes III and IV acts with complex I, coenzyme Q and cytochrome c and convert metabolites to carbon dioxide and water.

Mitochondria also have a role in apoptosis (programmed cell death).

Important Note

Mitochondrial DNA repair system is ineffective and mutation rate is higher as compared with nuclear DNA (10 times). Therefore, a large number of rare diseases due to mitochondrial DNA mutation have been traced, particularly in disorders of tissue associated with high metabolic rate.

2. Endoplasmic reticulum

Endoplasmic reticulum (ER) is a system of flattened, membrane-bound vesicles and tubules called *cisternae* (Fig. 1.2-1B). It is continuous with the outer membrane of the nuclear envelop, Golgi apparatus and possibly with the cell membrane. Morphologically, two types of endoplasmic reticulum can be identified: rough or granular and smooth or agranular.

i. Rough endoplasmic reticulum

The rough ER is characterized by presence of a number of ribosomes on its surface and transports proteins made by the ribosomes through the cisternae. Thus, the rough ER is especially well developed in cells active in protein synthesis, e.g. Russell's bodies of plasma cells, Nissl granules of nerve cells and acinar cells of pancreas.

ii. Smooth endoplasmic reticulum

Smooth ER is devoid of ribosomes on its surface. It is a site of lipid and steroid synthesis. Therefore, it is found in abundance with Leydig cells and cells of the adrenal cortex. In the skeletal and cardiac muscles, smooth ER is modified to form sarcoplasmic reticulum, which is involved in the release and sequestration of calcium ions during muscular contraction.

3. Golgi apparatus

The Golgi apparatus or complex is a collection of membranous vesicles, sacs or tubules, which is generally located close to the nucleus. It is

continuous with the endoplasmic reticulum. Golgi apparatus is particularly well developed in exocrine glandular cells (Fig. 1.2-1C).

Functions

Its main functions are:

- Synthesis of carbohydrates and complex proteins.
- Packaging of proteins synthesized in the rough ER into vesicles.
- Site of formation of lysosomal enzymes.
- Transport of the material to the other parts of cell or to cell surface membrane and secretion.
- Glycosylation of proteins to form glycoproteins.

4. Ribosomes

Ribosomes are spherical particles 15 nm in diameter which contain 80–85% of the cell's RNA. They may be present in the cytosol as free (unattached), or in bound form (attached to the membrane of endoplasmic reticulum). Slightly smaller forms of ribosomes are also found in mitochondria.

Functions

They are the site of protein synthesis. They synthesize all transmembrane proteins, secreted proteins and most proteins that are stored in Golgi apparatus, lysosomes and endosomes.

5. Lysosomes

Lysosomes are rounded to oval membrane-bound organelles 250–750 nm in diameter containing powerful lysosomal digestive (hydrolytic) enzymes. They are formed by the Golgi apparatus. As many as 40 different lysosomal enzymes have been synthesized. Some are listed in Table 1.2-1. These enzymes are acidic hydrolases and act best at acidic pH. The interior of lysosome is acidic (pH 5) as compared to rest of the cytosol (pH 7.2). The lysosomal acidic nature is maintained by proton pump or H⁺-ATPase.

TABLE 1.2-1

Lysosomal Enzymes and Cell Components as Their Substrates

Enzyme	Substrates
Deoxyribonuclease	DNA
Ribonuclease	RNA
Glycosidases	Glycosides and polysaccharides
Collagenases	Collagen
Arylsulphatases	Sulphate esters
Cathepsins	Proteins

Lysosomes are particularly abundant in the cells involved in phagocytic activity, e.g. neutrophils and macrophages. There are three forms of lysosomes:

- **Primary lysosomes or storage vacuoles**

are formed from the various hydrolytic enzymes synthesized by rough ER and packaged in the Golgi apparatus.

- **Secondary lysosomes or autophagic vacuoles**

are formed by fusion of primary lysosomes with parts of damaged or worn-out cell components.

- **Residual bodies**

are undigestible materials in the lysosomes.

Important Note

Acidic pH of lysosome is a safety feature for the cell, because if there is leakage of lysosomal contents into the cytosol, then lysosomal enzymes are not effective at pH 7.2, and thus, would not be able to digest cytosolic enzymes.

Applied Aspects

Congenital absence of lysosomal enzymes results in lysosomal storage disease, i.e. lysosomal engorgement with materials normally the enzymes degrade. Examples are:

- *Gaucher's disease* occurs due to deficiency of β -galactosidase.
- *Tay-Sachs disease* occurs due to hexoaminidase deficiency, which causes mental retardation and blindness.

6. Peroxisome

Peroxisomes, also known as microbodies, are spherical structures enclosed by a single layer of unit membrane. These are predominantly present in hepatocytes and tubular epithelial cells.

Functions

They essentially contain two types of enzymes:

- *Oxidases* which are active in oxidation of lipid, and
- *Catalases* which act on hydrogen peroxide to liberate oxygen.

7. Centrosome

The centrosome consists of two short cylindrical structures called centrioles (Fig. 1.2-1D). It is situated near the centre of the cell, close to the nucleus. The centrioles are responsible for movement of chromosomes during cell division.

B. Cytoplasmic inclusions

The cytoplasmic inclusions are the temporary components of certain cells. These may, or may not be enclosed in the membrane. A few examples of cytoplasmic inclusions are:

- *Lipid droplets*. These are seen in the cells of adipose tissue, liver and adrenal cortex.
- *Glycogen*. It is seen in the cells of liver and skeletal muscles.
- *Proteins as secretory granules* are seen in the secretory glandular cells (Fig. 1.2-1F).
- *Melanin pigment* is seen in the cells of epidermis, retina and basal ganglia.
- *Lipofuscin*. It is a yellow–brown pigment believed to be derived from secondary lysosomes and is seen in the cardiac muscle and brain cells of elderly people.

C. Cytoskeleton

The cytoskeleton is a complex network of fibres that maintains the structure of the cell and allows it to change shape and move. It primarily consists of microtubules, intermediate filaments and microfilaments,

along with proteins, which anchor and tie them together (Fig. 1.2-2).

FIGURE 1.2-2 Cytoskeleton showing various proteins.

1. Microtubules

Microtubules are long hollow tubular structures without limiting membrane, about 15–25 nm in diameter. These are made up of two globular protein subunits, α - and β -tubulin. The bundles of tubulin give structural strength to the cells. Microtubules form the transport system of the cells. Some of the other organelles and protein molecules move to different parts of the cell through the microtubules. *Kinesin* and *dynein*, known as molecular motors, help in the movement of molecules through the microtubules.

The *cilia and flagella*, which project from the surface of certain cells (spermatozoa, respiratory mucosa and fallopian tubes), are also composed of microtubules enclosed in plasma membrane and are active in the locomotion of the cells.

2. Intermediate filaments

Intermediate filaments are filamentous structures about 10 nm in diameter. Some of these filaments connect the nuclear membrane to the cell membrane. Their main function is to mechanically integrate the cell organelles within the cytoplasm. In their absence, cells rupture more easily; and when they are abnormal in humans, blistering of the skin is common.

3. Microfilaments

Microfilaments are long solid filamentous structures having a diameter

of 6–8 nm. These are made up of contractile proteins, actin and myosin. Actin is the most abundant protein in the mammalian cell. It attaches to various parts of the cytoskeleton by other proteins (anchor proteins). These are identified by numbers as 4.1, 4.2, 4.9 (Fig. 1.2-2). The actin filaments interact with integrin receptors to form focal adhesion complexes (Fig. 1.2-4). The microfilaments are scattered in an unorganized network. Extension of microfilaments along with the plasma membrane on the surface of the cells forms *microvilli*, which increase the absorptive surface of the cells (e.g. intestinal epithelium). In the skeletal muscle, the presence of actin and myosin filaments is responsible for their contractile property.

Molecular Motors Molecular motors help in the movement of different proteins, organelles and other cell parts (their cargo), to all parts of the cell. Broadly, the molecular motors can be divided into two types:

1. Microtubule-based molecular motors

This is a superfamily of many forms of molecular motors that produce motion along the microtubules. Two important molecular motors of this family are:

i. **Conventional kinesin.** It is a double-headed molecule that moves its cargo towards the positive ends of microtubules.

ii. **Dyneins.** These have two heads with their neck pieces embedded in a complex of proteins. These include:

- **Cytoplasmic dynein.** It moves particles and membranes towards the negative end of the microtubule.
- **Axonemal dynein.** It can oscillate, and is thus responsible for beating of flagella and cilia which project from the surface of certain cells.

2. Actin-based molecular motors

This is a superfamily of many molecular motors that produce motion along the actin. The important example of this group is *myosin*.

Myosin. The superfamily is further divided into 15 classes. The two important members of this family are myosin-I and myosin-II, which are described briefly:

- *Myosin-I*. Its molecules have a single head. Myosin-I is associated with actin in many cells.
- *Myosin-II*. Its molecules have two heads, but only one head is active in a molecule. Myosin-II is associated with skeletal muscle.

Mechanism of action. The myosins form cross-bridges to the actin molecules, and the myosin heads move generating force which is responsible for movement of various cells such as:

- Contraction of intestinal villi, and
- Contraction of skeletal, cardiac and smooth muscles.

Nucleus

Nucleus is present in all eukaryotic cells. It controls all the cellular activities, including reproduction of the cell. Most of the cells are uninucleated, except a few types of cells like skeletal muscle cells, which are multinucleated. Mostly, nucleus is spherical and situated in the centre of the cell,; however, its shape and location may vary in different types of cells. The nucleus consists of an outer nuclear membrane enclosing nucleoplasm and nucleoli (Fig. 1.2-1E).

1. Nuclear membrane

The nuclear membrane is a double-layered porous structure having a 40–70 nm wide space called *perinuclear cistern* which is continuous with the lumen of endoplasmic reticulum. The outer layer of the nuclear membrane is continuous with endoplasmic reticulum. The exchange of materials between nucleoplasm and cytoplasm occurs through the nuclear membrane.

2. Nucleoplasm

The nucleoplasm or the nuclear matrix is a gel-like ground substance containing large quantity of genetic material in the form of deoxyribonucleic acid (DNA). When a cell is not dividing, the nucleoplasm appears as a dark staining thread-like material called nuclear *chromatin*. During cell division, the chromatin material is converted into rod-shaped structures, the chromosomes. There are 46 chromosomes (23 pairs) in all the dividing cells of the body, except the gamete (sex cells) which contain only 23 chromosomes (haploid number).

Each chromosome is composed of two chromatids connected at the centromere to form 'X' configuration having variation of the location of centromere. The chromosomes are composed of three components, DNA, ribonucleic acid (RNA) and other nuclear proteins. The nuclear DNA carries the genetic information which is passed via RNA into the cytoplasm for synthesis of proteins of similar composition.

3. Nucleolus

The nucleus may contain one or more rounded bodies called nucleoli. The nucleoli are the site of synthesis of ribosomal RNA. The nucleoli are more common in growing cells or in cells actively synthesizing proteins.

The cell membrane

An understanding of the structure and properties of the cell membrane is most essential to understand the various physiological activities of the cell, including transport across cell membrane. Electron microscopy has shown that cell membrane/plasma membrane has a *trilayer* structure having total thickness of 7–10 nm (70–100 Å) and is known as *unit membrane*. The three layers consist of *two electron dense layers* separated by an *electron-lucent layer* (clear zone). Biochemically, the cell membrane is composed of complex mixture of lipids (40%), proteins (55%) and carbohydrates (5%).

Hypothesis for cell membrane structure

A few hypotheses have been proposed to explain the distribution of various biochemical components in the cell membrane. The most important hypothesis is the fluid mosaic model of Singer and Nicolson.

The fluid mosaic model of membrane structure

In 1972, Singer and Nicolson put forward the fluid mosaic model of membrane structure (Fig. 1.2-3), which is presently most accepted. According to this model:

- *Phospholipid bilayer* is the basic continuous structure forming the cell membrane. The phospholipids are present in fluid form. This fluidity makes the membrane quite flexible, and thus allows the cells to undergo considerable changes in the shape without disruption of structural integrity.

- The protein molecules are present as a discontinuous mosaic of globular proteins which float about in the fluid phospholipid bilayer forming a *fluid mosaic pattern*.

FIGURE 1.2-3 Fluid mosaic model of the cell membrane structure.

Arrangement of different molecules in cell membrane

The arrangement of molecules of phospholipids, proteins and carbohydrates forming the cell membrane is as follows:

Arrangement of lipid bilayer of the cell membrane

Each lipid molecule in the lipid bilayer of the cell membrane primarily consists of phospholipid, cholesterol and glycolipids. The presence of cholesterol is responsible for the characteristic which has the consistency of olive oil. The lipid molecule is clothes' pin shape and consists of a *head end* and a *tail end*.

The head end or the globular end of the molecule contains phosphate

moiety of phospholipid or hydroxyl radicle of cholesterol. It is positively charged and quite soluble in water (i.e. *polar* or *hydrophilic*). The tail end consists of two chains of fatty acids or steroid radicle of cholesterol. It is quite insoluble in water (nonpolar or hydrophobic). These lipid molecules are arranged as bilayers in such a way that their nonpolar hydrophobic tail ends are directed towards the centre of the membrane, whereas their polar hydrophilic head ends are directed outwards on either side of the membrane (Fig. 1.2-3). In this way, head ends of molecules face the aqueous phase, i.e. extracellular fluid on the outside and the intracellular fluid (cytoplasm) on the inner side. The major types of phospholipids are *phosphatidyl choline*, *phosphatidyl ethanolamine*, *glycosphingolipids*, *sphingomyelin* and *cholesterol*.

Functional significance of the lipid bilayer.

The lipid bilayer of the cell membrane makes it a semipermeable membrane which constitutes the major barrier for the water-soluble molecules like electrolytes, urea and glucose. On the other hand, fat-soluble substances like oxygen, fatty acids and alcohol can pass through the membrane with ease.

Arrangement of proteins in the cell membrane

Most protein molecules float about in the phospholipid bilayer forming a fluid mosaic pattern. The two types of proteins recognized in the cell membrane are:

- *Lipoproteins*, i.e. the proteins containing lipids which function as enzymes and ion channels, and
- *Glycoproteins*, i.e. the proteins containing carbohydrates which function as receptors for hormones and neurotransmitters.

The proteins in the cell membrane are described as:

1. Peripheral proteins.

These are present peripheral to the lipid bilayer, both inside and outside to it.

i. *Intrinsic proteins*. These are located in the inner surface of the lipid bilayer and serve mainly as enzymes. Some of these are anchored to the cytoskeleton of the cell (Fig. 1.2-2).

ii. *Extrinsic or surface proteins*. These are the proteins located on the outer surface of the lipid bilayer. These protein molecules are not associated tightly with the cell membrane, and thus can dissociate readily from the cell membrane. Some of these proteins serve as *cell adhesion molecules* (CAM) that anchor cells to neighbouring cells and to the basal lamina.

2. Integral proteins or transmembrane proteins.

These are the proteins that extend into the lipid bilayer. The proteins stay in the membrane because they have regions of hydrophobic amino acids which interact with fatty acid tails to exclude water. The rest of the protein is hydrophilic and faces into the cell or out into the external environment, both of which are aqueous (Fig. 1.2-3). Some proteins penetrate only part of the way into the membrane, while others penetrate all the way through. The integral proteins, on the basis of functions they serve, have been described as:

- *Channel proteins*. Some of the integral protein molecules serve as channels for water-soluble substances like glucose and electrolytes. These are also called the channel proteins.
- *Carrier proteins*. The protein molecules that help in transport of substances across the cell membrane by means of active and passive (facilitated diffusion) transport are called carrier proteins.
- *Receptor proteins*. Some of the proteins function as receptors that bind neurotransmitters and hormones, initiating physiologic changes inside the cell. The number of receptors of a cell are not constant, but keep on increasing (upregulation) or decreasing (down regulation) in response to various stimuli. Some of receptor proteins span (up and down movement) the entire thickness of the membrane several times like a sound wave and help in transport of substances.
- *Antigens*. Some proteins in the cell membrane also act as antigens. These are glycoproteins with branching carbohydrate side chains like antennae. There are an enormous number of possible shapes to these side chains, so each type of cell can have its own specific marker. This enables cells to recognize other cells and behave in an organized way, e.g. during development of tissue and organ in multicellular organisms. It also means that foreign antigen can be recognized. Thus, these proteins help in processing the antibodies and distinguish self from nonself.

- *Pumps*. There are certain proteins in the cell membrane which act as pumps, and form the active transport system of the cell, e.g. Na⁺-K⁺ATPase pump, K⁺-H⁺ ATPase pump and Ca²⁺ pump.

Arrangement of carbohydrates in the cell membrane

The carbohydrates are attached either to the proteins (glycoproteins) or the lipids (glycolipids). Throughout the surface of cell membrane, carbohydrate molecules form a thin loose covering called *glycocalyx*.

Functions of cell membrane carbohydrates

- Being negatively charged, the carbohydrate molecules of the cell membrane do not allow the negatively charged particles to move out of the cell.
- The glycocalyx helps in tight fixation of the cells with one another.
- Some of the carbohydrate molecules also serve as *receptors*.

Intercellular junctions

The cell membranes of the neighbouring cells are connected with one another through the *intercellular junctions* or the junctional complexes, which are of three types.

Before describing the types of intercellular junctions, it will be worthwhile to have some information about the cell adhesion molecules (CAMs).

Cell adhesion molecules

Cell adhesion molecules (CAMs) are the prominent parts of the intercellular connections by which the cells are attached to basal lamina and to each other.

Types of CAMs.

CAMs have been variously classified. Most simply, they can be divided into four broad families:

1. *Integrins*. These are heterodimers that bind to various receptors.
2. *Adhesion molecules of IgG subfamily*. Through these molecules the IgG

immunoglobulins bind to various antigens.

3. *Cadherins*. These are Ca^{2+} -dependent molecules that mediate cell-to-cell adhesions by haemophilic reactions.

4. *Selectins*. These are lectin-like domains that bind carbohydrates.

Mechanism of adhesions.

The CAMs act as adhesion proteins by following mechanisms:

- *Anchorage with cytoskeleton*. Many CAMs pass through the cell membrane and are anchored to the cytoskeleton inside the cell.
- *Homophilic binding*, i.e. some CAMs bind to like-molecules on the other cells.
- *Heterophilic binding*, i.e. some CAMs bind to different molecules on the other cells.
- *Binding to laminins*. Many CAMs bind to laminins, a family of large cross-shaped molecules with multiple receptor domains in the extracellular matrix.

Functions of CAMs.

In addition to *binding the neighbouring cells* to each other, the CAMs perform following other functions:

- They transmit signals into and out of the cells.
- They play a role in embryonic development and formation of the nervous system and other tissue.
- They hold tissue together in adults.
- They play an important role in inflammation and wound healing.
- They also play a role in metastasis of tumours.

Types of intercellular junctions

1. Tight junction.

This is also called *zona occludens* or the *occluding zone* (Fig. 1.2-4A). In this type of intercellular junction, the outer layer of the cell membrane of the neighbouring cells fuse with each other, thus obliterating the space between the cells. A tight junction is composed of parallel strands of tightly packed transmembrane proteins (mainly occludin, junctional adhesion molecules and claudins). Such junctions form a barrier to the movement of ions and other solutes from one cell to another. Following are few examples of the cells where tight junctions are present:

- Apical margins of epithelial cells, such as the intestinal mucosa.
- The renal tubular epithelial cells.
- Capillary endothelium in the brain forming the blood–brain barrier.
- Blood–aqueous barrier formed by the tight junctions between the cells of the inner non-pigmented epithelium of the ciliary body.
- Outer blood–retinal barrier formed by the tight junctions between adjacent cells of the retinal pigment epithelium.

FIGURE 1.2-4 Schematic diagram of a cell showing various intercellular junctions: **A**, tight junction; **B**, adherens junction; and **C**, gap junction.

2. Adherens junction.

This is also called *zonula adherens*. In this type of junction, cell membrane of the adjacent cells are separated by a 15–20 nm wide space which is at focal places obliterated by the dense accumulation of the proteins (cadherin and extracellular part of several transmembrane proteins) at the cell surface. Bundles of intermediate filaments project from the intercellular functional areas and radiate into the cytoplasm. This holds the adjacent cells at these focal places. These are of two types:

- *Desmosomes* are the adherens junctions where thickened focal areas are formed on both the opposing cell membranes (Fig. 1.2-4B).

- *Hemidesmosomes* are the adherens junctions where focal thickening is seen only on the membrane of one of the two adjacent cells. So, this is also known as half-desmosome. Adherens junctions are seen in the cells of epidermis. Focal adhesions attach the cell to the basal lamina and also to actin filaments present inside the cell, and thus help in cell movement.

3. Gap junction.

Gap junctions or the nexus are the channels on the lateral surfaces of the two adjacent cells through which the molecules are exchanged between the cells (Fig. 1.2-4C). Each half of the channel is surrounded by 6 subunits of proteins (the *connexins*). The intercellular space is reduced from the usual size of 15–20 nm to 2–3 nm at such junctions. The gap junctions are seen in the heart and basal part of epithelial cells of intestinal mucous membrane. They serve the following functions:

- These permit the intercellular passage of glucose, amino acids, ions and other substances which have a molecular weight of about 1000.
- These permit rapid propagation of electrical potential changes from one cell to another as seen in cardiac muscle and other smooth muscle cells.
- These help in the exchange of chemical messengers between the cells.

CHAPTER

1.3

Transport through cell membrane

PASSIVE TRANSPORT

- Diffusion
 - Simple diffusion
 - Facilitated diffusion
 - Factors affecting diffusion
- Osmosis
 - Osmotic pressure
 - Osmole, osmolality and osmolarity
 - Tonicity of fluids

ACTIVE TRANSPORT

- Primary active transport
 - Sodium potassium pump
 - Calcium pump
 - Potassium hydrogen pump
- Secondary active transport
 - Sodium cotransport
 - Sodium counter-transport

VESICULAR TRANSPORT

- Endocytosis
 - Pinocytosis
 - Phagocytosis
 - Receptor-mediated endocytosis
- Exocytosis
- Transcytosis

OTHER TRANSPORT PROCESSES

- Transport across epithelial membrane
- Ultrafiltration

The physiological activities of a cell depend upon substances like nutrients, oxygen and water, which must be transported into the cell, and at the same time, metabolic waste must be transported out of the cell. Various processes involved in the transport of substances across the cell membrane may be grouped as under:

- Passive transport
- Active transport
- Vesicular transport.

Passive transport

Passive transport refers to the mechanism of transport of substances along the gradient without expenditure of any energy. It depends upon the physical factors like concentration gradient, electrical gradient and pressure gradient. Since the transport of substances occurs along the gradient, this process is also called *downhill movement*. The passive transport mechanisms operating at the cell membrane level are diffusion and osmosis.

Diffusion

Diffusion refers to passive transport of molecules from areas of higher concentration to areas of lower concentration. Diffusion through cell

membrane is divided into two subtypes – simple diffusion and facilitated diffusion.

Simple diffusion

In simple diffusion transport of atoms or molecules occurs from one place to another due to their random movement. All the molecules, whether dissolved or undissolved, are at constant random movement except at absolute zero temperature. Due to constant random movement, the molecules collide with each other and also strike with the cell membrane. The frequency of collision and the probability of striking to the cell membrane will be higher on the side of the membrane having higher concentrations of that particular molecule. In this process, there occurs a net flux of the molecules from the areas of high concentration to areas of low concentration. The net movement of the molecules ceases when the concentration of molecules are equal, and there occurs a condition of *diffusional equilibrium*. Quantitatively the net movement of the molecules across a permeable membrane where only simple diffusion is occurring is expressed by *Fick's law of diffusion*, which states that rate of diffusion (J) is directly proportional to the difference in the concentration of the substance in two regions (concentration gradient, i.e. $C_1 - C_2$) and cross-sectional area (A) and inversely proportional to the distance to be travelled (thickness of the membrane, T)

$$\text{Thus } J = D \frac{A(C_1 - C_2)}{T}, \text{ where } D \text{ is the diffusion coefficient.}$$

The diffusion of molecules across the biological membranes differs depending upon the lipid solubility, water solubility, type of electrical charge and size of the molecules. Further, selective permeability of the semipermeable cell membrane also affects the diffusion of different molecules. How the different molecules diffuse across a cell membrane are discussed below.

Simple diffusion of lipid soluble substances through the cell membrane

The rate of diffusion through the lipid bilayer of the cell membrane is directly proportional to the solubility of a substance in lipids. Therefore, molecules of substances like oxygen, nitrogen, carbon dioxide, alcohol,

steroid hormones and weak organic acids and bases, being lipid soluble, diffuse very rapidly through the lipid bilayer of the cell membrane.

Simple diffusion of water and other lipid insoluble molecules through the cell membrane

Astonishingly, water and other lipid insoluble substances can also pass easily through the cell membrane. It has been shown that it is possible due to the presence of the so-called *protein channels* (made from transmembrane proteins) in the cell membrane.

Diffusion through protein channels

The protein channels are tube-shaped channels that extend in the cell membrane from the extracellular to the intracellular ends (Fig. 1.3-1). Therefore, even the highly lipid insoluble substances can diffuse by simple diffusion directly through these channels of the cell membrane. However, permeability of such substances depends upon their molecular size, shape and charge.

FIGURE 1.3-1 Simple diffusion.

The protein channels are equipped with following characteristics:

- Selective permeability and
- Gating mechanism.

Selective permeability of protein channels

The protein channels are highly selective, i.e. each channel can permit only one type of ion to pass through it. This results from the characteristics of the channel itself, such as, its diameter, its shape and nature of electrical charges along its inside surfaces. Examples of some selective channels are:

- *Sodium channels* are specifically selective for the passage of sodium ions. These are 0.3 by 0.5 nm in size and their inner surfaces are *strongly negatively charged* (Fig. 1.3-2).
- *Potassium channels* are specifically selective for the passage of potassium ions. These are 0.3 by 0.3 nm in size and *not negatively charged* (Fig. 1.3-3).

FIGURE 1.3-2 Voltage-gated sodium channels.

FIGURE 1.3-3 Voltage-gated potassium channels.

Gating mechanism in protein channels

Some protein channels are continuously open, whereas most others are 'gated', i.e. they are equipped with actual gate-like extensions of the transport protein molecule that can open and close as per requirement. This gating mechanism is a means of controlling the permeability of the channels. The opening and closing of gates are controlled by three principal ways:

1. **Voltage-Gated Channels.** These respond to the electrical potential across the cell membrane. As shown in Fig. 1.3-2, in the case of sodium channels, the gates are located at the outer end of the channels and these remain tightly closed, when there is a strong negative charge on the inside of cell membrane. When the inside of cell membrane loses its negative charge, these gates open and there occurs a tremendous inflow of sodium ions. This is the basis of occurrence of action potential in

nerves that are responsible for nerve signals.

In the case of potassium channels, the gates are located at the inner end of the channel (Fig. 1.3-3) and they too open when the inside of the cell membrane loses its negative charge, but this response is much slower than that for the sodium channel. The opening of potassium channel gates is partly responsible for terminating the action potential.

The ion current flow through a single voltage-gated channel protein can be recorded by the patch clamp technique.

Patch clamp method is a simple method in which a micropipette of tip diameter 1–2 micrometre is abutted against the outer surface of the membrane and suction is applied to suck small membrane inside the pipette, the edges of the pipette tip touching the membrane, creating a tight sealing. The patch of membrane inside the tip of the pipette contains 1–2 channel proteins. Three different types of patches are:

- *Cell-attached patch*: In this type, the patch remains intact with the cell (Fig. 1.3-4A).
- *Inside–out patch*: In this type, the patch is pulled loosely from the cell forming inside–out patch (Fig. 1.3-4B).
- *Whole-cell patch*: In this type the patch sucked out in the pipette is still attached on to the rest of the cell membrane, thus providing direct access to the interior of the whole cell and is also known as whole cell

recording (Fig. 1.3-4C).

These patches are so small that they contain only single channel proteins and that can be studied by varying the concentration of ions, as well as voltage, across the membrane. The transport characteristics and also the opening and closing of gates can be studied (Fig. 1.3-4D).

2. *Ligand Gated Channels*. Gates of these channels open when some other chemical molecule binds with the gate proteins, which is why this is also called *chemical gating*. The ligand (binding molecules) may be internal or *external*.

- The external or extracellular ligands are also called *first messengers*. One of the most important examples of external ligand channel gating is the effect of acetylcholine on the so-called *acetylcholine channels*. This gate plays an important role in transmission of nerve signals from one nerve cell to another and from nerve cells to muscle cells.
- The internal or the intracellular ligands are also called *second messengers*. The examples include intracellular Ca^{2+} , cAMP, or G protein produced in the cells. The second messenger generally activates protein kinases.

3. *Mechanically Gated Channels*. Some protein channels are opened by mechanical stretch. These mechanosensitive channels play an important role in cell movements.

FIGURE 1.3-4 Various types of patch clamps used to study the activity of ion channels across the membrane: **A**, cell attached patch; **B**, inside out patch; **C**, whole cell patch; and **D**, note the changes in the membrane current with time and its flow through sodium channels.

Facilitated diffusion

The water soluble substances having larger molecules, such as glucose, cannot diffuse through the protein channels by simple diffusion. Such substances diffuse through the cell membrane with the help of some carrier proteins. Therefore, this type of diffusion is called facilitated or carrier-mediated diffusion. There are many types of carrier proteins in the cell membrane, each type having binding sites that are specific for a particular substance. Among the most important substances that cross cell membranes by facilitated diffusion are *glucose* and most of the *amino acids*.

Mechanism of facilitated diffusion

Postulated mechanism for facilitated diffusion is shown in Fig. 1.3-5. As shown in the figure, a conformational change occurs in the carrier protein after the molecule to be transported is bound at the receptor site. The repetitive spontaneous configurational changes allow the diffusion of the molecule. Earlier belief was that the carrier protein acts like a shuttle between the outer and inner surfaces of the cell membrane, and it has been discarded now.

FIGURE 1.3-5 Postulated mechanism of facilitated diffusion.

Types of carrier protein systems

Three types of carrier protein systems are known: uniport, symport and antiport (Fig. 1.3-6). The symports and antiport are together known as cotransport.

1. **Uniport.** In this system, the carrier proteins transport only one type of molecules.
2. **Symport.** In this system, transport of one substance is linked with transfer of another substance. For example, facilitated diffusion of glucose in the renal tubular cells is linked with the transport of sodium.
3. **Antiport.** In this system, the carrier proteins exchange one substance for another. For example, $\text{Na}^+ - \text{K}^+$ exchange or $\text{Na}^+ - \text{H}^+$ exchange in the renal tubules.

FIGURE 1.3-6 Various types of carrier protein systems: **A**, uniport; **B**, symport; and **C**, antiport.

Differences between simple and facilitated diffusions

1. **Specificity.** The carrier proteins are highly specific for different molecules.
2. **Saturation.** As shown in Fig. 1.3-7, in simple diffusion, the rate of diffusion increases proportionately with the increase in the concentration of the substance and there is no limit to it. However, in facilitated diffusion, the rate of diffusion increases with increase in concentration gradient to reach a limit beyond which a further increase in the diffusion cannot occur. This is called *saturation* point, and here all the binding sites on the carrier proteins are occupied and the system operates at its maximum capacity.
3. **Competition.** When two molecules, say A and B, are carried by the same protein, there occurs a competition between the two molecules for the transport. Thus, an increase in the concentration of 'A' molecule will decrease the transport of molecule 'B', and vice versa. No such competition is known to occur in simple diffusion.

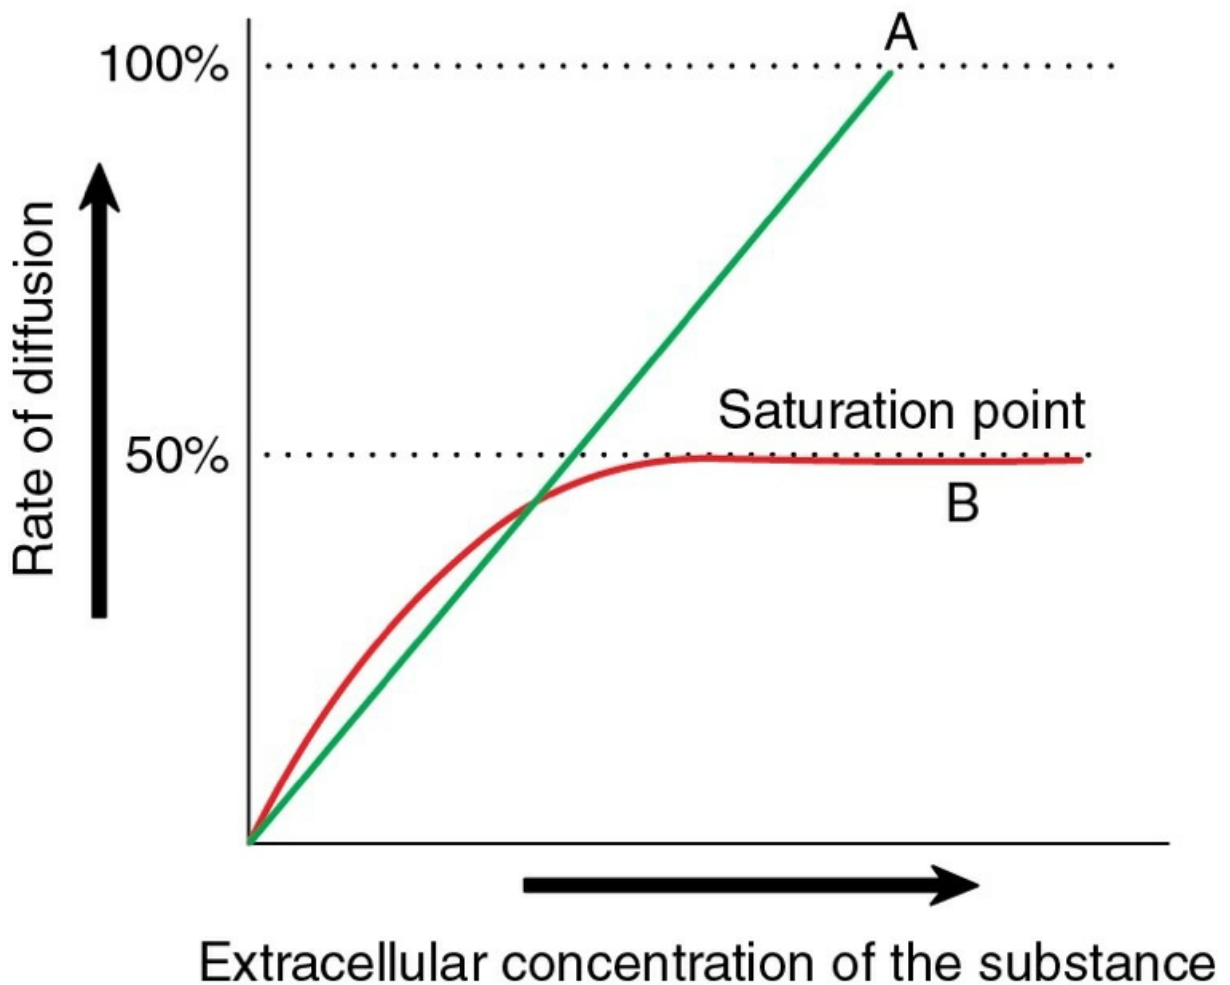

FIGURE 1.3-7 Effect of concentration of substance on rate of diffusion in: **A**, simple diffusion; and **B**, facilitated diffusion.

Factors affecting net rate of diffusion

The mechanisms described above deal with the diffusion of substances through the cell membrane. The diffusion of the substance can occur either way, i.e. ECF to ICF and vice versa, depending upon the prevailing environment. The factors that affect the net rate of diffusion in the desired direction are summarized:

1. **Cell membrane permeability.** Permeability of the cell membrane (P) is the major determining factor for the net diffusion, which in turn depends upon the following factors:

- **Thickness of the membrane.** The diffusion is inversely proportional to the thickness of the cell membrane, i.e. the greater the thickness, lesser is the rate of diffusion.

- *Lipid solubility.* Diffusion is directly proportional to the lipid solubility of the substance.
- *Distribution of protein channels in the cell membrane.* The rate of diffusion of lipid insoluble substance is directly proportional to the number of channels per unit area of the cell membrane.
- *Temperature.* Rate of diffusion increases with increase in the temperature. This is because of the increased motion of the molecules and ions of the solution with increase in temperature.
- *Size of the molecules.* Rate of simple diffusion is inversely proportional to the size of molecules.
- *Area of the membrane.* The net diffusion of the substance is directly proportional to the total area of the membrane.
- The total permeability is often expressed as the *diffusion coefficient* (D) of the entire membrane. It is calculated by multiplying the permeability through a unit membrane area with total area of the cell membrane (A). Thus:

$$D = P \times A$$

2. *Concentration gradient.* The simple diffusion is directly proportional to the concentration gradient (Fig. 1.3-8A) and is denoted by:

Net diffusion $\propto D (C_0 - C_1)$, where C_0 is concentration of the substance outside, C_1 is concentration of the substance inside and D is the diffusion coefficient of the

cell membrane for the substance.

The facilitated diffusion, however, has certain limitations beyond a certain level of concentration gradient (Fig. 1.3-7B).

3. *Electrical potential gradient.* Electrical potential across the cell membrane is another important factor which affects the diffusion of ions across the cell membrane.

As shown in Fig. 1.3-8B, the concentrations of negative ions are the same on both sides of the membrane, but there is an electrical gradient across the cell membrane because of positive charge outside and negative charge inside the membrane. The positive charge attracts the negative ions, whereas the negative charge repels them. Therefore, net diffusion occurs from inside to outside till the concentration gradient created balances the electrical gradient. In other words, net diffusion of any ion across the cell membrane (J) will be the resultant of the combined effect of concentration gradient and electrical potential gradient, and is denoted by the following equation:

$$J = - DA \left[dc/dx + \left(Z \frac{CF}{RT} \right) dv/dx \right]$$

J is the rate of ion diffusion,

D is diffusion coefficient,

A the area of plane through which ion movement is

taking place,

dc/dx the concentration gradient

Z the valency of the ion,

C the ion concentration,

F the Faraday constant (96,500 coulomb per mol of ion),

R the gas constant (8.316 joules per degree),

dv/dx the absolute temperature and the electrical potential gradient.

At normal body temperature (37°C), the electrical gradient that will balance the concentration gradient of a univalent ion can be determined by *Nernst equation*:

$$\text{EMF (in millivolts)} = \pm 61 \log \frac{C_0}{C_1}, \text{ where}$$

- EMF is the electromotive force between outside and inside of the membrane,
- C_0 is the concentration of ion outside the membrane and
- C_1 is the concentration of ion inside the membrane.

This equation is extremely important in understanding the membrane potential, hence discussed in detail in the relevant section (page 32).

4. *Pressure gradient.* It has been observed that the increased amounts of energy are available to cause net movements of molecules from the high pressure side towards the low pressure side. The pressure-gradient effect is demonstrated in Fig. 1.3-8C, which shows that high pressure developed by the piston on one side of the cell membrane causes greater number of molecules to strike the membrane resulting in net diffusion to the other side.

FIGURE 1.3-8 Factors affecting net rate of diffusion: **A**, concentration gradient; **B**, electrical gradient; and **C**, pressure gradient.

Osmosis

Osmosis refers to diffusion of water or any other solvent molecules through a semipermeable membrane, (i.e. membrane permeable to solvent but not to the solute) from a solution containing lower concentration of solutes towards the solution containing higher concentration of solutes, Fig. 1.3-9 shows osmosis across a selective permeable membrane. When a sodium chloride solution is placed on one side of the membrane and water on the other side (Fig. 1.3-9A); net movement of water occurs from the pure water into the sodium chloride solution (Fig. 1.3-9B).

FIGURE 1.3-9 Diagrammatic representation of phenomenon of osmosis: **A**, semipermeable membrane 'M' separates sodium chloride solution from pure water; **B**, net movement of water occurs through (M) from pure water side into the sodium chloride solution side; and **C**, demonstration of osmotic pressure (net movement of water from pure water side to sodium chloride solution is prevented by applying appropriate pressure on the solution side).

Osmotic pressure

Osmotic pressure refers to the minimum pressure which when applied on the side of higher solute concentration prevents the osmosis. Fig. 1.3-9C shows that when appropriate pressure is applied, the net diffusion of water into the sodium chloride solution is prevented.

The osmotic pressure in the body fluids refers to the pressure exerted by the solutes dissolved in water or other solvents. The osmotic pressure

exerted by the colloidal substances in the body is called *colloidal osmotic pressure*. The colloidal osmotic pressure due to plasma colloids (proteins) is called *oncotic pressure*.

The osmotic pressure depends upon the number of molecules or ions dissolved in a solution rather than their size, type or chemical composition. In case of nondissociated solutes, one gram molecular weight of any substance shall contain similar number of molecules, and hence exert similar degree of osmotic pressure, i.e. equal to 22.4 atmospheres, whereas, in case of dissociated solutes, the osmotic pressure depends upon the number of ions resulting from its dissociation.

Osmole, osmolality and osmolarity

Osmole.

is the unit used in place of grams to express the concentration in terms of number of osmotically active particles in a given solution. One osmole is equal to the molecular weight of a substance in grams divided by the number of freely moving particles liberated in solution by each molecule. Thus:

- A molar solution of glucose contains 1 mole and exerts osmotic pressure of 1 atmosphere.
- A molar solution of NaCl contains 2 osmoles (1 mole of Na⁺ and 1 mole of Cl⁻) and exerts osmotic pressure of 2 atmospheres.
- A molar solution of CaCl₂ contains 3 osmoles (1 mole of Ca²⁺ and 2 moles of Cl⁻) and thus exerts osmotic pressure of 3 atmospheres.
- One milli osmole (mOsm) is 1/1000 of an osmole.

Osmolality.

of a solution refers to the number of osmotically active particles (osmoles) per kilogram (kg) of a solution, while, *osmolarity* refers to the number of osmoles per litre (L) of a solution. Therefore, osmolarity is affected by the volume of the various solutes in the solution and the temperature, while osmolality is not. The osmotic pressure is determined by the osmolality and not osmolarity. However, the quantitative differences between the osmolarity and osmolality are less than 1%. In practice, *osmolarity* is more frequently used in physiological studies, since

it is far easier to measure osmolarity vis-a-vis osmolality.

Normal plasma osmolality. The normal osmolality of the extracellular and intracellular fluids is 290 milliosmoles per kilogram (mOsm/kg). In the plasma of the total osmolality, 270 mOsm are contributed by Na^+ , Cl^- and HCO_3^- . The remaining 20 mOsm are contributed by glucose and urea. Because of the large molecular weight and hence lesser number of particles, plasma proteins (70 g/L) contribute 2 mOsm to the total plasma osmolality.

Tonicity of fluids

In clinical practice the word tonicity always refers to tonicity of a solution with respect to that of plasma (290 mOsm). In other words, it is the red blood cell (RBC) membrane across which the tonicity is tested. Thus:

- *Isotonic fluids* are those which have osmolality similar to plasma. RBCs neither shrink nor swell in such solution (Fig. 1.3-10A). A solution of 0.9% NaCl is isotonic with plasma.
- *Hypertonic fluids* have osmolality higher than the plasma. The RBCs shrink in such solutions by losing water by osmosis (Fig. 1.3-10B).
- *Hypotonic fluids* are those whose osmolality is lower than that of plasma. The RBCs swell up in hypotonic solutions by gaining water by osmosis (Fig. 1.3-10C).

FIGURE 1.3-10 Tonicity of fluids: **A**, isotonic fluid (0.9% NaCl) has osmolarity similar to plasma, RBCs neither shrink nor swell in it; **B**, hypertonic fluid (2% NaCl) has osmolarity higher than plasma, RBCs shrink in it; and **C**, hypotonic fluid (0.3% NaCl) has osmolarity lower than plasma, RBCs swell in it and burst open.

Clinically Applied Aspects

- The total plasma osmolality may increase in patients having severe dehydration.
- Increased blood glucose levels in patients with severe diabetes also increase the plasma osmolality.
- Excessive intravenous administration of 5% glucose decreases plasma osmolality leading to swelling of the body tissues.
- Hyperosmolality can cause coma by causing water to flow out of the brain cells (hyperosmolar coma)
- Raised plasma levels of urea in patients with renal diseases also cause hyperosmolality.

Active transport

Active transport refers to the mechanism of transport of substances against the chemical and/or electrical gradient. Active transport involves expenditure of energy which is liberated by breakdown of high energy compounds like ATP. Since the transport of substances occur against the chemico-electrical gradient, this process is also called *up-hill movement*.

Mechanism of active transport

The active transport is also carrier mediated, but its mechanism is different from that of facilitated diffusion. However, since the carrier proteins are involved in the transport mechanism, so like facilitated diffusion the active transport also shows specificity, saturation and competition.

Since the active transport mechanism involves the expenditure of energy, the transporting carrier protein system is also called the '*active pump mechanism*'. The substance to be transported combines with the specific carrier protein on the cell membrane. The complex so formed undergoes conformational changes and is actively pumped towards the inner surface of cell membrane where the substance is released and the carrier protein moves back to the outer surface to transport another molecule.

Substances transported actively across the cell membrane include:

- *Ionic substances* such as Na^+ , K^+ , Ca^{2+} , Cl^- and I^- and
- *Nonionic substances* like glucose, amino acids and urea.

Types of active transport

The active transport is of two types:

- Primary active transport and
- Secondary active transport.

A. Primary active transport processes

In primary active transport process, the energy is derived directly from the breakdown of adenosine triphosphate (ATP) or some other high-energy phosphate compound. Some of the important pumps involved in the primary active transport processes are:

- Sodium–potassium pump,
- Calcium pump and
- Potassium–hydrogen pump.

1. Sodium–potassium pump

Sodium–potassium ($\text{Na}^+ - \text{K}^+$) pump is present in all the cells of the body. It is involved with the active transport of sodium ions outwards through the cell membrane and potassium ions inwards, simultaneously. Thus, this pump is responsible for maintaining the Na^+ and K^+ concentration differences across the cell membrane and for establishing a negative electrical potential inside the cells.

Structure of $\text{Na}^+ - \text{K}^+$ pump (fig. 1.3-11).

The carrier protein involved in $\text{Na}^+ - \text{K}^+$ pump is a complex consisting of two separate protein units, a larger the α subunit (molecular weight approximately 100,000) and a smaller β subunit (molecular weight approximately 55,000). The α subunit is mainly concerned with $\text{Na}^+ - \text{K}^+$ transport. It has got following binding sites:

- Three intracellular sites, one each for binding sodium ions (3Na^+) and ATP, and one phosphorylation site.
- Two extracellular sites, one each for binding potassium ions (2K^+) and ouabain.

FIGURE 1.3-11 Structure of sodium-potassium ATPase pump.

Mechanism of operation of $\text{Na}^+ - \text{K}^+$ pump (fig. 1.3-12).

The functioning of $\text{Na}^+ - \text{K}^+$ pump involves the use of enzyme ATPase. The enzyme ATPase is activated when three sodium ions and one ATP molecule bind to their respective binding sites. The activated ATPase catalyses the hydrolysis of ATP to ADP and liberates a high-energy phosphate bond of energy (phosphorylation). The energy so liberated is believed to cause a conformational change in the carrier protein molecule extruding sodium into the extracellular fluid. This is followed by binding of two potassium ions to the receptor site on extracellular surface of the carrier protein and dephosphorylation of α subunit which returns to its previous conformation, releasing potassium into the cytoplasm.

FIGURE 1.3-12 Mechanism of operation of sodium–potassium ATPase pump.

Functions of $\text{Na}^+\text{-K}^+$ pump.

The $\text{Na}^+\text{-K}^+$ pump subserves two main functions:

1. *Controlling the cell volume.* It is the most important function of the $\text{Na}^+\text{-K}^+$ pump, without which most cells of the body will swell up until they burst. Inside the cells are large number of proteins and other organic compounds that cannot escape from the cell. Being negatively charged, these also collect large number of positive ions. All these substances cause osmosis of water to the interior of the cell, which is prevented by the $\text{Na}^+\text{-K}^+$ pump. When the $\text{Na}^+\text{-K}^+$ pump fails the cells swell up and burst.
2. *Electrogenic activity.* $\text{Na}^+\text{-K}^+$ pump acts as electrogenic pump since it produces a net movement of positive charge out of the cell (3Na^+ out and 2K^+ in); Thus creating electrical potential across the cell membrane. This is a basic requirement in nerves and muscles to transmit the signals.

Regulation of $\text{Na}^+\text{-K}^+$ pump.

The activity of $\text{Na}^+\text{-K}^+$ pump is affected as:

- increased by cAMP, diacylglycerol (DAG), thyroid hormone, aldosterone, insulin and G actin, and

- Inhibited by low temperature, oxygen lack, dopamine, ouabain and related glycosides (digitalis) used for the treatment of heart failure.

2. Calcium pump

The calcium pump forms another important active transport mechanism. Like $\text{Na}^+ - \text{K}^+$ pump it also operates through a carrier protein which has ATPase activity. But the difference from $\text{Na}^+ - \text{K}^+$ pump is that the carrier protein binds calcium ions rather than sodium and potassium ions. The calcium pump helps in maintaining extremely low concentrations of calcium in the intracellular fluid (10,000 times less than the ECF). There are two primary active transport calcium pumps. One is in the cell membrane which extrudes Ca^{2+} out of the cell, and the other calcium pump actively transports cytoplasmic calcium into the one or more of the cellular organelles like sarcoplasmic reticulum of the muscle cells and mitochondria of all the cells.

3. Potassium–hydrogen pump

The primary active transport system of hydrogen ion also operates through ATPase ($\text{K}^+ - \text{H}^+$ ATPase) activity. These are present at following two places in the human body:

- *Parietal cells of gastric glands.* The $\text{K}^+ - \text{H}^+$ pump located in these cells actively transports H^+ out of the cells into the lumen of gastric glands and K^+ into the cell from the lumen. The H^+ combines Cl^- to form HCl in the lumen of gastric glands (for details see page 591).
- *Renal tubules.* The $\text{K}^+ - \text{H}^+$ pump is located in the intercalated cells of late distal tubules and cortical collecting ducts. Here large amounts of H^+ are secreted into the tubules to eliminate them from the body for the purpose of controlling blood H^+ concentration (for details see page 524).

B. Secondary active transport

In secondary active transport processes, the energy is derived secondarily from the energy which has been stored in the form of ionic concentration differences between the two sides of a membrane, created in the first place by primary active transport. At many areas in the body, transport of some other substance is coupled with the active transport of Na^+ , i.e. the same carrier protein which is involved in the active transport of Na^+ also secondarily transports some other substance. The secondary

active transport of substance may occur in the form of sodium cotransport or sodium counter-transport.

Sodium cotransport

The carrier protein here acts as symport, i.e. transports some other substance along with the sodium. Substances carried by sodium cotransport include glucose, amino acids, chloride and iodine.

1. *Sodium cotransport of glucose.* The glucose is transported into most cells against large concentration gradient. As shown in [Fig. 1.3-13A](#), the carrier protein has two receptor sites on the outer surface, one for sodium and other for glucose. The special feature of the carrier protein is that the conformational change in it occurs only when both the sodium and glucose molecules are attached to it. Due to conformational change in the carrier protein, both the sodium and the glucose are transported simultaneously inside the cell ([Fig. 1.3-13B](#)). The cotransport of glucose occurs during its absorption from the intestine into the blood and during the reabsorption of glucose from renal tubule in the blood ([Fig. 1.3-14](#)).

2. *Sodium cotransport of amino acids.* Occurs especially in the epithelial cells of intestinal tract and renal tubules during absorption of the amino acids into the blood. The mechanism of sodium cotransport of amino acids is similar to that of glucose, except that the carrier proteins involved are different. There are five sets of carrier proteins in the cell membrane, each transporting different amino acids depending upon their molecular weights.

FIGURE 1.3-13 Postulated mechanism of sodium cotransport of glucose (secondary active transport): **A**, carrier protein has two receptor sites, one for sodium and one for glucose; and **B**, conformational change in carrier protein causes transport of both glucose and sodium inside the cell simultaneously.

FIGURE 1.3-14 Composite diagram of the cell showing the various cotransport and counter-transport mechanisms and maintenance of membrane potential as an effect of primary active transport of Na^+ and K^+ .

Sodium counter-transport

The carrier protein involved here acts as *antiport*, i.e. sodium ion is exchanged for some other substance. Some of the sodium counter-transport mechanisms occurring in the body are:

1. **Sodium–calcium counter-transport** is known to occur in almost all cell membranes with sodium ions moving inside and calcium outside the cell (Fig. 1.3-14). The transport of these ions in the opposite direction is carried by the same carrier protein.
2. **Sodium–hydrogen counter-transport** is especially known in the proximal tubules of kidney. Here the Na^+ ions move inside the cell and the H^+ ions move out of the cell by the same carrier protein.
3. **Other counter-transport systems** which exist somewhere in the body are sodium–potassium counter-transport system, sodium–magnesium

counter-transport, calcium–magnesium countertransport system and chloride–bicarbonate counter-transport system.

Vesicular transport

Vesicular transport mechanisms are involved in the transport of macromolecules such as large protein molecules which can neither pass through the cell membrane by diffusion nor by active transport mechanisms. The vesicular transport mechanisms include endocytosis, exocytosis and transcytosis.

Endocytosis

Endocytosis is the process in which the substance is transported into the cell by infolding of the cell membrane around the substance and internalizing it (Fig. 1.3-15). It is further of three types:

1. ***Pinocytosis***, i.e. cell drinking refers to the process of engulfing liquid substances by the enfolding of cell membrane, e.g. reabsorption by renal tubular epithelial cells.
2. ***Phagocytosis***, i.e. cell eating is the process of engulfing of solid particles such as bacteria, dead tissue and foreign particles by the cells. The process of phagocytosis involves three steps (i) the attachment stage, (ii) the engulfment stage and (iii) killing or degradation stage (see page 169).
3. ***Receptor-mediated endocytosis***. In this process the substance to be transported binds with the special receptor proteins present on the cell surface. The receptor protein-substance complex is then engulfed by the cell membrane by the process of endocytosis. Transport of iron and cholesterol into the cells occurs by receptor-mediated endocytosis.

FIGURE 1.3-15 Constitutive pathway of endocytosis.

Mechanism of endocytosis

There are two pathways by which endocytosis takes place:

1. **Constitutive pathway (constitutive endocytosis).** In this process the molecule (substance) first makes contact with the cell membrane, then the cell membrane invaginates to form *endocytic vesicle* followed by fusion of noncytoplasmic sides of the cell membrane and invagination is pinched off (Fig. 1.3-15).

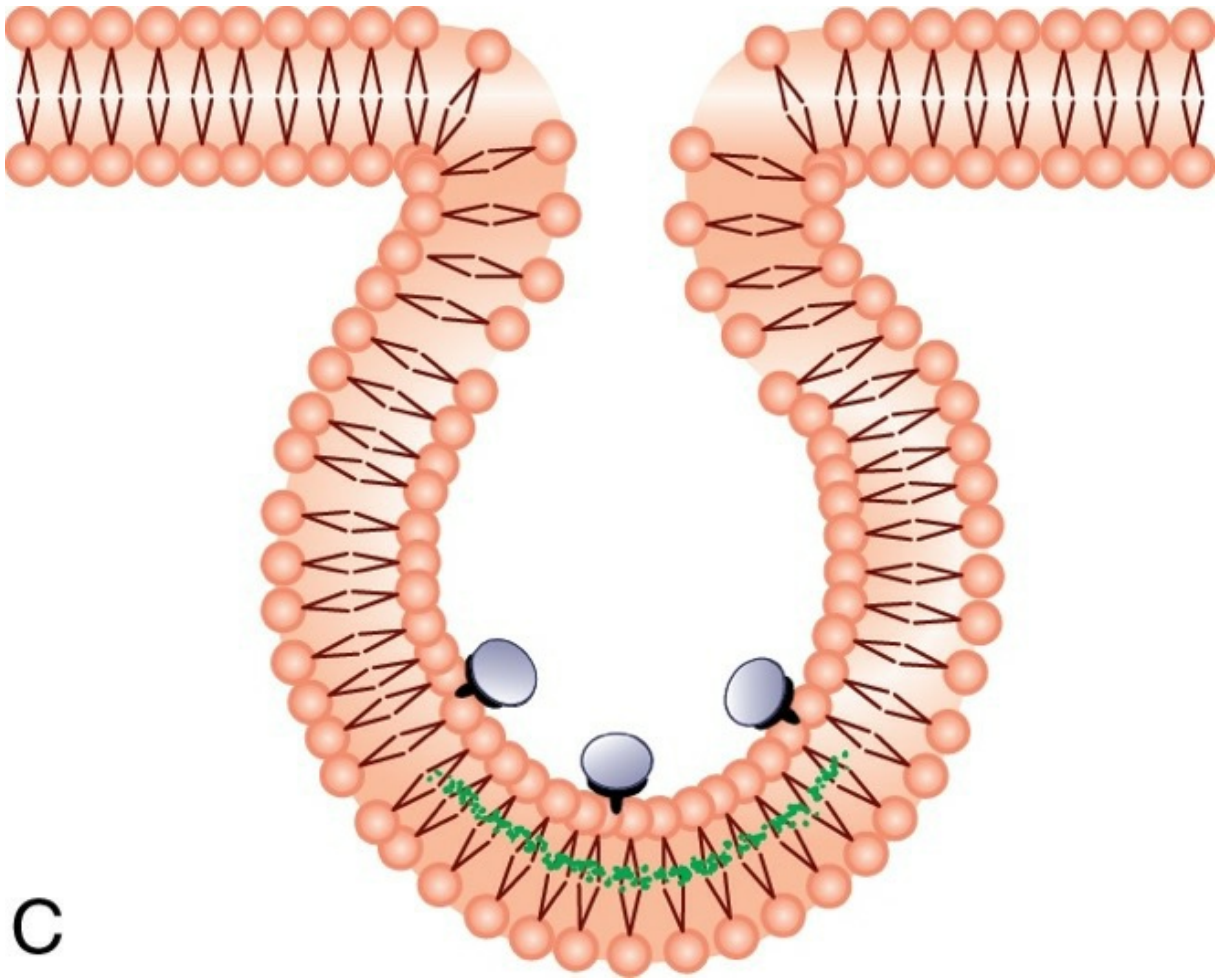

2. **Clathrin-mediated pathway (clathrin-mediated endocytosis).** Clathrin-mediated endocytosis occurs at the specific sites (indentation) on the cell membrane where clathrin (a protein) accumulates (Fig. 1.3-16A–D).

- **Structure.** Clathrin molecule is triskelion shaped with three legs radiating from the central hub.
- **Role of clathrin.** As the endocytosis progresses, clathrin molecule forms a geometrical array and surrounds the endocytic vesicle. After complete formation of the vesicle, the clathrin molecule falls off recycle to form another vesicle. During this process another protein called *dynamain* is also involved. It helps in pinching off

the vesicle at the neck region of the vesicle.

- *Clathrin-mediated* endocytosis is responsible for internalization of substances like, nerve growth factor, low density lipoproteins. Receptor-mediated endocytosis also occurs by this mechanism.

C

D

FIGURE 1.3-16 Clathrin-mediated endocytosis: **A**, the cell membrane showing receptors (to which the substance binds) and accumulation of clathrin; **B** and **C**, formation of endocytic vesicle; and **D**, complete internalization.

The cell membrane also contains small caveolae, indentations coated with protein caveolin involved in ingestion of various amino acids and peptides.

Exocytosis

Exocytosis (Fig. 1.3-17) is reverse of endocytosis, i.e. by this process the substances are expelled from the cell without passing through the cell membrane. In this process, the substances which are to be extruded are collected in the form of granules or vesicles which move towards the cell membrane. Their membrane then fuses with the cell membrane. The area of fusion breaks down releasing the contents to the exterior and leaving the cell membrane intact. Release of hormones and enzymes by secretory cells of the body occurs by exocytosis. The process of exocytosis requires

Ca^{2+} and energy along with docking proteins. Excretion of specific hormones and granules by the cells is termed as *exocytosis*.

FIGURE 1.3-17 Exocytosis.

There are two pathways by which secretion from the cell occurs.

1. **Nonconstitutive pathway.** In this process the proteins from the Golgi apparatus initially enter in the secretory granules, where processing of prohormones to mature hormones occur before exocytosis.
2. **Constitutive pathway.** It involves the prompt transport of proteins to the cell membrane in vesicles, with little or no processing or storage.

Transcytosis

Vesicular transport within the cell is called transcytosis or cytopemesis. It is quite similar to exocytosis and endocytosis. Three basic steps involved in this process are (i) vesicle formation, (ii) vesicle transportation and (iii) docking in the cell.

Role of various proteins in vesicular transport

The vesicles involved in the transport are coated with proteins. The different types of coating proteins have been identified which are:

- *AP-1 clathrin* present in vesicles involved in transportation from Golgi apparatus to lysosomes.
- *AP-2 clathrin* exists in endocytic vesicles involved in transportation to endosomes.

- *CO-PI and CO-PII* are coating proteins present in vesicles involved for transportation between endoplasmic reticulum and Golgi apparatus.
- *Dynamin* appears to be involved in vesicle formation from Golgi apparatus and also from cell membrane.
- *Docking protein*. Each target cell has a set of docking proteins (V snare protein) and latch proteins (T snare protein). The vesicle, when it reaches its target cell, then these proteins ensure that the vesicle will dock with the corresponding set of docking proteins.

Other transport processes

So far we have considered transport across the cell membrane, i.e. movement of substances between the intracellular fluid (ICF) and extracellular fluid (ECF) through the cell membrane. In addition to it, there are many situations in the body where transport of substances occurs through the epithelia and the capillary endothelial cell membrane. Some of these processes discussed briefly are:

- Transport across epithelia and
- Ultrafiltration.

Transport across epithelia

Transport across epithelia involves movement of the substances from one side of the epithelium to the other. The transepithelial transport occurs in body cavities lined by continuous sheet of cells such as in gastrointestinal tract, renal tubules, pulmonary airways and other structures. For transepithelial transport to occur, the cells need to be bound by tight junctions, and have different ion channels and transport protein in different parts of their membrane. Transport across epithelia may occur in two ways:

1. *Transport through the cells proper*. In gastro-intestinal tract and in urinary tubules substances are transferred from the lumen into the epithelial cells at their apical borders and then from the basal borders of the cells into interstitial fluid. From the interstitial fluid the substances are finally transported into the blood through the capillaries.

2. *Transport across the tight junctions.* It has been identified that in the epithelia of small intestine, proximal renal tubules and gall bladder, most of the sodium chloride passes through the tight junctions (areas of tight adherence between the two adjacent cells) rather than traversing the whole length of the epithelial cells.

Ultrafiltration

When a solution of protein and salt is separated from plain water or a less concentrated salt solution by a membrane permeable to salt and water and not to the protein, there will be a net movement of water on the protein side by diffusion and a movement of salt away from the protein side. This process is called dialysis (Fig. 6.5-7).

Ultrafiltration. Refers to occurrence of dialysis under hydrostatic pressure (Fig. 4.4-26). Ultrafiltration occurs at the capillary level in the body. The capillary blood is under hydrostatic pressure. The pressure is 35 mmHg near the arteriolar end and gradually declines to 12 mmHg near the venous end of the capillary. Through the capillaries there occurs ultrafiltration of all the constituents of the plasma except the proteins into the interstitial spaces. Ultrafiltration plays an important role in the formation of body fluids. Plasma proteins, to which the capillary wall is not permeable, exert an osmotic pressure of about 25 mmHg. This osmotic pressure opposes the hydrostatic pressure, resulting in limitation of outflow of fluid from the capillaries near the arteriolar end and backflow of interstitial fluid into capillaries (by osmosis) near their venous end where osmotic pressure (25 mmHg) is greater than the hydrostatic pressure of blood (12 mmHg) (Fig. 4.4-26).

- Technique of recording

Introduction

There exists a potential difference across the membrane of all living cells with the inside being negative in relation to the outside. This potential difference is named *membrane potential*, because the cations and anions arrange themselves along the outer and inner surfaces of the cell membrane. The magnitude of membrane potential varies from cell to cell and in a particular cell varies according to its functional status. For example, a nerve cell has a membrane potential of -70 mV (inside negative) at rest, but when it gets excited the membrane potential becomes about $+30$ mV (inside positive). The membrane potential at rest is called *resting membrane potential* or resting transmembrane potential or

simply resting potential. The term rest does not imply that the cell is metabolically quiescent but that it is not undergoing any electrical change. The membrane potential measured during the excited state of the cell is called *action potential*. For details of action potential see [page 61](#)

Genesis of membrane potential

Membrane potential is basically due to unequal distribution of ions across the cell membrane, which in turn results due to the combined effect of various forces acting on the ions. The factors involved in the genesis of membrane potential which need elaboration are:

- Selective permeability of the cell membrane,
- Gibbs–Donnan equilibrium,
- Nernst equation,
- Constant field Goldman equation and
- Sodium–potassium ATPase pump.

Selective permeability of the cell membrane

The cell membrane is selectively permeable, that is, to some ions it is freely permeable, to others impermeable and to some others it has variable permeability as:

- Ions like Na^+ , K^+ , Cl^- and HCO_3^- are diffusible ions. The cell membrane is freely permeable to K^+ and Cl^- and moderately permeable to Na^+ .
- Though the particle size of K^+ is larger (atomic weight 39) as compared to Na^+ (atomic weight 23), the permeability for K^+ is approximately 50–100 times greater than that for Na^+ . This is because hydrated K^+ is smaller than hydrated Na^+ . In other words, the energy required to separate water from Na^+ is greater as compared to K^+ , so the K^+ permeability is higher than Na^+ .
- The cell membrane is practically impermeable to intracellular proteins and organic phosphate, which are negatively charged ions.

- The presence of gated channels in the cell membrane is responsible for the variable permeability of certain ions in different circumstances.

Gibbs–Donnan membrane equilibrium

According to Gibbs–Donnan membrane equilibrium, when two ionized solutions are separated by a semipermeable membrane then at equilibrium:

- Each solution shall be electrically neutral, i.e. total charges on cations will be equal to total charges on anions.
- The product of diffusible ions on one side of the membrane will be equal to the product of diffusible ions on the other side of the membrane.

To understand, let us consider 'M' as a semipermeable membrane separating two ionized solutions of sodium chloride A and B (Fig. 1.4-1). Then according to Gibbs–Donnan equilibrium:

1. Each solution is electrically neutral, i.e.

$$(\text{cations})_A = (\text{anions})_A, \text{ and } (\text{cations})_B = (\text{anions})_B$$

OR

$$(\text{Na}^+)_A = (\text{Cl}^-)_A \text{ and, } (\text{Na}^+)_B = (\text{Cl}^-)_B$$

2. The product of diffusible ions on both sides will be equal, i.e.

$$\begin{aligned} &(\text{diffusible cations})_A \times (\text{diffusible anions})_A = \\ &(\text{diffusible cations})_B \times (\text{diffusible anions})_B \end{aligned}$$

OR

$$[(\text{Na}^+)_A \times (\text{Cl}^-)_A] = [(\text{Na}^+)_B \times (\text{Cl}^-)_B]$$

FIGURE 1.4-1 Semipermeable membrane 'M' separates ionic solutions of sodium chloride A and B.

From the above the ratio of diffusible ions will be as below:

$$\frac{(\text{diffusible cations})_A}{(\text{diffusible cations})_B} = \frac{(\text{diffusible anions})_B}{(\text{diffusible anions})_A}$$

OR

$$\frac{[\text{Na}^+]_A}{[\text{Na}^+]_B} = \frac{[\text{Cl}^-]_B}{[\text{Cl}^-]_A}$$

Thus there will be symmetrical distribution of ions at equilibrium. But if one or more nondiffusible ions 'X' are present on one side (A side) of the membrane, then according to Gibbs–Donnan, at equilibrium the distribution of diffusible ions will be as under:

1. Both solutions will be electrically neutral, i.e.

$$(\text{Na}^+)_{\text{A}} = (\text{Cl}^-)_{\text{A}} + (\text{X}^-)_{\text{A}} \text{ and, } (\text{Na}^+)_{\text{B}} = (\text{Cl}^-)_{\text{B}}$$

$$\text{So, } (\text{Na}^+)_{\text{A}} + (\text{Cl}^-)_{\text{A}} + (\text{X}^-)_{\text{A}} > (\text{Na}^+)_{\text{B}} + (\text{Cl}^-)_{\text{B}}$$

2. The product of diffusible ions on two sides will be equal, i.e.

$$(\text{Na}^+)_{\text{A}} \times (\text{Cl}^-)_{\text{A}} = (\text{Na}^+)_{\text{B}} \times (\text{Cl}^-)_{\text{B}} \quad (2)$$

From the relationship of (1) and (2), it is found that:

- $(\text{Na}^+)_{\text{A}} > (\text{Na}^+)_{\text{B}}$, and
- $(\text{Cl}^-)_{\text{A}} < (\text{Cl}^-)_{\text{B}}$

Hence there is unequal distribution of diffusible ions (asymmetrical). At equilibrium Na^+ being greater on the side which contains nondiffusible anions 'X⁻' (side A) and anion Cl^- being greater on the other side (side B). However, their concentration ratios are equal.

Since the intracellular fluid (ICF) contains nondiffusible anions like proteins and organic phosphate, so, according to Gibbs–Donnan equilibrium there should be an asymmetrical distribution of diffusible ions across the cell membrane with cations being more inside than the outside. However, in reality the interior of the cell is negatively charged which will be explained in the ensuing discussion.

Nernst equation

The asymmetrical distribution of diffusible ions across the cell membrane in the form of excess diffusible cation inside due to Gibbs–Donnan equilibrium (as explained above) results in a concentration gradient. As a result of which diffusible cations (K^+) will try to diffuse back into the ECF from ICF, but are counteracted by the electrical gradient, which will be created due to the presence of nondiffusible anions inside the cell. Thus, equilibrium will be reached between the concentration gradient and the electrical gradient resulting in diffusion potential (equilibrium potential) across the cell membrane. The magnitude of this equilibrium potential can be determined by Nernst equation as:

$$E_{(m)} = - \frac{RT}{ZF} \ln \frac{(\text{Conc})_i}{(\text{Conc})_o}$$

where:

$E_{(m)}$	Equilibrium potential (in millivolts) of the ions at which efflux and influx of the ions are equal
R	The natural gas constant and its value is 8.316 J/degree
T	The absolute temperature
F	The Faraday constant and its value is represented as number of C/mole of charge (96,500 C/mole)
Z	The valency of the ion
\ln	Symbol for natural logarithm
$(\text{Conc})_i$	The concentration of the ions in the intracellular fluid (inside)
$(\text{Conc})_o$	The concentration of the ions in the extracellular fluid (outside).

At normal body temperature (37°C), converting from the natural log to the base 10 log and replacing some of the constants with numerical values, the equation can be simplified to:

$$E_{(m)} = \pm 61 \log \frac{(\text{Conc})_i}{(\text{Conc})_o}$$

The equilibrium potential ($E_{(m)}$) for some of the important ions in the mammalian spinal motor neuron calculated from the simplified Nernst equation is shown in [Table 1.4-1](#).

TABLE 1.4-1

Equilibrium Potential ($E_{(m)}$) for Important Ions in a Mammalian Spinal Motor Neuron

Ion	Concentration (in mmol/L of H ₂ O)		Equilibrium potential (in mV)
	Outside the cell	Inside the cell	
Na ⁺	150	15	+60
K ⁺	05.5	150	-90
Cl ⁻	125	09	-70
Ca ²⁺	5	<1	+130

Goldmann–Hodgkin–Katz (GHK) equation

The Nernst equation helps in calculating the equilibrium potential for each ion individually. However, the magnitude of the membrane potential at any given time depends on the distribution of Na⁺, K⁺ and Cl⁻ and the permeability of each of these ions. The integrated role of different ions in the generation of membrane potential can be described accurately by the *Goldmann's constant field equation* or the so-called Goldmann–

Hodgkin–Katz (GHK) equation:

$$V = \frac{RT}{F} \ln \frac{P_k [K^+]_i + P_{Na^+} [Na^+]_i + P_{Cl^-} [Cl^-]_o}{P_k [K^+]_o + P_{Na^+} [Na^+]_o + P_{Cl^-} [Cl^-]_i}$$

where

V is the membrane potential,

R is the gas constant,

T is the absolute temperature,

F Faraday,

P_{K^+} , P_{Na^+} and P_{Cl^-} are the permeabilities of the membrane to K^+ , Na^+ and Cl^- , and brackets signify concentration and i and o refer to inside and outside of the cell, respectively.

Inferences of Goldman constant field equation

Following important inferences can be drawn from the Goldman constant field equation:

1. Most important ions for development

of membrane potentials in nerve and muscle fibres are sodium, potassium and chloride. The voltage of membrane potential is determined by the concentration gradient of each of these ions.

2. Degree of importance

of each of the ions in determining the voltage depends upon the membrane permeability of the individual ion. For example, if the membrane is impermeable to K^+ and Cl^- then the membrane potential will be determined by the Na^+ gradient alone and the resulting potential will be equal to the Nernst potential for sodium.

3. Positive ion concentration from inside the membrane to outside

is responsible for electronegativity inside the membrane. This is because of the fact that due to concentration gradient, the positive ions diffuse outside leaving the nondiffusible negative ions inside the cell.

4. Signal transmission

in the nerves is primarily due to change in the sodium and potassium

permeability because their channels undergo rapid change during conduction of the nerve impulse and not much change is seen in the chloride channels.

Role of Na⁺–K⁺ ATPase pump

The role of Na⁺–K⁺ ATPase lies in building the concentration gradient. It serves to pump back the Na⁺ that diffuses into the cell and K⁺ that diffuses out of the cell. In the resting membrane, these diffusions are negligible, so the Na⁺–K⁺ pump works very feebly in this stage. Further, although the Na⁺–K⁺ pump is potentially electrogenic (since it pumps out three Na⁺ ions for two K⁺ ions), at no stage is the pump able to build up a significant membrane potential. This is because of the fact that, as soon as the pump creates a negative potential inside the cell, chloride ions rush out of the cell and restore electroneutrality. Thus, in other words, this pump, pumps out three Na⁺ ions and one Cl⁻ ion for every two K⁺ ions it pumps in.

Recording of membrane potential

Instruments used for recording

The essential instruments used in recording the activity of an excitable tissue are:

- Microelectrodes,
- Electronic amplifiers and
- Cathode ray oscilloscope (CRO).

Basic principles of the functioning of these instruments are described on page 70.

Technique of recording

Technique of recording of membrane potential is described on page 71.

- Gene therapy

Genetics may rightly be claimed to be one of the most important

branches of biology. Foundation for the present day genetics was laid by the Mendel's work published in 1866. He demonstrated that characteristics do not blend but pass from parents to offsprings as discrete (separate) units. These units, which appear in the offspring in pairs, remain discrete and are passed on to subsequent generations by the male and female gametes each of which contain a single unit. The Danish botanist Johannied called these units genes in 1909 and the American geneticist Morgan, in 1912 demonstrated that they are carried on chromosomes. Since the early 1900, the study of genetics has made great advances. An overview of which is given here in brief.

Structural and functional characteristics of substrate for genetics

Chromosomes

Waldeyer in 1888 coined the term chromosomes to denote the thread-like structures present in the nucleus of eukaryotic cells during division. It is now established that the chromosomes are responsible for the transmission of the hereditary information from one generation to next. There are 46 chromosomes (23 pairs) in all the dividing cells of the body except the gametes (sex cells which contain only 23 chromosomes) haploid number.

Morphology of chromosomes

Each chromosome is composed of two chromatids connected at the *centromere*. Each chromatid consists of two *chromonemes*. *Telomeres* are the terminal ends of chromosomes DNA molecule.

Morphological types of chromosomes

Depending upon the location of the centromere, four morphological types of chromosomes are recognized (Fig. 1.5-1):

- *Metacentric chromosomes.* The centromere divides the chromosomes into two equal arms (Fig. 1.5-1A).
- *Submetacentric chromosomes.* The centromere divides the chromosomes into two unequal arms (Fig. 1.5-1B).

- *Acrocentric chromosomes*. The centromere is located in such a way that a very short arm of chromosomes is visible (Fig. 1.5-1C).
- *Telocentric chromosomes*. The centromere is located at one end (Fig. 1.5-1D).

FIGURE 1.5-1 Morphological types of chromosomes: **A**, metacentric; **B**, submetacentric; **C**, acrocentric; and **D**, telocentric.

Functional types of chromosomes

There are three types of eukaryotic chromosomes:

- *Autosomes* are the chromosomes present in somatic cells. The number of autosomes in a cell is fixed and is expressed as $2n$ or *diploid number*.

- *Sex chromosomes* are present in the sex cells and are responsible for determining the sex of an individual.
- *Supernumerary or redundant chromosomes* are also found in eukaryotic cells but their occurrence is quite uncommon.

Chemical structure of chromosome

The chromosomes are mainly composed of DNA. The chromosome also contains RNA, basic proteins called histones, complex proteins including enzymes, some organic phosphorus compounds and inorganic salts. The amount of DNA in a haploid cell is half the amount present in a diploid cell of the same species. Further, the concentration of DNA in any cell remains constant in every circumstance. An important feature of DNA is that it is metabolically stable.

Organization of DNA in a chromosome

See page 37.

Structure and function of DNA and RNA

DNA

DNA, i.e. deoxyribonucleic acid, is a molecule of inheritance and thus may be regarded as the “Reserve Bank” of genetic information. It is exclusively responsible for maintaining the identity of different species of organisms for millions of years.

Structure of DNA

DNA is a polymer of four monomeric deoxyribonucleotides, namely, deoxyadenylate (dAMP), deoxyguanylate (dGMP), deoxycytidylate (dCMP) and deoxythymidylate (dTMP). Each deoxyribonucleotide in turn is composed of a nitrogenous base purines or pyrimidines (A, G, C or T), a pentose sugar, i.e. deoxyribose and a phosphate. Each molecule of DNA has equal number of adenine and thymine residues ($A = T$) and equal number of guanine and cytosine residues ($G = C$). This is known as *Chargaff's rule*.

Watson–Crick model of DNA structure

The salient features of Watson–Crick model of DNA (now known as B-DNA) are (Fig. 1.5-2):

- *Double helix structure.* Each DNA molecule is a right-handed double helix composed of two polydeoxyribonucleotide chains (strands) twisted around each other on a common axis.
- *Antiparallel chains.* The two chains of each DNA molecule are antiparallel, i.e. one chain runs in the 5' to 3' direction while the other in 3' to 5' direction.
- *Dimensions.* The width of a double helix is 20 Å (2 nm). Each turn (pitch) of the helix contains 10 pairs of nucleotides, each placed at distance of about 3.4 Å (0.34 nm); thus each turn is 34 Å (3.4 nm) in dimension.
- *Arrangement of base, sugar and phosphate molecule.* Each chain has a sugar–phosphate backbone with bases that project at right angles and hydrogen bond with the bases of the opposite chain across the double helix (Fig. 1.5-3).
- *Complementary chains.* The two polynucleotide chains are not identical but complementary due to base pairing.
- *Genetic information.* The genetic information resides in one of two strands known as *template strand* or *sense strand*. The opposite strand is antisense strand.

FIGURE 1.5-2 Watson–Crick model of DNA structure.

FIGURE 1.5-3 Diagrammatic structure of straightened chains of DNA.

Types of DNA

Six forms of DNA, A to E and Z, have been identified. Among these A, B and Z forms are important.

- *A-DNA* is a right-handed helix. It contains 4 base pairs per turn.
- *B-DNA* as described by Watson and Crick (discussed above) contains 10 base pairs per turn spanning a distance of 3.4 nm. It is the most

predominant form under physiological conditions.

- **Z-DNA** is a left-handed helix and contains 12 base pairs per turn. The name Z-DNA has been derived from the zigzag fashion in which the polynucleotide strands of this DNA move.

Size of DNA

DNA molecules are huge in size. The term kilobase pair (Kb = 1000 base pairs) is commonly used in DNA structure. In humans 23 haploid chromosomes have 2,900,000 Kb with a total contour length of 990 nm. Thus, a human cell contains about 2 m of DNA distributed among 46 chromosomes. Each chromosome, therefore, contains about 4.8 cm (48,000 μm) of DNA. Human chromosomes are on average about 6 μm long, with a packing ratio of 8000:1. In order to maintain the high degree of organization when DNA is folded, the histone proteins form a precise architectural scaffolding for the DNA.

Organization of DNA in the cell

In human cells, the DNA is found in association with positively charged protein molecules called *histones*. Each DNA helix combines with a group of eight histone molecules to form structures known as *nucleosomes* which have an appearance of 'beads and string'. These nucleosomes, and the DNA strands linking them, are packed closely together to produce a 30 nm diameter helix with about six nucleosome per turn. This is known as 30 nm fibre or the *solenoid fibre*. The solenoid fibres in turn coil to form *chromatin fibres* which are further coiled and packed in the form of *chromatin* in which form DNA is present in the chromosome (Fig. 1.5-4).

FIGURE 1.5-4 Diagrammatic organization of DNA in a chromosome of the human cell.

RNA

Structure of RNA

RNA is a polymer of ribonucleotides held together by 3', 5'-phosphodiester bridges. Though an RNA molecule like that of DNA is composed of nucleotides consisting of a base sugar and phosphate but it has following structural differences:

- *Single-strand.* RNA is commonly a single-stranded structure unlike DNA. However, in certain forms of RNA this strand may fold at

certain places to give a double-stranded structure if complementary base pairs are in close proximity.

- *Ribose sugar*. The sugar molecule in RNA molecule is ribose in contrast to deoxyribose.
- *Base*. The pyrimidine base in a RNA molecule is uracil in place of thymine of a DNA molecule.
- *Chargaff's rule*. Due to the single-stranded structure Chargaff's rule is not obeyed, i.e. there is no specific relation between purine and pyrimidine contents.

Types of RNA

Following types of RNAs have been recognized:

- *Messenger RNA (mRNA)*. In the human cell, it is synthesized in the nucleus and enters the cytoplasm to participate in protein synthesis.
- *Transfer RNA (tRNA)*. There are about 20 species of tRNA corresponding to 20 amino acids present in protein structure. The structure of tRNA resembles that of clover leaf with four arms. tRNA delivers amino acids for protein synthesis.
- *Ribosomal RNA (rRNA)*. rRNAs are present in ribosomes (factories of protein synthesis). It is believed that rRNAs play a significant role in binding of mRNA to ribosomes in protein synthesis.

DNA replication

DNA replication is a process by which each original DNA molecule gives rise to two copies with identical structure. The method by which the DNA replicates is called *semiconservative replication* since each new double helix retains (conserves) one of the two strands of the original DNA double helices. Steps involved in the DNA replication are (Fig. 1.5-5):

1. *Initiation of replication*. The site from where the replication of DNA is initiated is called *origin of replication*. In prokaryotes, DNA replication initiates from only one site hence called monoreplicative replication and in eukaryotes it starts from multiple sites (*multireplicative replication*). The origin of replication mostly consists of A—T base pairs. When a specific

binding protein (dna protein) binds to the site of replication then there occurs separation of double-stranded DNA, and separated strands of DNA form a bubble at the site of origin.

2. *Formation of replication fork and replication eye.* The next step in the DNA replication is unwinding of double helix leading to formation of either Y-shaped *replication fork* (when DNA replication initiates from the terminal end of the double helix), or θ -shaped replication eye (when DNA replication starts from the intercalary position). This step is controlled by an enzyme called *helicase* and a protein called *single-strand binding* (SSB) protein.

- *Role of DNA helicases.* These enzymes bind to both the strands of DNA at replication fork and move along the DNA helix and separate the strands of the DNA double helix. The function of helicases can be compared to a zip opener.
- *Role of single-strand DNA binding (SSB) proteins.* As the name indicates, SSB protein binds only to single-stranded DNA (separated by helicase). Main function of this protein is to keep the two DNA strands separate, hence, also called helix destabilizing protein. SSB protein also provides template for new DNA synthesis and prevent degradation of single-stranded DNA.

3. *Formation of RNA primer.* RNA primer consists of a short fragment of RNA (about 5–50 nucleotides). It is required for synthesis of new DNA. The RNA primer is synthesized on DNA template by specific *RNA polymerase* (primase).

4. *DNA synthesis along the replication fork.* DNA replication occurs simultaneously in both the leading as well as lagging strands of Y-shaped replication fork and is of two types:

- *Continuous DNA replication.* In the leading strand, DNA polymerase III binds to the single-stranded DNA and

starts to move along the strand. Each time it meets the next base on DNA, free nucleotides approach the DNA strand, and one with the correct complementary base hydrogen bonds to the base in the DNA. The free nucleotide is then in place by the enzyme until it binds to the preceding nucleotide thus extending the new strand of DNA. The enzyme continues to move along one base at time with new DNA strand growing as it does so.

- *Discontinuous DNA replication.* Occurs in the lagging strand.

FIGURE 1.5-5 Simplified diagram showing main steps of DNA replication.

Genes

General considerations

The gene is the functional unit of DNA. A gene could therefore be defined as a piece of DNA which codes for a protein. In strictest sense, the gene can be defined as the DNA code for a single polypeptide chain. Since some proteins are made up of more than one polypeptide chains, they are therefore coded for by more than one genes.

Genome. The term genome refers to total genetic information contained in a cell.

Human genome. For humans, the genome is essentially equivalent to all of the genetic information which is present in a single set of 23 chromosomes.

Human genome project (1990–2003). The human genome project (HGP) which completed on April 14, 2003 has accomplished the following goals:

- Identified all the *approximate 30,000 genes in human DNA*.
- Determined the sequences of 3 billion chemical base pairs that make the human DNA.

Functional genomics. Understanding the functions of genes and other parts of genome is known as functional genomics.

Comparative genomics. Comparative genomics is the analysis and comparison of genome from different species.

Constitutive and inducible genes. The genes are generally considered under two categories:

- **Constitutive.** The products (proteins) of these genes are required all the time in a cell. Therefore, the constitutive genes (or housekeeping genes) are expressed more or less at a constant rate in almost all the cell and, further, they may not be subjected to regulation, e.g. enzymes of citric acid cycle.

- *Inducible genes.* The concentration of the proteins synthesized by inducible genes is regulated by various molecular signals. An inducer increases the expression of these genes while a repressor decreases, e.g. tryptophan pyrrolase of liver is induced by tryptophan.

Gene expression: Central dogma

As mentioned above, each cell of human body contains the entire genome, yet the genetic expression is very selective and different patterns of protein synthesis occur in different tissues. Not only this, even in the same tissue, there is wide variation in the proteins produced during the course of development.

The expression of genetic material occurs through the production of proteins. This involves two consecutive steps—transcription and translation. In transcription, the genetic information, stored in DNA, is transferred to an RNA intermediate, which in turn uses this information to direct the synthesis of proteins during translation. This unidirectional flow of information was described by FHC Crick in 1958 as the central dogma of molecular biology (Fig. 1.5-6). However, an important modification of this information flow was given by David Baltimore and H Temin, who described reversible sequence through reverse transcription or feminism in the presence of transcripts (revised central dogma).

FIGURE 1.5-6 Central dogma: the flow of genetic information.

Transcription

Transcription is a process in which RNA is synthesized from DNA. All the three types of RNAs (mRNA, tRNA and rRNA) are produced through transcription. The transcription process is selective, i.e. the entire molecule of DNA is not expressed in transcription, but the RNAs are synthesized only for selected regions of DNA. The strand of DNA that directs the synthesis of mRNA via complementary base pairing is called the *template strand* or coding or sense strand, and the other strand is known as noncoding strand or antisense strand. Transcription is accomplished by an enzyme *RNA polymerase* that gets physically associated with DNA. Only one type of such an enzyme is found in prokaryotes in contrast to eukaryotes (where three different forms of RNA polymerase are found). RNA I, II and III catalyse the synthesis of rRNA, mRNA and tRNA, respectively.

Promoter sites. RNA polymerase binds to a region of DNA called promoter site. In eukaryotes, a sequence of DNA bases has been

identified. This sequence, known as Hogness box or TATA box (Fig. 1.5-7), is located on left about 25 nucleotides away (upstream) from the starting site of mRNA synthesis. There also exists another site of recognition between 70 and 80 nucleotides upstream from the start of transcription. This second site is referred to as CAAT box. One of these two sites (or sometimes both) helps RNA polymerase II to recognize requisite sequence of DNA for transcription.

FIGURE 1.5-7 Promoter sites of DNA in eukaryotes.

Salient features of transcription in eukaryotes vis-à-vis prokaryotes are:

- Transcription in eukaryotes unlike prokaryotes occurs within the nucleus and mRNA moves out of the nucleus into the cytoplasm for translation.
- The initiation and regulation of transcription in eukaryotes is more extensive than prokaryotes.

Post-transcriptional modifications

- The mRNA in eukaryotes is processed from the primary RNA transcript, a process called maturation which includes:
- Releases of the introns and joining with two adjacent exons to produce mature mRNA.
- *RNA editing*. Besides, these two post-transcriptional modifications, RNA editing may also take place before translation begins.

Reverse transcription

refers to formation of DNA from RNA. The enzyme reverse transcriptase is responsible for this process. The DNA so formed is complementary (cDNA) to viral RNA can be transmitted to host DNA. Reverse transcription is known to occur in retroviruses which include human immunodeficiency virus that causes AIDS.

Translation: Biosynthesis of proteins

Translation is the process by which genetic message carried by mRNA from the DNA is converted in the form of a polypeptide chain having specific sequence of amino acids. Before discussing the process of translation, it will be worthwhile to know something about the genetic code.

Genetic code

Process by which the information coded in the mRNA is decoded into polypeptide is referred to as *deciphering the genetic code*. Dr Hargobind Khorana shared 'Nobel Prize' in 1968 with Nirenberg and Holly for the discovery of genetic code. The genetic code (codons) is formed by three nucleotides (triplet) base sequences in mRNA. The codons are formed of

four nucleotide base (A, G, C and U). These four bases produce 64 different combinations of three base codons. Of the 64 codons, the 61 codons code for 20 amino acids found in proteins and the three codons (UAA, UAG and UGA) are *termination codons* which act as stop signals in protein synthesis. The codons AUG and sometimes GUG act as *initiating codons*.

Characteristics of genetic code are:

- *Universality*, i.e. same codons are used to code for the same amino acids in all the living organisms with a few exceptions.
- *Specificity*, i.e. a particular codon always codes for the same amino acid, e.g. AUG is the codon for methionine.
- *Nonoverlapping*, i.e. the genetic code is read from a fixed point as a continuous base sequence.
- *Degenerate*, i.e. one amino acid is coded by more than one codon. The codons that designate the same amino acid are called synonyms.

Process of protein biosynthesis

The process of protein synthesis in addition to mRNA requires amino acids tRNA, energy sources (ATP and GTP) and protein factors. Protein synthesis occurs over ribosomes which are also called *protein factories*. The protein biosynthesis involves three processes:

I. ***Activation of amino acids***. Amino acids are activated and attached to tRNA in a two-step reaction. A group of enzymes, namely aminoacyl tRNA synthetases, is required for this process. In the first step, an amino acid reacts with ATP in the presence of specific amino acid tRNA to form *enzyme-AMP-amino acid complex*. This complex then reacts with a specific tRNA and the amino acid is transferred to 3' end of the tRNA to form aminoacyl tRNA.

II. ***Translation proper*** involves three steps—initiation, elongation and termination.

1. ***Initiation***. The translation of mRNA begins with the formation of initiation complex.

2. *Elongation*. Ribosomes elongate the polypeptide chain by a sequential addition of amino acids to the growing carboxyl end.

The elongation process is repeated again and again with addition of one amino acid each time till signal for termination is reached.

3. *Termination* of polypeptide synthesis is evoked by a nonsense or termination codon (UAA, UAG or UGA).

III. *Post-translational modifications*. The proteins synthesized in translation are as such not functional. Many changes take place in the polypeptides after the initiation of their synthesis or, most frequently, after the protein synthesis is completed. Post-translational modification includes:

- Proteolytic degradation and
- Covalent modifications (phosphorylation, hydroxylation and glycosylation).

Regulation of gene expression

As discussed earlier, each nucleated somatic cell in the body contains full genetic message, yet there is great differentiation and specialization in the functions of various types of adult cells. It is because of the fact that there exists a foolproof system for regulation of gene expression that maintains orderly growth in cells and prevents uncontrolled growth. The genes are controlled both spatially and temporally. The regulation of gene expression is thus absolutely essential for growth, development and differentiation of an organism. A positive regulator increases the gene expression whereas a negative regulator decreases.

Regulation of gene expression in prokaryotes

In prokaryotes, gene expression is regulated by operon system. Operons are segments of genetic material which function as regulated units that can be switched on and switched off. The operon systems are of two

types:

1. **Inducible operon system** (lac operon system). An inducible operon system is that regulated genetic material which remains switched off normally but becomes operational in the presence of an inducer. It occurs in catabolic pathway.
2. **Repressible operon system** (tryptophan operon system). A repressible operon system is that regulated genetic material which normally remains active/operational. It usually occurs in anabolic pathways.

Regulation of gene expression in eukaryotes

The regulation of gene expression in eukaryotes is very complex and involves various mechanisms. Some of the mechanisms are:

1. **Gene amplification.** In this mechanism, the expression of gene is increased several folds. An example of gene amplification in humans includes development of drug resistance by the malignant cells to long-term administration of methotrexate. This occurs by amplifying the gene coding for dihydrofolate reductase.
2. **Gene rearrangement.** The process of gene rearrangement is responsible for the generation of 10 billion antigen-specific immunoglobulins.
3. **Regulation of gene expression through transcription factors.** Transcription factors are products of other genes and hence mediate transregulation by binding to specific DNA segments. This specific interaction of protein to DNA in over 80% of the nontranscription factors is brought about by one of the four DNA-binding motifs: zinc finger motif, lucine zipper motif, helix–turn–helix motif, and helix–loop–helix motif.
4. **Regulation of gene through mRNA.** Gene expression is also regulated by regulation of synthesis transport, processing and stability of mRNA.

Applied genetics

Applications of genetics are many more and beyond the scope of a book on physiology, only a few of interest described here include some aspects of:

- *Molecular genetics and biotechnology, and*
- *Molecular genetics and medicine.*

Molecular genetics and biotechnology

Biotechnology involves use of living organisms or products of living organisms for the welfare of human. Presently, molecular biology has combined with genetics to give us more powerful biotechnology. The tools of molecular genetics have provided improved way to make use of living organisms for the benefit of humans. The subject of molecular genetics and biotechnology is expanding fast and has already become very vast. The present discussion includes only a few important aspects viz.

- Genetic engineering,
- Stages of recombinant DNA technology
- Application of recombinant DNA technology,
- Polymerase chain reaction
- Blotting techniques
- Cloning
- Apoptosis.

Genetic engineering/recombinant DNA technology

The terms genetic engineering/recombinant DNA technology/DNA cloning/molecular cloning/gene cloning all refer to the process of transfer of a DNA fragment of interest from one organism to a self-replicating genetic element such as a bacterial plasmid. In other words, this technology involves cutting, modifying and joining DNA molecules using enzymes such as restriction enzymes and DNA ligase.

Stages of recombinant technology

Stages of recombinant technology are:

Stage 1: Generation of a copy of gene required.

This is the most difficult part of the process. Three methods are used to get a copy of a gene:

- Making a copy of the gene from its mRNA, using reverse transcriptase,
- Synthesizing the gene artificially and
- Using a *shotgun approach* which involves chopping up the DNA with *restriction enzymes* and searching for the piece with the required gene (Fig. 1.5-8).

FIGURE 1.5-8 Stages of recombinant DNA technology.

Stage 2: Joining the gene to a vector or carrier molecule.

A vector is a carrier of a DNA molecule to which the generated gene is attached for cloning. Three commonly used vectors in recombinant DNA technology are (Fig. 1.5-8):

- Plasmids,
- Bacteriophages and

- Cosmids.

Stage 3: Introduction of vector DNA into the host cell to produce chimeric DNA.

The main aim of genetic engineering is to insert a DNA of interest (generated gene) into a vector DNA so that the DNA fragment replicates along with the vector after annealing. This hybrid combination of two fragments of DNA is referred to as *chimeric DNA* or *hybrid DNA* or *recombinant DNA*.

Stage 4: Cloning of chimeric DNA (fig. 1.5-9).

A clone is a large population of identical molecules, bacteria or cells that arise from a common ancestor. The chimeric DNA contained in a plasma (vector) can be introduced into bacterial cells by a process called *transfection*. The replicating bacterial cell (host cell) permits the amplification of the chimeric DNA of the vector. In this way, cloning results in the production of large number of identical target DNA molecules. The cloned target DNA is released from the vector by cleavage (using appropriate restriction endonucleases), isolated, characterized and used for various purposes.

FIGURE 1.5-9 Cloning of a recombinant DNA.

Applications of genetic engineering

Genetic engineering has revolutionized the application of molecular biology to medical/agricultural sciences that has immensely benefitted the mankind. A few important applications are:

1. **Production of proteins/hormones.** It is possible to produce proteins/hormones in large amount for therapeutic purposes. These

include insulin, growth hormone, erythropoietin, interferons, vaccines and blood clotting factors.

2. *Molecular analysis of diseases* such as sickle cell anaemia, thalassaemia, cystic fibrosis using recombinant DNA technology has led to better understanding of these diseases.

3. *Laboratory diagnostic applications.* Using this technique, the diagnosis of diseases like AIDS has become simple and rapid.

4. *Gene therapy* for correcting a genetic defect is very useful application of RBT (see page 48).

5. *Prenatal diagnosis of genetic diseases* such as sickle cell anaemia is possible from the DNA collected from the amniotic fluid by using DNA probes.

6. *Transgenesis* refers to transfer of genes into the fertilized ovum which will be found in somatic as well as germ cells and passed on to successive generation.

7. *Application in forensic medicine: DNA fingerprinting* applying southern blot technique is useful in identifying criminals and settling the disputes of parenthood of children.

8. *Industrial applications.* Enzymes synthesized by this technology are used to produce sugar, cheese and detergents.

9. *Agricultural applications* include development of genetically engineered plants to increase the yield of crops, to resist draught and to resist diseases.

10. *Evolution.* This technique helps in bridging several missing links in the evolution by amplifying the DNA by PCRs from the archaeological sample of extinct animals.

Polymerase chain reaction

Polymerase chain reaction (PCR) is a sensitive, selective and extremely rapid method of amplifying a target sequence of DNA.

Technique of PCR involves following steps:

- *Denaturation of DNA* refers to separation of double-stranded target

DNA into single strand by heating.

- *Annealing with two primers* (one for each strand) is allowed to occur after cooling the single DNA strand.
- *DNA amplification* occurs by synthesis of new DNA strand in the presence of enzyme DNA polymerase and the substrates deoxyribonucleotide triphosphates. These strands are compliments to the target DNA. The cycle of DNA amplification is repeated again and again. The Taq DNA polymerase is *heat resistant*; this special feature makes it suitable for automation of PCR. PCR results in the amplification of target DNA by about a million (10^6) fold with high specificity.

Application of PCR. PCR is highly sensitive; it can detect even the presence of a single molecule of DNA. PCR amplification of sequences of human genomic DNA produces an amount of target DNA (up to 1 mg) which is sufficient for direct application in any one of a wide range of molecular biological procedures, including direct DNA sequencing.

PCR has several applications:

- Rapid diagnosis of AIDS;
- DNA fingerprinting is useful in kinship analysis and in the identification of crime suspects;
- Prenatal diagnosis of genetic diseases;
- Study of evolution from DNA of archaeological samples and
- Sex identification.

Blotting techniques

Blotting techniques refer to the analytical techniques used for the identification of a special DNA, or RNA or a protein. These include:

- Southern blotting (for DNA),
- Northern blotting (for RNA) and
- Western blotting (for protein).

Southern blotting

Southern blotting technique is named after the scientist who identified it while the northern and western blot techniques are the laboratory jargons which are now accepted.

Steps of southern blotting are:

- *Extraction of DNA* from the cells (say leucocytes).
- *Cleavage of DNA* into fragments by restriction endonucleases.
- *Separation of the fragments* of DNA is done by gel electrophoresis.
- *Denaturation of DNA* is done either prior to or during transfer by placing the gel in an alkaline solution (NaOH).
- *Transfer of DNA fragments to a sheet of nitrocellular paper* from the agarose gel is done by blotting (hence the name blot).
- *Fixation of DNA fragments to the membrane* is then done by any of the following methods:
 - oven baking 80°C, or
 - ultraviolet cross-linking.
- *Formation of labelled DNA hybrid complexes.* After fixing the DNA fragments, the membrane is placed in a solution of labelled DNA probe. This leads to hybridization reaction forming labelled DNA hybrid complexes.
- *Identification of labelled DNA hybrid complex.* After the hybridization reaction has been carried out, the membrane is washed to remove unbound radioactivity and regions of hybridization are identified by *autoradiography* by placing the membrane in contact with X-ray film.

Applications. Important applications of southern blotting are:

- DNA fingerprinting, and
- Detection of mutant gene causing cystic fibrosis.

Northern blotting

Northern blotting is similar to southern blotting except that it is for RNA instead of DNA.

Applications. Important applications of northern blotting are analysis of the expression of a gene in a particular tissue.

Western blotting

Western blotting is the technique for identification of a specific protein. It involves the transfer of electrophoresed protein bands from SDS polyacryl amide gel onto a nitrocellulose membrane followed by probing using a labelled antibody probe.

Applications. Western blot test is widely used as confirmatory test of HIV. In combination with a positive enzyme-linked immunosorbent assay (ELISA), a positive western blot is 99.9% accurate in detecting HIV infection.

Cloning

Cloning refers to making many identical copies of a molecule.

Certain terms which need to be defined before discussing the different types of cloning include:

- *Transformation* refers to introduction of any DNA molecule into any living cell.
- *Transfection* refers to introduction of purified DNA molecules into cultured cells.
- *Transduction* is the transfer of genetic material or DNA from one cell to another with the help of a virus.
- *Microinjection* is a method of introducing new DNA into a cell by injecting it directly into the nucleus.
- *Biolistics* refers to the means of introducing DNA into cells that involves bombardment with high-velocity microprojectiles located with DNA.

Types of cloning. Some important types of cloning are:

- Gene cloning/DNA cloning,
- Reproductive cloning,

- Therapeutic cloning and
- Tissue culture.

Gene cloning

Gene cloning refers to the process of transfer of a DNA fragment of interest from one organism to a self-replicating genetic element (cloning vector) such as bacterial plasmid and subsequent propagation of the recombinant DNA molecule in the host organism (Fig. 1.5-9). Other terms used to denote gene cloning are DNA cloning and recombinant DNA technology (RDT).

Details of this process have already been described on page 42.

Applications of gene cloning, i.e. recombinant DNA technology have already been highlighted (see page 42). Important genetic applications include:

- Gene therapy,
- Gene engineering of organisms and
- Sequencing genomes.

Reproductive cloning

Reproductive cloning is a technology used to generate an animal that has same nuclear DNA as another currently or previously existing animal.

Technique. Reproductive cloning uses the technique of somatic cell nuclear transfer (SCNT). In this technique, genetic material is transferred from the nucleus of a donor adult cell to an egg whose nucleus, and thus its genetic material, has been removed. The reconstructed egg containing the DNA from a donor cell is then treated with chemicals or electric current to stimulate cell division. Once the cloned embryo reaches a suitable stage, it is transferred to the uterus of a female host where it continues to develop until birth. A sheep (Dolly) was created by somatic cell nuclear transfer process from a cell taken from the parent's udder by the research team at the Roslin Institute in Edinburgh (Scotland) in February 1997.

Applications. *Reproductive cloning can be used to repopulate endangered animals or animals that are difficult to breed. Examples are:*

- In 2001, the first clone of an endangered animal, a wild ox called a *gaur* was born. The young gaur died from an infection about 48 hours after its birth.

- In Italy (2001), a successful cloning of a healthy baby *mouflon*, an endangered wild sheep was reported. The cloned mouflon is living at a wild centre in Sardinia.

Embryo cloning (therapeutic cloning)

- Therapeutic cloning refers to the production of human embryos for use in research.
- This process is aimed at harvesting stem cells that can be used to study human development and to treat diseases rather than to create a cloned human being.
- Stem cells are extracted from the egg at the blastocysts stage of development and can be used to generate virtually any type of specialized cells in the human body.
- First human embryo for the purpose of therapeutic research was cloned in November, 2001 by the scientists from Advanced Cell Technologies (ACT), a biotech company in Massachusetts.

Applications. Stem cells can be used to serve as replacement cells to treat heart disease, Alzheimer's disease, cancer and other diseases.

Tissue culture

Cells may also be cloned for special purposes. This technique is called *tissue culture*. Certain cells when placed in a suitable medium can be cultured indefinitely.

Applications. The use of cloned cells allows the study of the action of such chemicals as hormones, drugs, antibiotics, cosmetics and pharmaceutical products to be made on cells. Such a technique is a useful substitute for laboratory animals such as rats, cats and dogs.

Apoptosis

Apoptosis versus cell necrosis. Apoptosis, also called as programmed cell death (PCD), occurs under genetic control. Since the cell's own genes play an active role in its demise, so apoptosis can also be called *cell suicide*. It should be distinguished from necrosis in which the healthy cells are destroyed by some injury inflicted on the cells, e.g. inflammation. Since necrosis is caused by some external process, it can be also called *cell murder*. Thus, apoptosis is a natural process while necrosis

is an unnatural process. Consequently, apoptosis does not induce a local inflammatory response while cell necrosis does.

Need and examples of apoptosis. Apoptosis is a very common process during development as well as adulthood, the need of which is highlighted with some examples:

1. *Apoptosis for proper development of tissues*

- *In the central nervous system, large number of neurons are produced and then die during the remodelling that occurs during development and synapse formation.*
- *During formation of the fingers and toes of the fetus, the apoptosis plays an important role of removing the web tissue between the finger and toes.*
- *During sexual development in fetal life, apoptosis is responsible for regression of duct systems.*

2. *Apoptosis for normal functioning of adult tissues.* Examples are:

- *Cyclic breakdown of endometrium that leads to start of menstruation is caused by apoptosis.*
- *Epithelial cells that lose their connection to the basal lamina and surrounding cells undergo apoptosis.*
- *Enterocytes sloughed off the tips of intestinal villi undergo apoptosis.*

3. *Apoptosis to destroy the cells that represent a threat to the integrity of the organism.* Examples are:

- *Apoptosis of the cells infected with virus;*
- *Apoptosis of the cells of the immune system to prevent*

them from attacking body constituents;

- Apoptosis of the cells with DNA damage and
- Apoptosis of the cancer cells.

Mechanism of apoptosis

The *final common pathway* leading to apoptosis is the activation of a group of cysteine proteases called *caspases* which exist in cells as inactive proenzymes (Fig. 1.5-10).

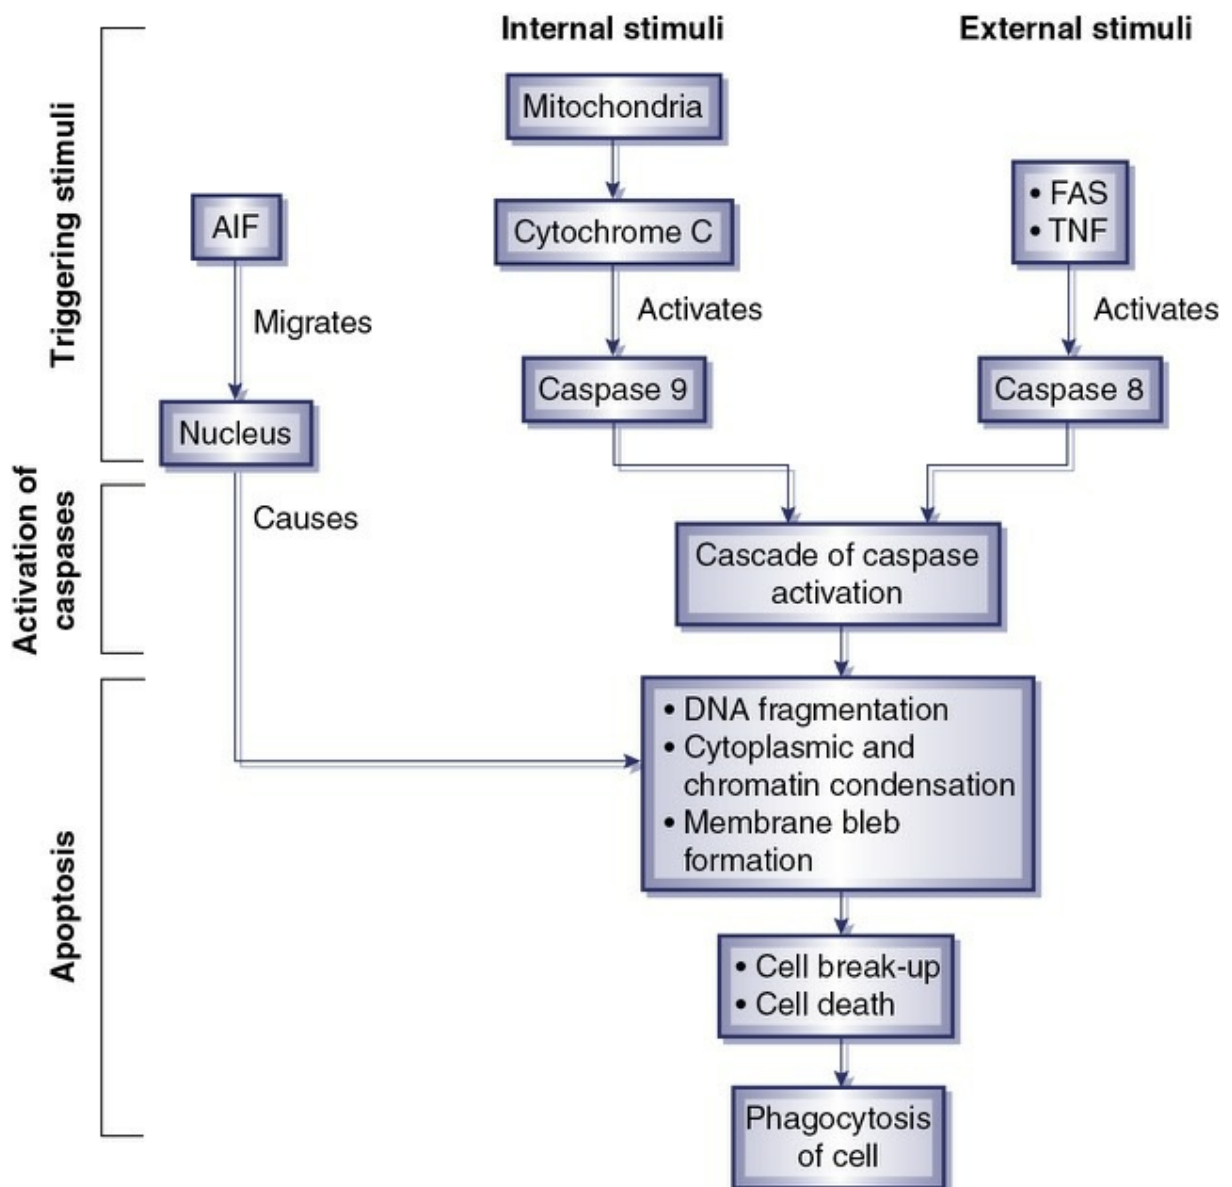

FIGURE 1.5-10 Steps involved in apoptosis.

Triggering stimuli. Apoptosis can be triggered by external and internal stimuli (Fig. 1.5-10).

- *Internal stimuli.* One of the important pathways goes through the mitochondria, which release *cytochrome* and a protein called *smac/DIABLO*, causing activation of the *caspase 9*.
- *Apoptosis-inducing factor (AIF)* located in the intermembrane space of mitochondria migrates to nucleus and destroys DNA after binding leading to cell death.
- *External stimuli.* One ligand that activates receptors triggering apoptosis is FAS (a transmembrane protein that projects from natural killer cells and T lymphocytes but also exists in circulating form). Another ligand is tumour necrosis factor (TNF). These activate the enzyme caspase 8 followed by cascade of caspase activation.

Net result of caspase activation is DNA fragmentation, cytoplasmic and chromatin condensation and eventually membrane bleb formation with cell breakup and removal of the debris by phagocytosis(Fig. 1.5-10).

Molecular genetics and medicine

Clinical applications of molecular genetics in medicine are rapidly increasing owing to research and advances in the molecular aspect of genetics, regulation of gene expression and protein synthesis. Some of the aspects in relation to molecular genetics and medicine described here are:

- Mutations and genetic human diseases;
- Detecting human genetic variations (genetic screening);
- Genetics and cancer and
- Gene therapy.

Mutations and genetic human diseases

Mutations

Mutation refers to a change in the DNA structure of a gene. The

substances or factors that are responsible for the mutations are called *mutagens*, e.g. X-rays, ultraviolet light, certain chemicals, etc.

There are two major types of mutations:

1. ***Point mutations.*** In this type, one base pair of DNA is replaced by another. Point mutations are further of two subtypes: transitions and transversions.

- ***Transitions.*** In this type of mutation, purine or pyrimidine is replaced by another purine or pyrimidine, respectively.
- ***Transversions.*** In this type of mutation, a purine is replaced by pyrimidine or pyrimidine is replaced by purine.

Effects of point mutations. Point mutations can lead to one of the following effects:

- a. ***Silent mutation.*** No detectable effect is produced when the codon (of mRNA) containing change base codes for same amino acid. For example, UCA codes for serine but when there is change in third base (UCU) still it codes for serine. Therefore, when no effect is detected it is called *silent mutation*.
- b. ***Missense mutation.*** This occurs when altered base codes for different amino acid and that amino acid in a protein molecule may be acceptable or partially acceptable or not acceptable as far as the action of protein molecule is concerned. The amino acid so formed is called *mistaken* or *missense amino acid*. The classical example of effect of missense mutation is sickle cell anaemia.

c. *Nonsense mutation.* When the codon with changed base may become the *termination codon* and acts as stop signal and thus causes termination of protein synthesis at that point, the effect produced is called nonsense mutation.

2. *Frame shift mutations.* This occurs when one or more than one base pairs are either deleted or inserted into the DNA of gene. Therefore, frame shift mutations are also called deletion or insertional mutations.

Effects of frame shift mutations. The consequences as a result of insertion or deletion of a base in a gene cause altered reading frame of the mRNA. Thus, the machinery of mRNA (containing codon) is unable to recognize that a new base is added or missing. Since there is no punctuation in reading of codons, translation continues and as a result of that the proteins synthesized will have many altered amino acids and/or premature terminated proteins.

Genetic human diseases

Salient aspects of some common genetic human diseases associated with mutations are summarized in [Table 1.5-1](#).

TABLE 1.5-1

Some Common Genetic Diseases

Genetic disease/disorder	Chromosome affected	Type of mutation	Expression of gene	Main symptoms	Defect	Frequency at birth
Gene Mutations						
Sickle cell anaemia	11	Substitution	Codominant (sometimes described as recessive) autosomal	Anaemia and interference with circulation	Abnormal haemoglobin molecule	1 in 1600 among black people
Cystic fibrosis	7	In 70% of cases is a deletion of three bases	Recessive autosomal	Unusually thick mucus clogs lungs, liver and pancreas	Failure of chloride ion transport mechanism in cell surface membranes of epithelial cells	1 in 1800 among white people
PKU (phenylketonuria)	12	Substitution	Recessive autosomal	Brain fails to develop normally	Enzyme phenylalanine hydroxylase defective	1 in 18,000
Huntington's chorea (disease)	4	A newly discovered type of mutation—the normal gene has 10–34 repeats of CAG at one end, the HC gene has 42–100 repeats of CAG	Dominant autosomal	Gradual deterioration of brain tissue starting on an average in middle age	Brain cell metabolism is inhibited	1 in 10,000 to 1 in 20,000 worldwide
Haemophilia	X	Substitution	Recessive sex-linked	Blood does not clot	Factor VIII or IX protein defective	1 in 7000
Chromosome Mutations						
Down's syndrome	21	Extra chromosome (trisomy 21)		Reduced intelligence, characteristic facial features		1 in 750
Klinefelter's syndrome (XXY)	Sex	Extra X chromosome in male (trisomy)		Feminized male		1 in 500
Turner's syndrome (XO)	Sex	Missing X chromosome in female (monosomy)		Sterile female		1 in 2500

Autosomal – affecting nonsex chromosome (autosome).

Monosomy – one chromosome missing ($2n - 1$).

Trisomy – one extra chromosome ($2n + 1$).

Monosomy and trisomy are examples of **aneuploidy**, where the total number of chromosomes is not an exact multiple of the haploid number.

Genetic screening

Genetic screening refers to detection of mutant genes in an individual (detecting human genetic variations). Modern genetics is making this much earlier than it was in the past.

Field of genetic screening

There are three situations where genetic screening is of particular relevance:

1. **Prenatal diagnosis.** Prenatal diagnosis aims at identifying the health problems of unborn babies. Parents can be provided counselling and option for abortion as per situation.

Techniques of prenatal diagnosis include:

- Chorionic villus sampling (CVS),

- Amniocentesis and
- Preimplantation diagnosis.

2. *Carrier diagnosis*. This is the identification of people who carry a particular genetic disease, usually with no visible symptom or harm to themselves. Examples include sickle cell anaemia, cystic fibrosis and phenylketonuria (PKU).

3. *Predictive diagnosis*. This is the prediction of a future disease from which one is likely to suffer. The classic example of this 'genetic time bomb' is Huntington's chorea where the onset of disease occurs in middle age.

Genetics and cancer

Cancer is a disease characterized by uncontrolled cell growth.

Points favouring genetic basis for cancer

- *Hereditary predisposition* is noted in some cancers like colon cancer and retinoblastoma.
- *Chromosomal abnormalities* are noted in many forms of cancers like Burkitt's lymphoma and acute myeloid leukaemia.
- *Defective DNA repair mechanisms* have been associated with occurrence of cancers.
- *Genetic damages* (mutagenesis) by the action of various agents like ionizing radiations and UV rays are associated with occurrence of cancer.

Genes and molecular factor involved in pathogenesis of cancer

1. Oncogenes.

Over 100 oncogenes (cancer-causing genes) have been described. These genes are derived by somatic mutations from the closely related *proto-oncogenes* (normal genes that encode proteins having a role in cell's normal activities).

Genetic changes converting proto-oncogenes into oncogenes are:

- *Missense mutation*, i.e. change in the amino acid sequence of proto-oncogene protein converts it into oncogene.
- *Gene amplification*, e.g. Myc genes have been amplified in human leukaemia, breast, stomach, lung and colon cancer.
- *Chromosomal translocations*, e.g. in Burkitt's lymphoma, a region of chromosome 8 is translocated to either chromosome 2, 14 or 22. The breakpoint in chromosome 8 causes the overexpression of c-myc gene.
- *Retroviral integration*, e.g. in avian lymphomas, the integration of the avian leucosis virus can enhance the transcription of the c-myc gene.

2. Tumour suppressor gene (antioncogenes).

Over 10 tumour suppressor genes have been described which produce proteins that suppress a tumour. When a tumour suppressor gene becomes inactivated by mutation, it becomes more likely that cancer will occur. It is important to note that for causing cancer, both alleles of tumour suppressor genes should be mutated. The most studied of these genes are RB gene (retinoblastoma gene) and P⁵³ gene.

- **RB gene.** Retinoblastoma (RB) gene functions as cancer suppressor. After two mutations (Knudson's two-hit hypothesis) when both copies of the gene at the retinoblastoma locus (14.1 band on the long arm of chromosome 13, i.e. 13q 14.1) are lost, deleted or inactivated, retinoblastoma (tumour of retina occurring in early childhood) develops.
- **P⁵³ gene.** About 50% of all human cancer are associated with defects in P⁵³ gene.

Induction of the P⁵³ gene leads to the synthesis of P⁵³ protein that functions as a transcription factor and can:

- Activate genes that promote DNA repair,
- Activate genes that arrest cell division and may generally repress other genes that are required for cell

division.

- Activate genes that promote apoptosis.

Mutation in P⁵³ gene leads to production of P⁵³ protein that fails to perform the aforementioned functions and permit other mutations in DNA to persist. The accumulated mutations eventually cause cancer.

3. Mutator genes.

Normal cells have caretaker genes that regulate DNA repair, i.e. they prevent faulty DNA transcription and regulation. The mutated version or mutator gene is characterized by loss of normal surveillance function that renders DNA susceptible to accumulation of mutation, and therefore progression of cancer.

4. Telomeres in cancer.

Telomeres take care of the terminal tips of the chromosomes, which progressively shorten due to repetitive cell division. Telomerase is the enzyme required for continued recognition of telomere in successive cell divisions. Cancer cell expresses telomerase with consequent telomerase lengthening and this helps the transformed cells to maintain their cancerous state.

Conclusion.

To conclude, cancer is a multistep phenomenon where series of genetic changes with or without virus infection cause the development of final cancerous state (Fig. 1.5-11). These genetic changes can be produced by:

- Ionizing radiations,
- Chemic carcinogens,
- Radioactive material,
- Spontaneous mutations and
- Inherited mutations.

FIGURE 1.5-11 Multistep phenomena of series of genetic changes leading to development of cancer.

Gene therapy

Gene therapy is the name given to methods that aim to cure an inherited disease by providing the patient with a correct copy of the defective gene. Gene therapy has now been extended to include the attempts to cure any disease by introduction of a cloned gene into the patient.

Basic principles

Basic principles involved in correcting a genetic defect are:

- *Gene replacement*, i.e. replacement of a mutant gene with a normal gene.
- *Gene correction*, i.e. correction of the mutated area (specific bases) of

DNA leaving the rest of DNA unchanged.

- *Gene augmentation*, i.e. insertion of a foreign DNA into the genome of a cell to rectify the genetic defect.

Basic approaches to gene therapy are:

- *Germ line therapy* can be carried out by microinjection of DNA into the isolated egg cell that is reimplanted into the mother. If successful, the gene is present and expressed in all cells of the resulting individual. Thus, theoretically the germ line therapy can be used to treat any inherited disease. At the moment such treatment is regarded as unethical in humans because the gene would be passed on to future generations.
- *Somatic cell therapy*. In humans, at the moment the focus is on somatic cell therapy. This involves changing some, though not all, of the somatic cells which are nonsex cells of the body. Changes in these cells cannot be inherited. The patients treated will therefore be cured but they will still be able to pass the faulty gene on to their offspring. Steps involved in this therapy are:
 - Isolation of the cells with the gene defect from a patient;
 - Growing the isolated cells in culture;
 - Transfecting the isolated cell with a remedial gene construct;
 - Selecting, growing and testing the transfecting cells and
 - Either transplanting or transfusing the transfecting cells back into the patients.

Examples of successful trials of gene therapy

Somatic cell therapy in cystic fibrosis of the lung. The gene (cDNA) cloned in adenovirus vectors or contained in liposomes, when introduced into the respiratory tract via an inhaler, is taken up by the epithelial cells. These epithelial cells then synthesize normal protein

called CFTR. Probably, 10% of the cells need to be corrected to eliminate the problem.

Somatic cell therapy in severe combined immunodeficiency disease (SCID). In this disease, the mutated gene is unable to synthesize the enzyme ADA adenosine deaminase. ADA is needed by the white blood cells (lymphocytes) responsible for immunity against infection. Without ADA, the child develops SCID and dies of infection in the early childhood.

Two children, aged 4 and 9, suffering from SCID were selected for gene therapy in USA in 1990. Lymphocytes were isolated from the children, then a normal gene was introduced by means of a retrovirus vector and the cells were replaced. These children had shown significant improvement after 1 year of therapy, repeated every 1 to 2 month.

Gene therapy in cancer may have great potentiality:

- Inactivation of oncogenic gene by introduction of a gene or an antisense RNA of an oncogenic gene;
- Introduction of an active version of tumour suppressor gene;
- Introduction of a gene that will selectively kill the cancer cells and
- Gene therapy to improve the natural killing of cancer cells by the patient's immune system.

Nerve Muscle Physiology

OUTLINE

Introduction

2.1. The nerve

2.2. Neuromuscular junction

2.3. Skeletal muscle

2.4. Smooth muscle and cardiac muscle

Introduction

The nerve and muscle cells are *excitable*, that is, capable of generation of electrical impulses at their membranes. For this very reason, the physiological aspects of these excitable tissues are discussed together in this section.

The electrical impulses generated in the excitable tissues, in most instances, can be used to transmit signals along the membranes. A neuron is the basic unit of nervous tissue. It is specialized for the function of reception, integration and transmission of information in the body. Muscles, like neurons, are excitable tissues but are characterized by the

fact that a mechanical contraction follows an action potential.

To understand the physiological aspects, it is imperative to have knowledge about the *functional anatomy* and physiological properties of the nerve, the muscle and the neuromuscular junction. Further, to understand the fundamental aspects of generation of the electrical impulses by the excitable tissues, it will be worthwhile to revise the basics of membrane potential which have been described in [Chapter 1.4](#) (page 32).

Functional anatomy

Neuron

Neuron or the nerve cell is the structural and functional unit of the nervous system. An aggregation of the neuronal cell bodies located inside the central nervous system (CNS) is called a *nucleus* and that located outside the CNS is called a *ganglion*. The nervous system of humans is made up of innumerable neurons. The total number of estimated neurons in the human brain is more than 10^{12} . The neurons are linked together in a highly intricate manner. It is through these connections that the body is made aware of changes in the environment or of those inside the body itself; and appropriate responses to such changes are produced.

Structure

Neurons vary considerably in size, shape and other features. However, most of them have some major features in common. The neuron is like any other cell in the body except that it has processes. The basic structure of a neuron is best studied in a spinal motor neuron. A neuron primarily consists of the cell body and processes called *neurites*, which are of two kinds, the dendrites and the axon (Fig. 2.1-1).

FIGURE 2.1-1 Structure of a typical neuron.

Cell body

The cell body of a neuron is also called the *soma* or *perikaryon* and may be round, stellate, pyramidal or fusiform in shape. Like any other cell it consists of a mass of cytoplasm with all its principal constituents surrounded by a cell membrane. The cell body contains a large nucleus with one or two nucleoli but there is no centrosome. The absence of centrosome indicates that the neuron has lost ability for division. Thus, neurons once destroyed are replaced by neuroglia only. In addition to the general features of a typical cell (page 12), the cytoplasm of a neuron has following distinctive characteristics (Fig. 2.1-1):

Nissl granules/bodies.

These are basophilic granules, and when seen under electron microscope these bodies seem to be composed of rough-surfaced endoplasmic reticulum. The presence of abundant granular endoplasmic reticulum is

an indication of the high level of protein synthesis in neurons. The proteins are needed for the maintenance and repair and for the production of neurotransmitters and enzymes. The Nissl bodies are present in the dendrites as well, but are usually absent from axon hillock and the axon. These bodies disintegrate into fine dust and finally disappear (*chromatolysis*) on fatigue, due to the effect of certain poisons and on sectioning of the axon.

Neurofibrillae.

The presence of a network of neurofibrillae in the cytoplasm of the neuron is another distinctive feature. These consist of microfilaments and microtubules. In certain degenerative diseases like Alzheimer's disease, the neurofilament protein gets altered, resulting in the formation of characteristic lesions called *neurofibrillary tangles*.

Pigment granules.

These are seen in some neurons. For example, *neuromelanin* is present in the neurons of substantia nigra. Aging neurons contain the pigment *lipofuscin*.

Dendrites

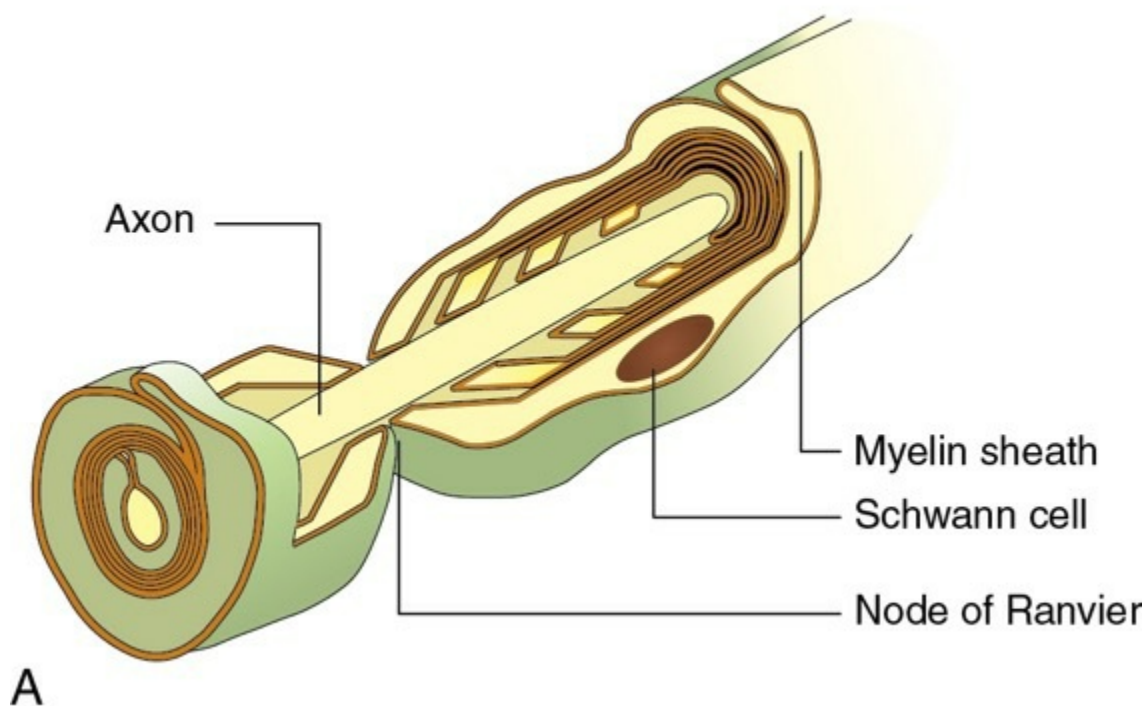

The dendrites are multiple small branched processes. Dendrites contain Nissl bodies and neurofibres. These often look thorny due to numerous minute projections called *spines* present on their surface. The spines are the site of synaptic contact.

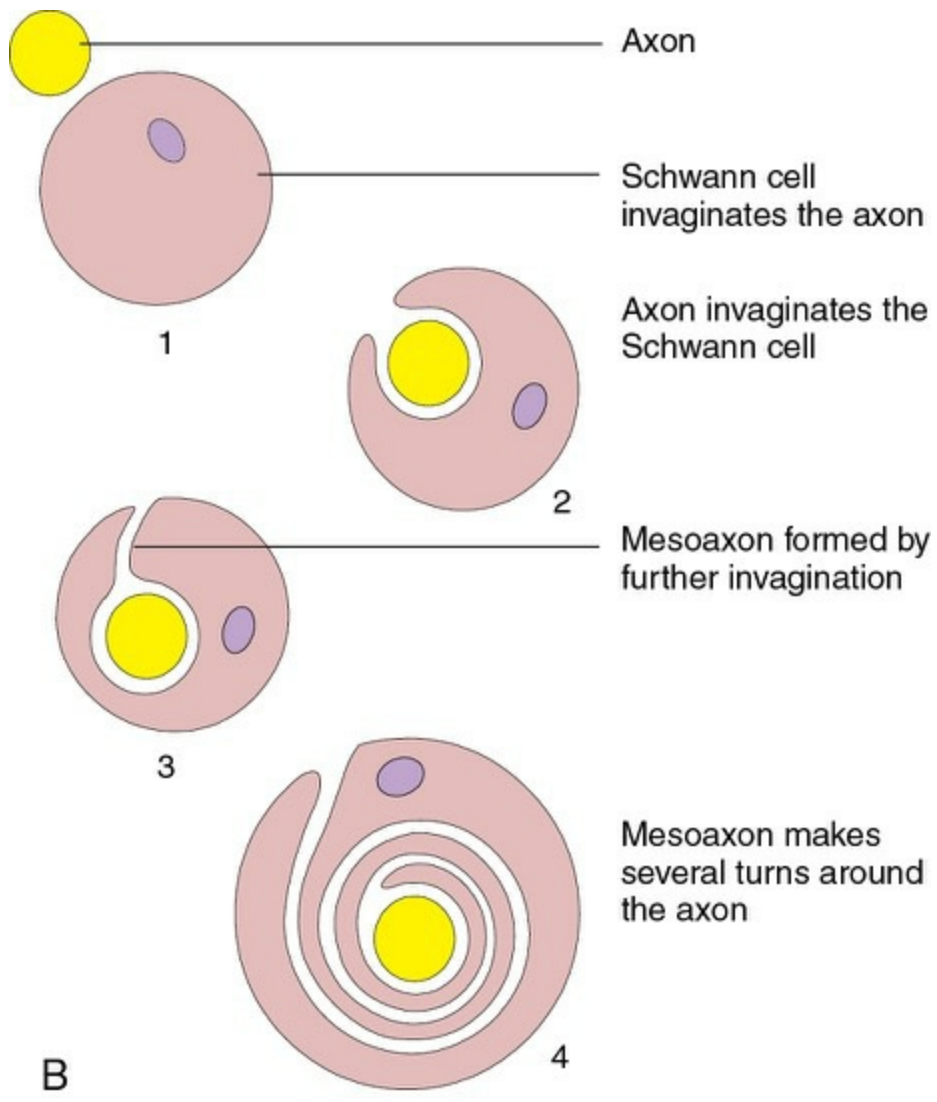

Dendrites are the *receptive processes* of the neuron receiving signals from other neurons via their synapses with axon terminals. The synaptic inputs produce *graded local potentials* which get algebraically summated on the surface of dendrites. Dendrites usually do not produce action potentials. They mostly conduct graded potentials. Some very long dendrites like axons may conduct action potentials.

Axon

The axon is the single longer process of the nerve cell. It varies in length from a few microns to one metre. It arises from the conical extension of the cell body called *axon hillock*, which is devoid of Nissl bodies. The part of the axon between the axon hillock and the beginning of the myelin sheath is called the *initial segment*. In the axon, the cell membrane continues as *axolemma* and the cytoplasm as *axoplasm*. The axon terminates by dividing into a number of branches, each ending in a

number of *synaptic knobs* also known as *terminal buttons* or axon telodendria. Synaptic knobs contain microvesicles in which chemical neurotransmitters are stored. *Myelin sheath* is present around the axons in the so-called myelinated nerve fibres (Fig. 2.1-2A). Myelin sheath, which consists of protein–lipid complex is produced by glial cells called *Schwann cells* which encircle the axon, forming around it a thin sleeve (Fig. 2.1-2B). The Schwann cell wraps its membranes about 100 times around an axon and then the myelin is compacted by an extracellular membrane protein called protein zero (Po). Each Schwann cell provides the myelin sheath for a short segment of the axon. At the junction of any two such segments, there is a short gap, i.e. (periodic 1 μm constrictions at about 1 mm distance). These gaps are the *nodes of Ranvier*. In the central nervous system of mammals myelin sheath is formed by oligodendrocytes rather than Schwann cells. There are some axons which are devoid of myelin sheath. These *unmyelinated axons* invaginate into the cytoplasm of Schwann cells (Fig. 2.1-2C).

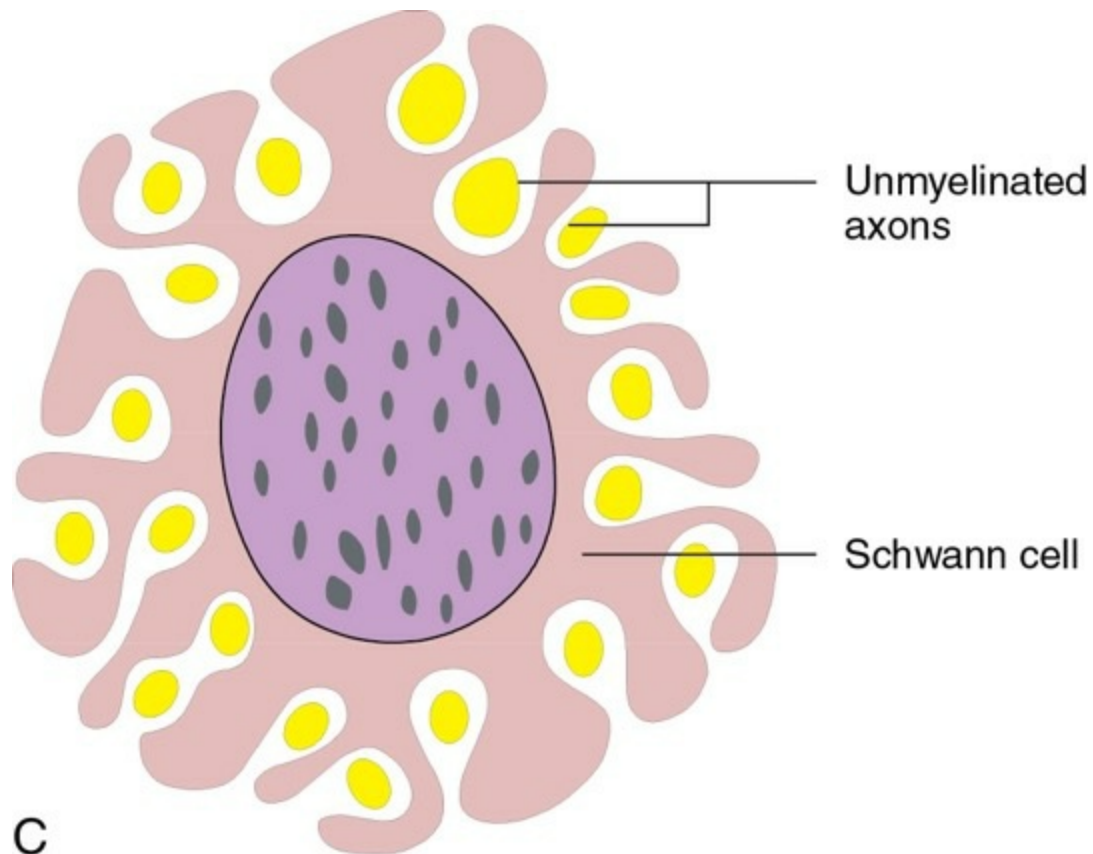

FIGURE 2.1-2 Structure of a myelinated neuron: **A**, Schwann cell encircles the axon to form myelin sheath; **B**, stages of myelination; and **C**, structure of an unmyelinated neuron.
Note: Unmyelinated axons invaginate cytoplasm of Schwann cell.

Myelination of axons increases the speed of conduction and greatly increases their diameter. In motor nerves, speed is important. Hence motor neurons to muscles and sensory (proprioceptive) fibres from muscles are heavily myelinated.

Axons perform the specialized function of conducting impulses away from the cell body. They transmit propagated impulses (all or none transmission).

Applied Aspects

In demyelinating disorders such as *multiple sclerosis* there occurs patchy destruction of myelin sheath in the central nervous system.

Multiple sclerosis is an autoimmune disease in which antibodies and white blood cells attack the myelin sheath leading to inflammation and injury to myelin sheath. Due to loss of myelin sheath there is leakage of K^+ through voltage-gated channels resulting in hyperpolarization and thus failure of action potential conduction.

Sign and symptoms: In patients with multiple sclerosis the

physiological deficit ranges from muscle weakness, fatigue, diminished motor function & sensory disturbances. The diagnosis of these patients are based on following tests:

- i. *Nerve conduction tests* which detect slow conduction in motor and sensory pathways.
- ii. *Cerebrospinal fluid analysis* which detects oligoclonal bands indicative of an abnormal autoimmune response against myelin sheath.
- iii. *Magnetic resonance imaging (MRI) assessment* visualizes multiple sclerotic area in the brain.

Treatment: Although there is no specific treatment of multiple sclerosis, drugs like *interferon* can suppress autoimmune response.

Types of neurons

Neurons have been variously classified as:

I. Depending upon the number of poles

Depending upon the number of poles from which processes arise, neurons are divided into unipolar, bipolar and multipolar (Fig. 2.1-3).

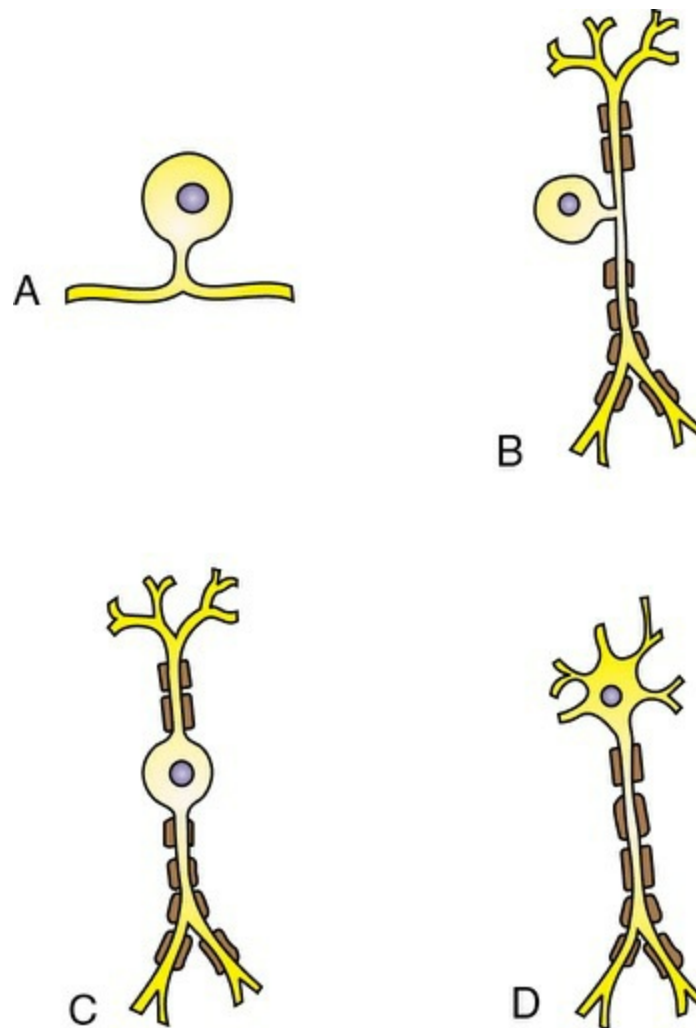

FIGURE 2.1-3 Different types of neurons: **A**, unipolar; **B**, pseudounipolar; **C**, bipolar; and **D**, multipolar.

1. Unipolar neurons

have a single pole, from which both the processes—axons and dendrites arise (Fig. 2.1-3A). True unipolar cells are present only in embryonic stage in human beings. However, the primary sensory neurons (neurons conveying impulses from a sensory receptor to spinal cord) are *pseudounipolar* (Fig. 2.1-3B).

2. Bipolar neurons

have two poles, one for axons and the other for dendrites (Fig. 2.1-3C). Bipolar neurons are found in the vestibular and cochlear ganglia and in the nasal olfactory epithelium and as bipolar cells in the retina.

3. Multipolar neurons

have many poles. One of the poles gives rise to axons and all others to dendrites (Fig. 2.1-3D). Most vertebrate neurons, especially in the CNS

are multipolar. The dendrites branch profusely to form the dendritic tree.

II. Depending upon the function

Depending upon the functions, the neurons are of two types—motor and sensory.

1. Motor neurons,

also known as efferent nerve cells, carry the motor impulses from CNS to the peripheral effector organs like muscles, glands and blood vessels. These neurons have very long axons and short dendrites.

2. Sensory neurons,

also known as afferent nerve cells, carry sensory impulses from periphery to the CNS. These neurons have short axons and long dendrites.

III. Depending upon the length of axons

Depending upon the length of axons the neurons are divided into Golgi type I and Golgi type II.

1. Golgi type I neurons

also known as projection neurons, have long axons. Their cell body lies in the CNS and axons reach the remote peripheral organs. They include the neuron forming peripheral nerves and long tracts of brain and spinal cord.

2. Golgi type II neurons,

also known as *short circuit neurons* have short axons. They are usually small and especially numerous in the cerebral cortex, cerebellar cortex and retina.

Zones of the neuron

From the functional point each neuron is divided into four zones (Fig. 2.1-4):

FIGURE 2.1-4 Functional zones of the neuron.

1. Receptor zone

(dendritic zone) is the region where local potential changes are generated by integration of the synaptic connections.

2. Site of origin of conducted impulse

is the site where propagated action potentials are generated. In case of spinal motor neurons, *initial segment* and in cutaneous sensory neurons the *first node* of Ranvier is the site of origin of conducted impulses. The distribution of ion channels along the axon plays an important role in initiation of propagated action potential. The concentration of voltage-gated Na^+ channels is very high in the initial segment and the first node of Ranvier. The estimated distribution of Na^+ channels in different parts of a mammalian myelinated neuron is as under [Table 2.1-1](#).

TABLE 2.1-1**Distribution of Sodium Channels in Human Myelinated Neuron**

Part of the neuron	Number/ μm^2
Cell body	50–75
Initial segment	350–500
Surface of myelin sheath	<25
Node of Ranvier	2000–12,000
Axon terminals	20–50
Unmyelinated axon	~ 110

3. Zone of all or none transmission

in the neuron is the axon.

4. Zone of secretion of transmitter

(nerve endings). The propagated impulses (action potential) to nerve endings cause the release of neurotransmitter.

Neuroglia

Neuroglia or the glial cells are the supporting cells present within the brain and spinal cord. They are numerous, about 10 times more than the neurons. Glial cells may be divided into two major categories ([Fig. 2.1-5](#)):

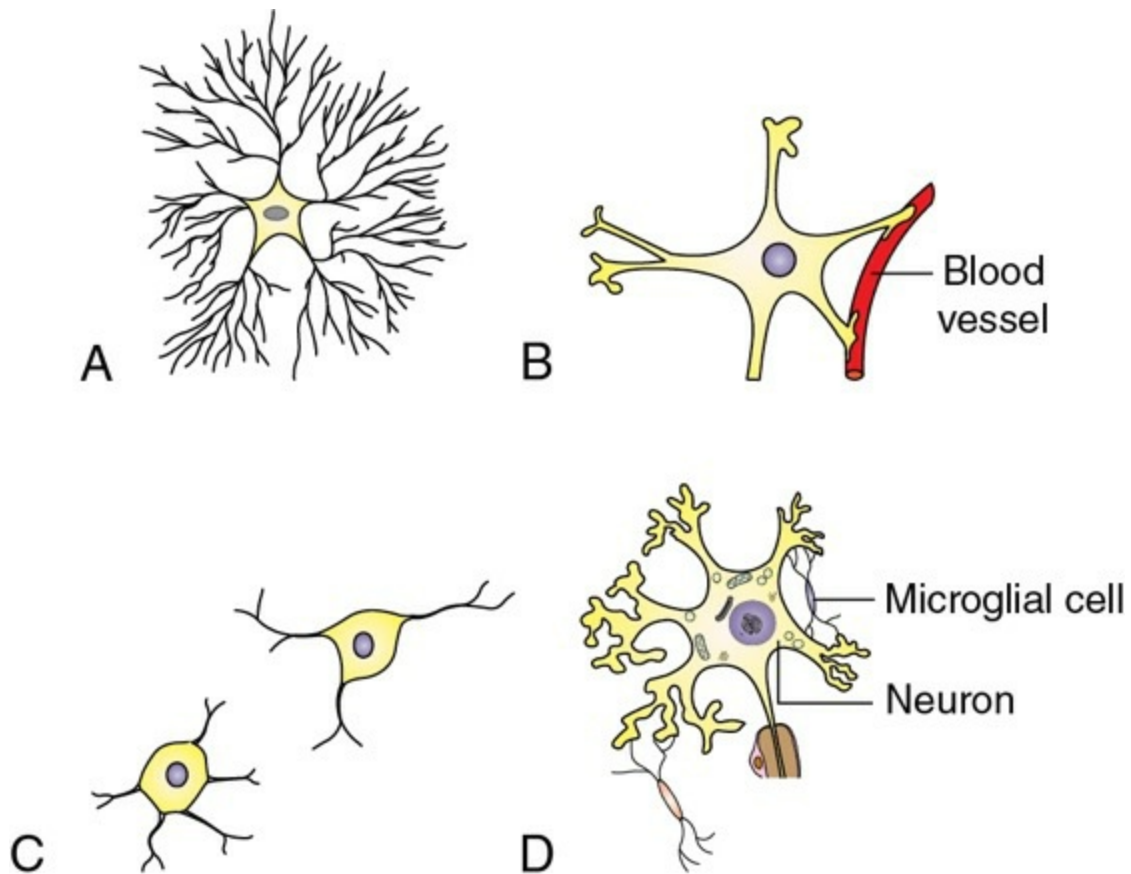

FIGURE 2.1-5 Different types of glial cells: **A**, fibrous astrocyte; **B**, protoplasmic astrocyte; **C**, oligodendrocyte; and **D**, microglial cells.

1. Macroglia

Macroglia or large glial cells are ectodermal in origin. These are of two types:

- *Astrocytes* which may be subdivided into fibrous and protoplasmic astrocytes; and
- *Oligodendrocytes*.

i. Astrocytes

These are small star-shaped cells that give off a number of processes which frequently end in expansions in relation to blood vessels and in relation to the surface of brain. *Fibrous astrocytes* (Fig. 2.1-5A) are seen mainly in the white matter and *protoplasmic astrocytes* (Fig. 2.1-5B) in the grey matter.

Functions.

In addition to supportive function, the astrocytes play a role in:

- Regulation of synaptic activity,
- Metabolism of neurotransmitters and of neuromodulators and
- Maintenance of blood–brain barrier.

ii. Oligodendrocytes

Oligodendrocytes have rounded or pear-shaped bodies with scanty processes (Fig. 2.1-5C). These cells provide myelin sheath to nerve fibres that lie within the brain and spinal cord. Oligodendrocytes give off multiple processes which form myelin sheath on many neighbouring axons.

2. Microglia

Microglia or the small glial cells are mesodermal in origin. These are the smallest neuroglial cells having flattened cell bodies and short processes (Fig. 2.1-5D). They are more numerous in grey matter than in white matter. These act as phagocytes and become active after damage to nervous tissue by trauma or disease.

Peripheral nerve

A compact bundle of axons located outside the CNS is called a nerve. In a nerve the axons are arranged in different bundles called fasciculi (Fig. 2.1-6).

- Each axon or nerve fibre is covered by *endoneurium* which is bounded internally by basal lamina around the Schwann cells and externally by the relatively impermeable inner basal lamina of the perineurium.
- Each fasciculus is covered by *perineurium*. The cells of perineurium are tightly adherent and act as a barrier to passage of particulate traces, dye molecules or toxins into the endoneurium.
- The whole nerve is covered by *epineurium* which is a tubular sheath formed by areolar membrane. It limits the extent to which the nerve can be stretched by body movements or external pressure, thereby protecting the fragile axons inside the nerve.

FIGURE 2.1-6 Cross-section of a peripheral nerve.

Biological activities

Protein synthesis

The cell bodies (soma) of all the neurons contain cellular apparatus required for protein synthesis, i.e. the ribosomes and the Golgi apparatus. Since the axons do not have these organelles, all the proteins including the neurotransmitters are synthesized in the cell body and then transported along the axon to the synaptic knobs by the process of *axoplasmic flow*, as discussed below. Thus, the cell body maintains the functional and anatomic integrity of the axon. Therefore, if the axon is cut, the part distal to cut degenerates (Wallerian degeneration).

Axoplasmic transport

Axoplasm, the cytoplasm of the neurons is in constant motion. The axoplasmic transport is vital to nerve cell functions, since movement of various materials occur through it. The axoplasmic transport is of two types: rapid and slow.

1. Rapid transport

Some materials travel 100–400 mm a day along the axoplasm and constitute the rapid transport. Microtubules play an important role in this form of transport. Rapid transport is bidirectional, i.e. both away from and towards the cell body.

i. Anterograde or orthograde rapid transport

occurs from the neuron cell body to the axon terminal. It is driven by the molecular motors *kinesin* and *dynein*. The materials transported by anterograde rapid transport include membrane-bounded organelles like short tubules of reticulum, mitochondria, small vesicles, actin, myosin and the clathrin used in recycling of synaptic vesicle membrane.

ii. Retrograde rapid transport

occurs from the nerve terminals towards the cell body of the neuron, returning materials for degradation or reuse. Retrograde rapid transport is driven by the molecular motor *dynein*, and has a velocity 200 mm/day. The materials transported by this mode include proteins and small molecules picked up by the axon terminals. Retrograde axoplasmic flow may also carry tetanus toxin and neurotropic viruses (e.g. polio, herpes simplex and rabies) along the axon into the neuronal cell bodies in the CNS. It has also been employed by neuroanatomists for charting out neural pathways.

2. Slow transport

The materials travelling slowly (0.1–2 mm in a day) in the axoplasm constitute the slow transport. Slow transport is only unidirectional, away from the cell body (anterograde). It is responsible for flow of axoplasm containing protein subunits of neurofilaments, tubulins of the microtubules and soluble enzymes.

The exact mechanism of slow axonal transport is not known. Probably, axoplasmic matrix moves with the cytoskeleton which moves as a whole due to the continual polymerization at the leading end and depolymerization at the trailing end.

Metabolism and heat production in the nerve fibres

Like other cells of the body, the metabolic activities occur in the nerve fibres as well; but the metabolism in nerve fibres occurs at a very low

level. About 70% of the total energy required is used to maintain polarization of the membrane by the action of $\text{Na}^+\text{-K}^+$ ATPase pump. The energy required to maintain polarization of the resting membrane is supplied mainly by combustion of sugars and phospholipids.

During nerve activity, the ATP and creatine phosphate breakdown, i.e. undergo hydrolysis and supply energy for the propagation of the nerve impulse. At maximum activity, the metabolic rate of nerve fibres just doubles the metabolic rate at resting stage. Whereas, in skeletal muscles the metabolic activity rate may increase by 100 times than the metabolic rate at rest. However, the chemical changes during metabolic activity are almost the same in a nerve and a muscle, i.e. if oxygen supply is deficient, pyruvic acid and lactic acids are formed and accumulate. The nerve fibres are rich in vitamin B_1 , which is essential for complete oxidation of pyruvic acid and lactic acids. Further, unlike muscles, even in the absence of oxygen, processes like excitability, conductivity and recovery can go on in a nerve for a considerable period.

Heat production in the nerve fibres

As discussed above, the metabolism in the nerve fibre is very slow; therefore, during resting phase only a small amount of heat is produced, which increases to some extent during phase of activity. In a nerve fibre, heat is produced in three phases:

1. Resting heat

is the amount of heat produced during the inactive stage.

2. Initial heat

is the amount of heat produced during action potential (stage of activity). It is about 10 per cent of the total heat produced. It results from anaerobic metabolic activity due to breakdown of ATP and creatine phosphate.

3. Delayed or recovery heat

is produced during the recovery phase which follows the phase of activity. The energy is produced by aerobic metabolic activities and is about 30 times the initial heat. The delayed heat is produced in two stages: the first stage lasts for a few seconds and produces only a small amount of heat, and the second stage lasts for 10–30 min and contributes the major amount of the total heat produced. The energy produced during recovery stage is used for resynthesis of ATP and creatine phosphate and as such for restoring the normal excitability of the nerve

fibre.

Electrical properties of nerve fibre

The main electrical properties of the nerve fibres are:

- *excitability*, i.e. the capability of generating electrical impulses (action potential), and
- *conductivity*, i.e. the ability of propagating the electrical impulses generated along the entire length of nerve fibres.

Excitability

Excitability is that property of the nerve fibre by virtue of which it responds by generating a nerve signal (electrical impulses or the so-called action potentials) when it is stimulated by a suitable stimulus which may be mechanical, thermal, chemical or electrical. In experimental studies, electrical stimulus is more frequently employed since its strength and frequency can be accurately controlled.

Before discussing the excitability (production of action potential), it will be useful to know about the electrical potential in the nerve fibre at rest, i.e. before it is stimulated (resting membrane potential). Further, when the stimulus is subthreshold it does not produce action potential but it causes some change in the resting membrane potential termed as electrotonic potential. After discussing the production of action potential, various characteristics of the stimulus which can affect the production of action potential will be discussed.

Resting membrane potential

There exists a membrane potential of -70 mV (inside negative) across the membrane of nerve fibre at rest. This is called *resting membrane potential*. The study of electrical activity of a tissue has been made possible due to advances in the method of the recording electrical potentials, especially the development of microelectrodes and 'cathode ray oscilloscope (CRO)' (for details see page 70).

As shown in Fig. 2.1-7A, when two electrodes are placed on the surface of a nerve fibre and connected to a CRO, no potential difference is observed. However, if one of the microelectrodes is inserted inside the nerve fibre (Fig. 2.1-7B), a steady potential difference of -70 mV (inside

negative) is observed on the CRO. This is resting membrane potential (RMP) and indicates the resting state of cell also called *state of polarization*.

FIGURE 2.1-7 Recording of resting membrane potential: **A**, both electrodes are on the surface of axon, no potential difference is recorded; and **B**, one electrode on the surface and other inserted inside the axon, potential difference (-70 mV) is recorded.

Ionic basis of resting membrane potential (RMP)

The details of the processes concerned with the ionic basis of RMP, i.e. selective permeability of cell membrane, Gibbs–Donnan equilibrium, Nernst equation, Goldman’s constant field equation and role of $\text{Na}^+\text{-K}^+$ pump have been discussed in [Chapter 1.4](#) on *membrane potentials* (page

32). However, the ionic basis of RMP is summarized here.

In a nutshell, the distribution of ions across the cell membrane and the nature of cell membrane are responsible for the RMP. Basically, RMP is diffusion potential modified to some extent by the activity of Na⁺-K⁺ pump as:

- Because of large concentration gradient the K⁺ ions diffuse out of the membrane via K⁺ channels, but the *electrical gradient* created opposes it.
- Consequently, equilibrium is reached where the potential difference is such that it effectively balances the outward diffusion of K⁺ due to concentration gradient.
- At the equilibrium, there is slight excess of cations on the outside and anions on the inside. This condition is maintained by Na⁺-K⁺ pump, which pumps Na⁺ back and keep the intracellular concentration of Na⁺ low.
- Na⁺-K⁺ pump being electrogenic (because it pumps 3 Na⁺ ions out of the cell for every 2K⁺ ions it pumps in), it also contributes a small amount to the membrane potential by itself.

At rest, membrane permeability to K⁺ is greater due to more opened K⁺ channels than the Na⁺ channels. Therefore, the intracellular and extracellular K⁺ concentration is the main determinant of resting membrane potential and that is why RMP is closed to equilibrium potential for K⁺.

Action potential

When the stimulus is subminimal or subthreshold, it does not produce action potential, but does produce some changes in the RMP. There is slight depolarization for about 7 mV which cannot be propagated, since propagation occurs only if the depolarization reaches a firing level of 15 mV (-55 mV). Therefore, this is a local response or phenomenon termed the *electrotonic potential*. As depicted in Fig. 2.1-8, the electrotonic potential does not obey all or none law. As is clear from Fig. 2.1-8, when the intensity of stimulus is increased gradually, every time there is an increase in the amplitude of the local response till firing level of 15 mV is reached. Once the firing level is reached, there occurs action potential, i.e. there occurs abrupt depolarization with propagation (action potential) of the cell membrane which was in a polarized state. The adequate strength

of stimulus necessary for producing the action potential in a nerve fibre is known as *threshold* or *minimal stimulus*. In other words, the *action potential* may be defined as the brief sequence of changes which occur in the resting membrane potential when stimulated by a threshold stimulus.

FIGURE 2.1-8 Electrotonic potentials (local response).

Phases of action potential

The action potential basically occurs in two phases: depolarization and repolarization. When the nerve is stimulated, the polarized state (-70 mV) is altered, i.e. RMP is abolished and the interior of the nerve becomes positive ($+35$ mV) as compared to the exterior. This is called *depolarization phase*. Within no time there occurs a reverse to the nearly original potential and this second phase of action potential is called *repolarization phase*.

Action potential curve

obtained when resting membrane potential is being recorded on a CRO and the nerve fibre is stimulated at a short distance away from the recording electrode (Fig. 2.1-9A), has the following components (Fig. 2.1-

9B):

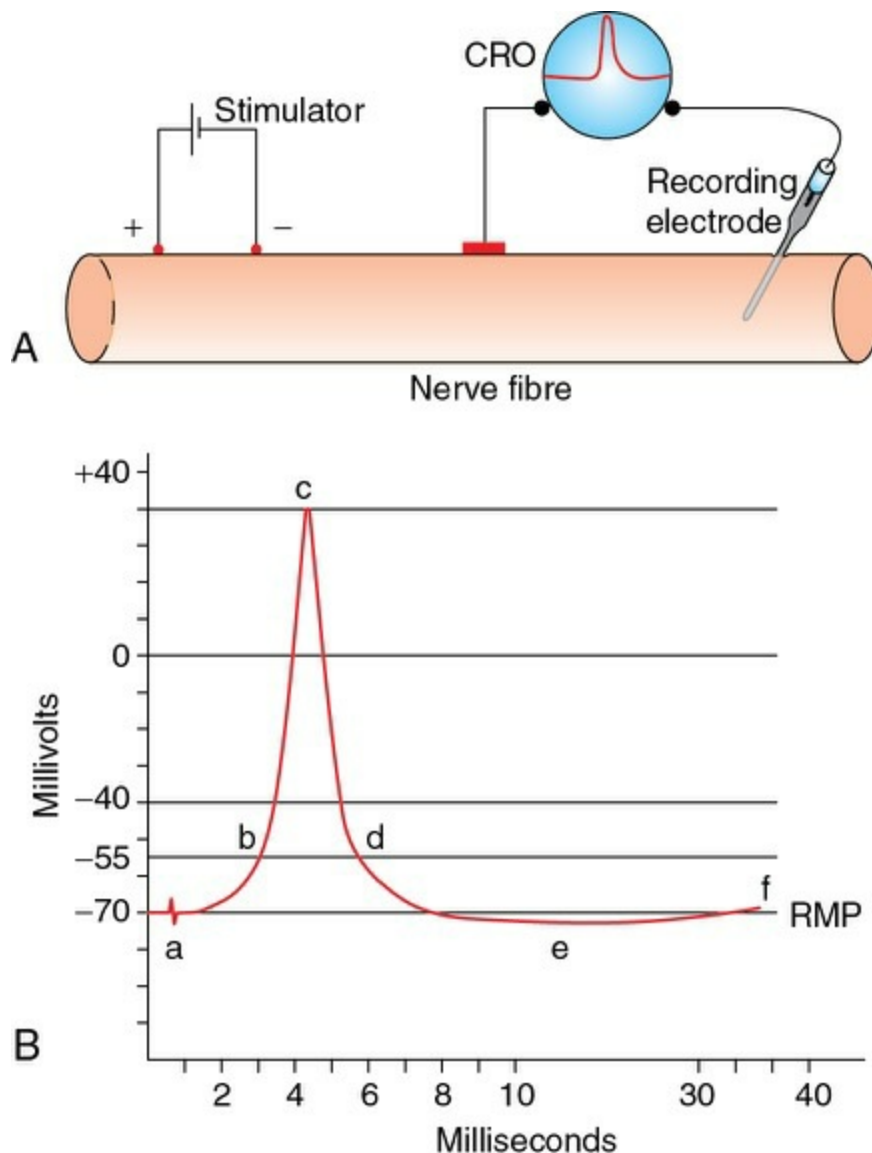

FIGURE 2.1-9 Recording of action potential of a large mammalian myelinated nerve fibre: **A**, arrangement for recording action potential; and **B**, various phases (components) of action potential. (a = stimulus artefact, b = firing level, b to c = depolarization, c to d = repolarization, d to e = after depolarization and e to f = after hyperpolarization).

1. Resting membrane potential

is recorded as a straight baseline at 270 mV.

2. Stimulus artefact

is recorded as mild deflection of the baseline as soon as the stimulus is

applied. The stimulus artefact occurs due to leakage of current from the stimulating electrode to the recording electrode.

3. Latent period

is recorded as short isoelectric period (0.5–1 ms) following the stimulus artefact. It represents the interval between the application of stimulus and the onset of action potential. It depends upon the distance between the site of stimulation and the point of recording and the velocity of action potential along the particular axon.

4. Firing level.

After the latent period, phase of depolarization starts. To begin with depolarization proceeds relatively slow up to a level called the *firing level* (25 mV), at which depolarization occurs very rapidly.

5. Overshoot.

From the firing level, the curve reaches the zero potential rapidly and then *overshoots* the zero line up to +35 mV.

6. Spike potential.

After reaching the peak (+35 mV), the phase of depolarization is completed and the phase of repolarization starts and the potential descends quickly near firing level. The phase of rapid rise of potential in depolarization and a rapid fall in repolarization phase, combinedly constitute the so-called *spike potential*. Its duration is approximately 1 ms in an axon.

7. After depolarization

is the slow repolarization phase which follows a rapid fall in spike potential and extends up to attainment of RMP level. It is called phase of *negative after potential* and lasts for about 4 ms.

8. After hyperpolarization.

After reaching the resting level (-70 mV) the potential further falls and becomes more negative (-72 mV). This phase is called *after hyperpolarization* or phase of *positive after potential*. It lasts for a prolonged period (35–40 ms). Finally the RMP is restored.

Ionic basis of action potential

Role of voltage-gated Na^+ and K^+ channels

The development of action potential was studied by Hodgkin and Huxley using the *voltage clamp technique*. According to *Hodgkin–Huxley theory*, the sequence of events is:

Polarization phase.

Resting membrane potential (-70 mV) is due to distribution of more cations outside the cell membrane and more anions inside the cell membrane. At this point, though Na^+ is more in ECF, it cannot enter the cell due to the impermeability of the membrane.

Depolarization phase.

When threshold stimulus is applied to the cell membrane, at the point of stimulation (Fig. 2.1-10) the permeability of the membrane for Na^+ ions increases. At first the rise of permeability for Na^+ is slow till it reaches *firing level*. When the membrane potential depolarizes, the Na^+ channels start opening up. The opening of the Na^+ channels depolarizes the membrane further, leading to the opening of greater numbers of Na^+ channels. Thus, there is *positive feedback spiral*, the so-called Hodgkin cycle (Fig. 2.1-11), resulting in rapid change in membrane potential. Once firing level is reached, the voltage-gated Na^+ channels open massively and as the concentration gradient and electrical gradient of this ion are directed inward, there occurs a rapid influx of Na^+ ions into the cell (Fig. 2.1-12A). This rapid entry of Na^+ is sufficient to overwhelm the repolarizing forces and the membrane potential seems to be carried towards the equilibrium potential of Na^+ ($+60$ mV). However, the depolarization does not reach a value greater than $+35$ mV because of following reasons:

- Na^+ channels are inactivated in a fraction of ms and the gates close again.
- Due to rapid influx of Na^+ , the concentration gradient diminishes and during overshoot phase the electrical gradient for Na^+ also reverses.
- Change in the membrane potential during depolarization results in opening of voltage-gated K^+ channels (Fig. 2.1-12B). Therefore, within a fraction of ms of the threshold excitation K^+ leaves the cell along its concentration gradient.

FIGURE 2.1-10 Changes in sodium (Na^+) and potassium (K^+) conductance during action potential.

HODGKIN CYCLE

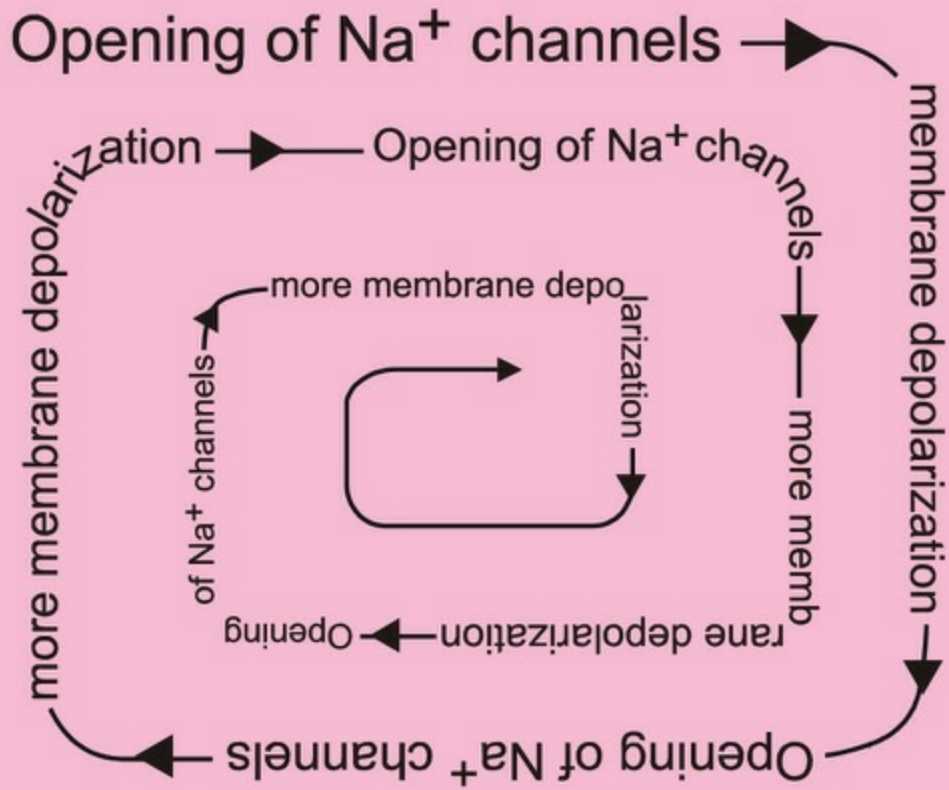

FIGURE 2.1-11 Positive feedback spiral (Hodgkin cycle).

FIGURE 2.1-12 Schematic diagram to show the role of voltage-gated ion channels in resting state and during action potential: in resting state (Na^+-K^+ ATPase pump active); **A**, during depolarization phase (Na^+ channels open up and K^+ channels remain closed); **B**, during rapid repolarization phase (K^+ channels open up resulting rapid efflux of K^+ and Na^+ influx decreases); **C**, during after depolarization and hyperpolarization phases, (Na^+ channels get closed, K^+ efflux slows down); and **D**, restoration of resting membrane

potential by activation of Na⁺-K⁺ ATPase pump (resulting efflux of **three** Na⁺ and influx of **two** K⁺).

Repolarization phase.

Repolarization occurs due to decrease in further Na⁺ influx and K⁺ efflux through the voltage-gated K⁺ channels which open later than Na⁺ channels but remain activated for a prolonged period (Fig. 2.1-10, 2.1-12B).

Decrease in Na⁺ influx and efflux of K⁺ causes net transfer of positive charge out of the cell that serves to complete the repolarization.

After depolarization.

After the rapid initial repolarization (spike potential), further repolarization occurs slowly. This is due to the fact that rate of K⁺ efflux slows down as the electrical gradient responsible for initial rapid diffusion declines. This last phase of slow repolarization due to slow efflux of K⁺ is called *after depolarization* (Fig. 2.1-12C).

After hyperpolarization.

The slow efflux of K⁺ continues even after the resting membrane potential is reached, resulting in a prolonged phase of *hyperpolarization* during which the membrane potential falls up to -72 mV. However, little after, the voltage-gated K⁺ channels also shut down. The final ionic distribution is brought to the resting state by the action of Na⁺-K⁺ pump and the leak channels (K⁺ and Cl⁻) (Fig. 2.1-12D).

Role of calcium ions

In addition to Na⁺ and K⁺ ions, the Ca²⁺ ions also play some role in the development of action potential. The concentration of Ca²⁺ in ICF is very low as compared to ECF. Therefore, when Na⁺ channels are open, some Ca²⁺ ions also move inside the cell through these opened up Na⁺ channels. Further, a separate class of channels known as *slow calcium channels* also exists in the cell membrane. These calcium channels also open up admitting Ca²⁺ during development of action potential.

Important Note

- Low extracellular Ca²⁺ concentration increases the excitability of nerve and muscle by decreasing the amount of depolarization necessary for initiating changes in Na⁺ and K⁺ conductance required for action

potential, and

- Increase in Ca^{2+} concentration stabilizes the membrane by decreasing excitability.

The *calcium channels* are especially important in cardiac and smooth muscles where these are in abundance. In fact, in some types of smooth muscles, the fast sodium channels are hardly present, so the action potentials then are caused almost entirely by activation of the slow calcium channels.

Characteristics of nerve excitability vis-à-vis characteristics of the stimulus

The excitable nerve fibre exhibits some peculiar characteristics of the excitability depending upon the strength and duration of the stimulus used and the electrogenic state of the nerve fibre when stimulus is applied. Some of the important excitability characteristics are described.

1. Strength–duration curve

It has been observed experimentally that an action potential is produced if the nerve fibre is stimulated by a stimulus of adequate strength (intensity) and duration. The minimal intensity of stimulating current acting for a given duration producing an action potential is called *threshold intensity*. The relationship between the strength and duration of a stimulus has been studied by varying the duration of a stimulus and finding out the threshold strength for each duration. The record of results plotted on a semilog-graph paper gives the *strength–duration curve* (Fig. 2.1-13). Following inferences can be drawn from the strength–duration curve:

- **Rheobase (R)** refers to the minimum intensity of stimulus which if applied for adequate time (utilization time) produces a response.
- **Chronaxie (C)** refers to the minimum duration for which the stimulus of double the rheobase intensity must be applied to produce a response. Within limits, chronaxie of a given excitable tissue is constant, In other words, the chronaxie is an index of the excitability of a tissue and can be used to compare the excitability of various tissues. For example, a nerve fibre has far shorter chronaxie value than a muscle fibre indicating greater excitability of the former.

- When a stimulus of weaker intensity than the rheobase is applied, it will not produce a response, no matter how long the stimulus is applied.
- Stimulus of extremely short duration will not produce any response, no matter how intense that may be.

FIGURE 2.1-13 Strength–duration curves: **A**, for nerve; and **B**, for muscle.

Important Note

Plotting of strength–duration curve has significance in following situations:

- Nerve injury: Following an injury the affected nerve fibres become inexcitable after a few days. If only most excitable fibres get injured then the strength–duration curve will represent the response of intact less excitable fibres.
- If there is complete injury to the motor nerve, then all the fibres

completely degenerate. In this situation, denervated muscle will respond only on direct stimulation.

- When denervated muscle fibres completely degenerate, then no response will be obtained on direct stimulation.
- On resuturing the nerve, if motor nerve fibre regenerate later, then strength–duration curve gradually returns to normal.
- If the motor neurons are destroyed, then no regeneration occurs; therefore, no recovery can occur and functional loss is purely motor.

2. All or none response

A single nerve fibre always obeys ‘all or none law’, that is, when a stimulus is applied, either the axon does not respond with a spike production of action potential or it responds to the maximum of its ability. In other words:

- When a stimulus of subthreshold intensity is applied to the axon, then no action potential is produced (*none response*);
- A response in the form of spike of action potential is observed when the stimulus is of threshold intensity; and
- There occurs no increase in the magnitude of action potential when the strength of stimulus is more than the threshold level (all response).

This all or none relationship observed between the strength of stimulus and the response achieved is known as ‘All or None Law’ (Fig. 2.1-14).

FIGURE 2.1-14 All or none response in a single nerve fibre: **A** and **B**, represent subthreshold; **C**, threshold; and **D**, suprathreshold stimuli.

Membrane excitability during action potential

When a stimulus is applied to the nerve fibre membrane during the stage of action potential (produced by a previous threshold stimulus) the response elicited depends upon the stage of action potential. Depending upon the response elicited to the stimulus the period of action potential can be divided into: refractory period, supernormal period and subnormal period (Fig. 2.1-15).

FIGURE 2.1-15 Membrane excitability during different phases of action potential: ARP (absolute refractory period), RRP (relative refractory period) and ERP (effective refractory period).

i. Refractory period

Refractory period refers to the period following action potential (produced by a threshold stimulus) during which a nerve fibre either does not respond or responds subnormally to a stimulus of threshold intensity or greater than threshold intensity. It is of two types:

Absolute refractory period (ARP).

It is a short period following action potential during which second stimulus, no matter how strong it may be, cannot evoke any response (another action potential). In other words during absolute refractory period the nerve fibre completely loses its excitability. The absolute refractory period corresponds to the period of action potential from firing level until repolarization and is almost one-third complete (spike potential). During this period, neither a fresh impulse can be generated, nor can an impulse generated elsewhere pass through this area.

Ionic basis of absolute refractory period.

During upstroke of action potential (depolarization), the *m gates* of sodium channels in the membrane of nerves are opened rapidly. During downstroke (early repolarization), the channels are closed by closure of inactivation (*h gates*) of the sodium channel and slow potassium channels are not yet opened. These sodium channel gates do not open unless potential comes back to resting level. Therefore, during this period (absolute refractory period) the nerve fibre is not stimulated at all.

Relative refractory period (RRP).

It is a short period during which the nerve fibre shows response, if the strength of stimulus is more than normal. It extends from the end of absolute refractory period to the start of *after depolarization* of the action potential.

Ionic basis of relative refractory period.

During this stage the Na⁺ channels are coming out of inactivated stage and voltage-gated potassium channels are still opened. The stronger stimulus (suprathreshold) at this stage is able to open more Na⁺ channels through 'm' gates and thus excite a response. The action potential elicited during this period, however, has a lower upstroke velocity and lower overshoot potential than the normal action potential.

Effective refractory period.

The effective refractory period (ERP) includes the absolute refractory period and the early part of relative refractory period. At the end of an effective refractory period, the nerve membrane is able to produce and conduct the action potential.

ii. Supernormal period

During supernormal period, the membrane is hyper-excitable, i.e. the threshold of stimulus is decreased. This period corresponds with the *after depolarization* phase of the action potential.

Ionic basis of supernormal period.

During 'after depolarization' phase the Na⁺ channels have come out of inactivated state but the K⁺ channels (voltage gated) are mostly closed and the membrane potential is nearer to the firing level, so a stimulus of low intensity will be able to excite action potential. In other words, the threshold level of stimulus is decreased during this stage.

iii. Subnormal period

During this period the membrane excitability is low, i.e. the threshold of stimulus is increased. This period corresponds with the *after hyperpolarization* stage of the action potential.

Basis of subnormal period.

During *after hyperpolarization* phase the intracellular negativity further increases (approximately -72 mV). Thus the membrane potential goes farther away from the firing level and so the threshold of stimulus increases. This phase of subnormal period lasts for about 40 ms.

3. Accommodation

We have studied that when a stimulus of sufficient strength (threshold level) is applied quickly, then the action potential is produced. However, when the stimulus strength is increased slowly to the firing level (during constant application), no *action potential is produced*. This is because of the fact that firing level of depolarization of the nerve fibre is not reached as the membrane adapts to the applied stimulus. This phenomenon of adaptation to the stimuli is called *accommodation*. Therefore, a *square pulse stimulus* (Fig. 2.1-16A) which rises sharply to its peak level effectively triggers an action potential. Whereas, a *saw-tooth pulse stimulus* (Fig. 2.1-16B), which rises to its peak slowly, often fails to trigger an action potential.

FIGURE 2.1-16 Single nerve fibre response to: **A**, square pulse stimulus; and **B**, saw tooth pulse stimulus.

Ionic basis of accommodation.

When the membrane depolarizes, both Na^+ and K^+ channels open up. If depolarization occurs rapidly, the opening of the Na^+ channels overwhelm the repolarizing forces and the typical action potential is produced. However, when the induced depolarization is produced slowly, more and more Na^+ channels open up, only to get inactivated after 1 ms, while the K^+ channels remain open which tend to restore the membrane potential. Thus, the repolarizing forces overwhelm the depolarizing forces and so the action potential is not produced.

4. Infatigability

A nerve fibre cannot be fatigued, even if it is stimulated for a long time. This property of infatigability is due to the fact that during action potential neither a fresh impulse (action potential) can be generated nor

the action potential can be conducted through the nerve fibre. In other words, once stimulated, the nerve cannot be stimulated immediately again due to absolute refractory period (see page 66) and thus cannot be fatigued.

Electrotonic potential and local response

When a nerve fibre is stimulated by subminimal or subthreshold stimuli, the action potential is not produced, but there do occur some changes in the resting membrane potential. These local nonpropagated changes are called *electrotonic potentials* or *acute subthreshold potentials*.

Types of electrotonic potentials

Depending upon the nature (negative or positive) of subthreshold level current used to stimulate, (Fig. 2.1-17) the electrotonic potentials are of two types:

B

C

FIGURE 2.1-17 Electrotonic potential: **A**, arrangement of recording electrotonic potentials; **B**, catelectrotonic potential recorded by application of subthreshold stimuli (varying intensities) at cathode; and **C**, anelectrotonic potential recorded by application of stimuli (varying intensities) at anode.

Catelectrotonic potential.

Catelectrotonic potentials are localized depolarizing potential changes in the membrane potential produced when the stimulus of subthreshold strength is applied with cathode. This potential change rises sharply and then decays exponentially with time.

Anelectrotonic potential.

Anelectrotonic potentials are the localized hyperpolarizing potential changes in the membrane potential when anodal subthreshold current is applied.

Production of electrotonic potentials

The electrotonic potentials are produced due to passive changes in the membrane polarization caused by addition or subtraction of the charge by the particular electrode.

Graded potentials

As shown in Fig. 2.1-17, the electrotonic potentials produced by varying intensities of stimuli are proportionate to the magnitude of stimulation. Therefore, these are also known as *graded potentials*. The graded response is achieved both at cathode and anode up to 7 mV of depolarization or hyperpolarization. At anode, the graded response is achieved even with stronger stimuli. However, the cathodal responses become greater than the proportionate increase in the stimulus intensities to produce depolarization 7–15 mV. This disproportionate response at cathode occurs due to opening of more voltage-gated Na⁺ channels, and is called *local response*. A further increase in the intensity of cathodal stimulus may produce *firing level* (15 mV) initiating the action potential (Fig. 2.1-17B).

Differences between graded potentials and action potential are summarized in Table 2.1-2.

TABLE 2.1-2

Differences between Graded Potential and Action Potential

<i>Graded potential</i>	<i>Action potential</i>
1. The amplitude of graded potential is proportionate to the intensity of the stimulus and can get summated.	The amplitude of action potential remains constant with increasing intensity of stimulus, therefore it cannot be summated.
2. Graded potentials can be either depolarizing or hyperpolarizing	Action potential is always depolarizing.
3. Graded potential can be generated either spontaneously or in response to either	Action potential is generated only in response to membrane depolarization.

physical or chemical stimuli.	
4. Graded potentials cannot conduct impulse	Action potential can conduct impulses
5. Examples are: • Receptor potential at sensory nerve endings • Motor end plate potential	Examples are: Action potential of a nerve fibre, skeletal muscle and cardiac muscle

Changes in excitability during electrotonic potential

1. During catelectrotonic potential,

the threshold of neuron to stimulation decreases, i.e. the excitability increases. The cathodal currents move the membrane potential towards firing level. Therefore, when cathodal stimuli of subthreshold strength are applied in quick succession, the passive depolarizing potential is added up (summated) and firing level may be reached. At this potential, depolarizing forces are stronger than repolarizing forces. This property is called *summation of subminimal stimuli* (Fig. 2.1-17B).

2 During anelectrotonic potential

Threshold of neuron stimulation is elevated, i.e. the membrane excitability is decreased. It is because the anodal currents take the membrane potential farther away from the firing level (i.e. the membrane potential becomes about -85 mV) and thus inhibit impulse formation (Fig. 2.1-17C). The size of anelectrotonic potential is proportionate to the magnitude of anodal current strength. When stimulation with anodal current is stopped, it may lead to overshoot of membrane potential towards depolarization direction. This *rebound depolarization* response is sometimes so large that the firing level may be reached producing the action potential.

Inhibition of excitability

There are certain factors which inhibit the excitability of the nerve fibres. These factors are called *membrane-stabilizing factors*. Some of the factors or the conditions which lead to inhibition or decrease in excitability are:

1. High extracellular calcium concentration.

A high extracellular Ca^{2+} concentration decreases membrane permeability to Na^+ ions thereby decreasing the membrane excitability.

2. Local anaesthetics.

Local anaesthetic agents like *procaine*, *tetracaine* and *lidocaine* act directly by binding to the activation gates of the Na^+ channels. These agents block

the Na⁺ channels thus reducing the membrane excitability. Therefore, effect of local anaesthetics on membrane excitability depends upon the distribution or density of Na⁺ channels. For example, in myelinated nerves, the density of Na⁺ channels is high at *node* of Ranvier. The local anaesthetics are unable to block all the Na⁺ channels, hence myelinated nerve fibres are less sensitive to local anaesthetics, whereas unmyelinated nerve fibres are highly susceptible to local anaesthesia.

Recording of resting membrane potential and action potential

See page 70.

Conductivity

Conductivity refers to propagation of nerve impulse (action potential) in the form of a wave of depolarization through the nerve fibre. Normally in the body, the action potential is transmitted through nerve fibre in one direction, but in experimental conditions when nerve fibre is stimulated in the middle, the action potential initiated is conducted equally in either direction (Fig. 2.1-18B). Mechanism of conduction of action potential along an unmyelinated nerve fibre and a myelinated nerve fibre is described below.

FIGURE 2.1-18 Electrotonic conduction of impulse in an unmyelinated nerve fibre: **A**, resting phase (polarized state); **B**, conduction of impulse in both directions when stimulus applied at the middle of nerve fibre; **C**, when stimulus applied at one end of the nerve fibre; **D** and **E**, propagation of impulse in one direction along the nerve fibre; and **F**, repolarization (occurs in same direction).

Propagation of action potential in an unmyelinated axon

The steps of propagation of action potential along an unmyelinated axon are summarized:

- In the resting phase (polarized state) the axonal membrane is outside positive and inside negative (Fig. 2.1-18A).
- When an unmyelinated axon is stimulated at one site by a threshold stimulus, there occurs action potential at that site, i.e. that site is depolarized. In other words, that site's outside becomes negative and inside positive (reversal of polarity) but the neighbouring areas up to now remain in polarized state (Fig. 2.1-18C).
- As ECF and ICF are both conductive to electricity, a current will flow from positive polarized area to negative activated area through ECF and in the reverse direction in ICF (Fig. 2.1-18C). Thus, a *local circuit current* flows between the resting polarized site to the depolarized site of the membrane (current sink).
- This circular current flow depolarizes the neighbouring area of the membrane upto firing level and a new action potential is produced which in turn depolarizes the neighbouring area ahead. Thus, due to successive depolarization of the neighbouring area, the action potential is propagated along the entire length of the axon (Fig. 2.1-18D). This type of conduction is known as *electrotonic conduction*. Once initiated, the moving impulse cannot spread to reverse direction because the proximal site is in *refractory state* and thus the distal sites being in polarized state keep on getting depolarized. Thus, the direction of propagation of impulse is that of current flow inside the nerve fibre (Fig. 2.1-18E).
- The depolarization remains at any site for some length of time, therefore, portion which depolarizes first also repolarizes first. Thus, the repolarization is also propagated following the depolarization (Fig. 2.1-18F).
- The magnitude of action potential does not change as it is conducted along the membrane, because the new action potentials are being generated constantly. However, the speed of propagation of action potential varies in different tissues.

Propagation of action potential in a myelinated axon

As discussed in the functional anatomy of nerves, the myelinated nerve fibres have a wrapping of myelin sheath with gaps at regular intervals which are devoid of myelin sheath (nodes of Ranvier). The axonal membrane in the naked area (nodes of Ranvier) bears densely packed ion channels. The myelin sheath acts as an insulator and does not allow the current flow. Therefore, in myelinated nerve fibres, the *local circuit of current flow* only occurs from one node of Ranvier to the adjacent node (Fig. 2.1-19). That is, the impulse (action potential) jumps from one node of Ranvier to next. This is known as *saltatory conduction*. Since the impulse jumps from one node to other, the speed of conduction in myelinated fibres is rapid (50 to 100 times faster) than the unmyelinated fibre.

FIGURE 2.1-19 Saltatory conduction along a myelinated nerve fibre.

Orthodromic versus antidromic conduction

Normally, the action potential is propagated in one direction. That is, usually the nerve impulse from the receptors or synaptic junctions travels along the entire length of the axon to their termination. This type of conduction is called *orthodromic conduction*. The conduction of nerve impulse in the opposite direction, as seen in the sensory nerve supplying the blood vessels, is called *antidromic conduction*.

Conduction velocity

Factors affecting conduction velocity

The velocity of conduction in nerve fibres varies from as little as 0.25 m/s in very small unmyelinated fibres to as high as 100 m/s in very large myelinated fibres. In general, the factors affecting conduction velocity are:

A. Factors attributable to action potential generation

1. Temperature

affects conduction velocity by its effect on the duration of the action potential. A decrease in temperature causes a marked increase in the duration of action potential (specially the spike) and thus delays conduction, i.e. slows down the conduction velocity.

2. Level of resting membrane potential (RMP)

affects the conduction velocity variably. Where the RMP is less negative, it slows down both generation of action potential and electrotonic conduction. When RMP is more negative, it slows down the generation of action potential but speeds up electrotonic conduction. The resultant effect on conduction velocity is variable but usually a decrease.

3. Level of threshold potential (firing level)

if it is low the conduction velocity is increased. It is due to the fact that at low firing level one action potential can trigger a second action potential a distance away where the local currents are feeble. A decrease in the firing level occurs when the concentration of divalent ion in the extracellular fluid (ECF) decreases.

B. Factors attributable to electrotonic conduction

1. Axon diameter

affects the conduction velocity through the *resistance offered by the axoplasm* (R_i) to the flow of axoplasmic current. Greater this resistance, weaker is the electrotonic conduction. If the diameter of the axon is greater, the axoplasmic resistance (R_i) is lesser and hence the velocity of conduction is higher.

- In an unmyelinated nerve fibre, the conduction velocity is directly

proportional to the square root of the fibre diameter (D), i.e.

$$\text{Conduction velocity} \propto \sqrt{D}$$

2. Myelination

increases conduction velocity by its following effects:

- By increasing the axon diameter.
- By the saltatory conduction produced due to its insulating effect (as discussed above).
- *Resistance offered by the membrane* (R_m) is high in thick myelinated nerve fibres. When R_m is high, the membrane current falls resulting in higher axoplasmic current and stronger electrotonic conduction.
- Electrical capacitance (C_m) is low in thick myelinated nerve fibres. The lesser the membrane capacitance, the stronger the electrotonic conduction.

In a myelinated nerve fibre the conduction velocity is directly proportional to the fibre diameter as below:

$$\text{Conduction velocity (in m/s)} = 6 \times \text{axonal diameter (in } \mu\text{)}$$

3. Resistance offered by extracellular fluid (R_o)

to the outer longitudinal current also affects the conduction velocity. Greater this resistance (R_o), weaker is the electrotonic conduction. However, R_o usually remains constant.

Recording of membrane potentials and action potentials

The recording of membrane excitation and action potential is made possible by the use of highly sophisticated equipment. The mammalian axons are about $20 \mu\text{m}$ or less in diameter, so being relatively small, it is very difficult to separate them out from other axons. In certain

invertebrate species like in crab (*Carcinus*), cuttlefish (*Sepia*) and squid (*Loligo*) have giant cells. The largest axon found in the neck region of *Loligo* is about 1 mm in diameter. The fundamental properties are quite similar to human axons. Therefore, these animals can be used for recording various events.

Instruments used for recording

The membrane potential changes during activities of nerve fibre are very rapid (occurring in less than a second); therefore, the recording instrument should be capable of responding extremely rapidly, i.e. it must be inertia-less. Further, the potential changes occurring are in millivolts and hence need to be amplified before being recorded. The essential instruments used in recording the activity of excitable tissue are:

- Microelectrodes,
- Electronic amplifiers, and
- Cathode-ray oscilloscope (CRO).

Basic principles of the functioning of these instruments are discussed briefly.

1. Microelectrodes

Microelectrodes are usually very small pipettes (micropipette) of tip size less than 1 mm diameter, filled with strong electrolyte solution (KCl) and having very high resistance (one billion ohms) to electrical flow. The tip of micropipette electrode is impaled through the cell membrane of the nerve fibre. Another electrode called *indifferent electrode* is placed in the extracellular fluid (Fig. 2.1-20).

FIGURE 2.1-20 Cathode ray oscilloscope and simplified diagram to record action potential from a nerve fibre.

The microelectrode can be connected to cathode-ray oscilloscope through a suitable amplifier for recording rapid changes in membrane potential during nerve impulse transmission.

2. Electronic amplifier

This device can magnify the potential changes of the tissue to more than thousand times so that these can be recorded on the oscilloscope screen.

3. Cathode-ray oscilloscope

Cathode-ray oscilloscope (CRO) is almost an inertialess instrument which can record and measure the electrical events of living tissues instantaneously. The CRO primarily consists of a glass tube with a cathode, fluorescent surface (screen) and two sets of electrically charged plates (Fig. 2.1-20).

Cathode

is in the form of an electronic gun. When connected to a suitable anode

and electric current is passed, the electronic gun emits electrons.

Fluorescent surface

(the face of glass tube coated with fluorescent material) acts as a screen. The electrons emitted from the cathode are directed into a beam which hits this screen.

Electrically charged plates

are arranged in two sets: vertical and horizontal

• Horizontal deflection plates

are placed on either side of the electron beam. These are connected to sweep generator (*electronic sweep circuit*). When a voltage is applied across these plates, the beam of electrons (being negatively charged) is attracted towards the positively charged plate and repelled away by the negatively charged plate. If 'saw-tooth voltage' (i.e. voltage increased slowly, then suddenly reduced, and again slowly increased) is applied, the electron beam will steadily move towards the positively charged plate (with slowly increasing voltage), then back to its original position (with sudden reduction in the voltage), and again move towards the positively charged plate. In this way the electron beam is made to sweep across the fluorescent screen horizontally, which will give a continuous marking of line of glowing light.

• Vertical deflection plates

are placed above and below the electron beam. These are connected to recording electrodes placed on the nerve through an electronic amplifier. The potential change occurring in the nerve will charge these plates which will cause vertical (upward and downward) deflection of the electron beam. The magnitude of deflection will be proportional to the potential difference between the two plates. Thus, action potential is recorded as vertical deflection of the beam as it moves across the fluorescent screen of the cathode ray oscilloscope.

Recording of resting membrane potential

The arrangement of electrodes for recording membrane potential is shown in [Fig. 2.1-7](#). The electrical potential is recorded at the surface of the membrane (exterior) and inside the membrane at each point in a nerve fibre. Starting from one end of the nerve fibre (left side of the figure) and passing to the other end (right side) and when both the

electrodes (indifferent and microelectrodes) are on the surface (outside) of the nerve fibre membrane, then no potential difference was recorded (zero potential), which is potential of extracellular fluid. However, when microelectrode is made to penetrate into the interior of cell, a constant potential difference (-70 mV) is observed. This is known as resting membrane potential (Fig. 2.1-7).

Recording of action potential

Monophasic recording of action potential

For monophasic recording of action potential, one microelectrode is placed inside the nerve fibre and the other electrode on the outside surface. These electrodes are then connected to the cathode-ray oscilloscope (Fig. 2.1-20). When the nerve is stimulated, as shown in Fig. 2.1-21, a typical monophasic record of action potential obtained has the following components:

- Depolarization
- Repolarization

FIGURE 2.1-21 A typical monophasic record of action potential.

It has been described in detail on page 61.

Biphasic recording of action potential

For biphasic recording of action potential, both the exploring electrodes (x and y) are placed on the outside surface of nerve fibre, and they are connected to a cathode-ray oscilloscope (Fig. 2.1-22). When the nerve is stimulated, the excitation of one electrode will cause deflection opposite to that of another during the passage of impulse. Record of this alternate deflection (one negative below the baseline and one positive above the baseline (called *biphasic action potential*) is depicted:

- During *resting state* only baseline is recorded as both electrodes are equipotential (Fig. 2.1-22A).
- When a threshold stimulus is applied, an action potential is initiated and first the membrane under electrode x gets depolarized (outside

-ve) but the membrane under electrode y is still polarized (outside +ve). Because of the potential difference between the two electrodes, a downstroke is recorded by CRO (Fig. 2.1-22B).

- When impulse passes beyond 'x' but has not reached 'y', and membrane under electrode x is repolarized (outside +ve), then the record comes back to a baseline as again the membrane under the two electrodes becomes equipotential (Fig. 2.1-22C).
- As shown in Fig. 2.1-22D, when the impulse reaches y electrode, the membrane under it gets depolarized (outside -ve). Since at x the membrane is repolarized (outside +ve), the potential difference between the two electrodes is recorded as upstroke by CRO.
- When impulse passes beyond 'y', and membrane under it is repolarized (outside +ve); once again the record comes to baseline as both electrodes are again equipotential (Fig. 2.1-22A).
- A typical complete record of biphasic action potential is shown in Fig. 2.1-23.

FIGURE 2.1-22 Arrangement for recording biphasic action potential (recording electrodes x and y are on the surface of nerve fibre connected to cathode-ray oscilloscope): **A**, resting state; **B**, on stimulation when wave of excitation reaches at electrode 'x'; **C**, when impulse passes beyond electrode 'x'; **D**, when impulse reaches at electrode 'y', and **E**, when impulse passes away from electrode 'y'.

FIGURE 2.1-23 A typical complete record of biphasic action potential.

Advantages of biphasic recording

1. Comparatively easy process, since both the electrodes are placed on the outside surface of the nerve.
2. Propagation of action potential can also be recorded.

Disadvantages of biphasic recording

1. Graph obtained is variable depending upon the distance between the electrodes and the rate of conduction of impulse in the nerve fibre.
2. Proper analysis of action potential cannot be done as can be done in monophasic recording.
3. Potential difference recorded is somewhat smaller than actual, as nerve

fibre has to be kept in a solution to prevent drying.

Compound action potential and its recording

Compound action potential is the monophasic recording of action potential from a *mixed* nerve which contains different types of nerve fibres with varying diameter. Therefore, the compound action potential represents an algebraic summation of the all or none action potentials of many axons.

Response of a mixed nerve to stimulus

Response of a mixed nerve to a stimulus will depend upon the thresholds of the individual axon in the nerve and their distance from the stimulating electrode as below (Fig. 2.1-24):

FIGURE 2.1-24 Typical record of compound action potential (recorded from a mixed nerve) showing multiple peaks.

- **Subthreshold stimulus**

stimulates none of the axons and thus no response is observed.

- **Threshold intensity stimulus**

makes the axons with low threshold to fire and thus a small potential change is observed.

- **With further increase in the intensity of stimulus,**

the axons with higher thresholds also fire. The electrical response increases proportionately until the stimulus is strong enough to excite all of the axons in the nerve. The stimulus which excites all the axons is called *maximal stimulus*.

- **Supramaximal stimulus**

does not produce any further increase in the potential.

Features of a compound action potential

- It has a unique shape (multiple peaks), because a mixed nerve is made up of different fibres with various speeds of conduction.
- The number and size of the peaks vary with the types of fibres in the particular nerve being studied.
- When less than maximal stimuli are used, the shape of compound action will depend upon the number and type of fibres stimulated.
- Thus, a typical record of compound action potential will contain three different curves labelled as α , β and γ (Fig. 2.1-24).

Physiological properties of nerve fibres

The properties of the nerve fibres are mainly because of the nerve cells being excitable tissue, i.e. having a low threshold for excitation. Therefore, the main properties of the nervous tissue are excitability and conductivity and all other properties are secondary to these. After studying the electrical activities of the nerve fibres in detail, their important physiological properties can be summarized as:

1. Excitability,

i.e. the nerve fibres when stimulated produce waves of depolarization, called *excitation impulse* (for details see page 60).

2. All and none response,

i.e. when stimulated, the nerve fibre either shows no excitation or responds to the maximum of its ability (for details see page 65).

3. Refractory period,

i.e. when the nerve fibre is stimulated by two successive stimuli of more than threshold intensity:

- it responds to the first stimulus, but
- is unable to respond to the second stimulus for quite some time, called the refractory period (for details see page 65).

4. Summation,

i.e. response to the successive subthreshold stimuli can be summated. When one subthreshold stimulus is applied, the nerve fibre does not respond. However, if two or more subthreshold stimuli are applied within a short interval of about 0.5 ms, the response may be produced. This is because the subthreshold stimuli are summed up. This property is called summation (also see page 68).

5. Accommodation,

i.e. the excitability of the nerve fibre is decreased when a constant current is passed through it. A similar feature of the nerve endings is called adaptation. That is, the nerve fibres accommodate and the nerve endings adapt when a constant current is passed (for details see page 66).

6. Infatigability,

i.e. a nerve fibre cannot be fatigued, even if it is stimulated continuously for a long time (also see page 67).

7. Conductivity,

i.e. the nerve fibres possess the ability to transmit the excitation impulse along its entire length (for details see page 68).

Nerve fibre types

Various schemes for classification of nerve fibres on the basis of their diameter and their conduction velocity have been proposed. The best known classification is of Erlanger and Gasser. Before discussing this important classification it will be useful to be familiar with the various terminologies used in relation to nerve fibres and certain facts about the conduction velocity in nerve fibres.

Terminology used in relation to nerve fibres

- *Myelinated versus nonmyelinated fibres.* The myelinated nerve fibres are covered by a myelin sheath while the nonmyelinated nerve fibres have no such sheath.
- *Somatic versus visceral nerve fibres.* Somatic nerve fibres supply the skeletal muscles of the body while visceral nerve fibres supply the various internal organs (viscera).
- *Cranial versus spinal nerves.* Nerve fibres arising from the brain form the cranial nerves while those arising from the spinal cord form the spinal nerves.
- *Motor versus sensory nerve fibres.* Motor nerve fibres, also known as *efferent fibres* carry motor impulses from CNS to different parts of the body. The sensory nerve fibres, also known as *afferent fibres* carry sensory impulses from different parts of the body to CNS.
- *Adrenergic versus cholinergic nerve fibres.* Adrenergic nerve fibres secrete noradrenaline while cholinergic fibres secrete acetylcholine as neurotransmitter.

Certain facts about the conduction velocity in nerve fibres

- Fibres of larger diameter conduct impulses more rapidly than those of smaller diameter.
- The impulse conducted through larger diameter nerve fibres will have greater magnitude and lesser duration of spike, lesser threshold of excitation and lesser refractory period, as compared to the impulses conducted through nerve fibres of smaller diameter.
- The speed of conduction is about 6 times the diameter of a myelinated nerve fibres. Since the diameter of myelinated nerve fibres varies from 1 to 20 μm , the conduction velocity will vary from 6 to 120 m/s.
- In unmyelinated nerve fibres the speed of conduction is proportional to the square root of the diameter of the nerve fibre. Since the largest unmyelinated nerve fibres have a diameter of 1 μm , their maximum conduction velocity will be 1 m/s.
- By and large, the larger nerve fibres are concerned mainly with proprioceptive sensations and somatic functions, and the smaller

diameter fibres are concerned with pain and temperature sensations and autonomic functions.

Classifications of nerve fibres

1. Letter classification of erlanger and gasser

This is the best known classification based on the diameter and conduction velocity of nerve fibres. The nerve fibres have been classified as follows:

'Type A' nerve fibres.

The fastest conducting fibres are called type A fibres. Their diameter varies from 12–20 μm and conduction velocity from 70 to 120 m/s. They are myelinated fibres.

Type A fibres have been further subdivided into α , β , γ and δ fibres. Type A fibres subserve both motor and sensory functions:

Motor 'type A' fibres

- *A α fibres* supply extrafusal fibres in skeletal muscles.
- *A γ fibres* supply intrafusal fibres in muscle spindles.
- *A δ fibres* are collaterals of A α fibres (to extrafusal fibres) that innervate some intrafusal fibres.

Sensory 'type A' fibres

- *A α sensory fibres* carry impulses from encapsulated receptors in skin, joints and muscles. Some of them carry impulses from the gut.
- *A δ sensory fibres* are afferents from thermoreceptors and nociceptors (pain receptors).

'Type B' nerve fibres.

These fibres are myelinated, have a diameter of less than 3 μm and their conduction velocity varies from 4 to 30 m/s. They form preganglionic autonomic efferent fibres and afferent fibres from skin and viscera, and free nerve ending in connective tissue of muscle.

'Type C' nerve fibres.

These are unmyelinated, have a diameter of 0.4–1.2 μm and their

conduction velocity varies from 0.5 to 4 m/s. These form the postganglionic autonomic fibres, some sensory fibres carrying pain sensations, some fibres from thermoreceptors and some from viscera.

The salient features of type A, B and C nerve fibres are summarized in [Table 2.1-3](#).

TABLE 2.1-3
Salient Features of Type A, B and C Nerve Fibres

Fibre Type	Myelinated/nonmyelinated	Fibre diameter (µm)	Conduction velocity (m/s)	Spike duration (ms)	Absolute refractory period (ms)	Function		
						Efferent	Afferent	
A	α	Myelinated	12-20	70-120	0.4-0.5	0.4-1	Somatic motor	Proprioception
	β	Myelinated	5-12	30-70	0.4-0.5	0.4-1	—	Touch and pressure
	γ	Myelinated	3-6	15-30	0.4-0.5	0.4-1	Motor to muscle spindles	—
	δ	Myelinated	2-5	12-30	0.4-0.5	0.4-1	—	Pain, cold and touch
B	—	Myelinated	<3	3-15	1.2	1.2	Preganglionic autonomic	—
C	—	Nonmyelinated	0.4-1.2	0.5-2	2	2	Postganglionic autonomic (sympathetic)	Pain, temperature some mechano receptors and reflex responses

2. Numerical classification

Some physiologists have classified sensory nerve fibres by a numerical system into type Ia, Ib, II, III and IV. A comparison of the numerical classification and the letter classification is shown in [Table 2.1-4](#).

TABLE 2.1-4
Numerical vis-à-vis Letter Classification of Sensory Nerve Fibres

Types of nerve fibre		
Numerical classification	Letter classification	Origin
Ia	A α	Muscle spindle (annulospiral endings)
Ib	A α	Golgi tendon organ
II	A β	Muscle spindle, (flower spray endings), touch and pressure
III	A δ	Pain and cold receptors, some touch receptors
IV	C	Pain, temperature and other receptors.

3. Susceptibility of nerve fibres to hypoxia, pressure and local anaesthetics

Hypoxia.

As shown in [Table 2.1-5](#), the type B fibres are most susceptible to hypoxia. Since, the preganglionic autonomic fibres are of type B, therefore, hypoxia is associated with alteration of the autonomic functions in the body such as rise in heart rate, blood pressure and respiration.

TABLE 2.1-5

Susceptibility of Nerve Fibres to Hypoxia, Pressure and Local Anaesthetics

Sensitivity to	Type of nerve fibre		
	Most susceptible	Intermediate susceptible	Least susceptible
Hypoxia	B	A	C
Pressure	A	B	C
Local anaesthetics	C	B	A

Pressure.

Type A fibres are most susceptible to pressure and type C least. Therefore, pressure on a nerve can produce temporary paralysis due to loss of conduction in motor, touch and pressure fibres (type A), while pain sensation (carried by type C fibres) remain relatively intact. This is a common observation after sitting cross-legged for long periods and after sleeping with arms under the head.

Local anaesthetics.

Type C fibres (conducting pain, touch and temperature sensations generated by cutaneous receptors) are most susceptible to local anaesthetics. This fact is useful for surgical interventions under local anaesthesia.

Degeneration and regeneration of neurons

When the axon of neuron is injured, a series of degenerative changes are seen at three levels:

- In the axon distal to injury,

- In the axon proximal to injury and
- In the cell body.

Along with the degenerative changes, the reparative process (regeneration) also starts soon if the circumstances are favourable. The effects of injury to a nerve and the occurrence of regenerative changes thereafter will depend upon the degree and type of damage.

Grading of nerve injury

Common causes of nerve injury are: transection (through and through cut), crushing of nerve fibres, local injection of toxic substances, ischaemia due to obstruction of blood flow and effects of hyperpyrexia on the neurons. Sunderland had graded the injury to nerve fibres in order of severity into the following degrees:

- **First degree injury**

involves only transient loss of function resulting from a mild pressure on the nerve. The temporary loss of function is caused by local anoxia produced by ischaemia following obstruction to the blood flow. The lost function of the nerve fibres returns within few hours to few weeks of the removal of the causative pressure, since the axon is not destroyed.

- **Second degree injury**

includes severe nerve damage with intact endoneural tube. It results from a severe and prolonged pressure on the nerve. The nerve fibre is severely damaged at the pressure point and is followed by degenerative changes. However, the regeneration and restoration of the function of the nerve are facilitated as the endoneural tube remains intact.

- **Third degree injury**

includes severe damage to the nerve fibre with interruption of the endoneural tube.

- **Fourth degree injury**

refers to a severe damage to the nerve fibres associated with disorganization of nerve fasciculi.

- **Fifth degree injury**

is labelled when there occurs complete transection, i.e. the nerve fibres are cut through and through. Degenerative changes are initiated very early following fifth degree injury to the nerve fibres.

Stage of degeneration

The degenerative changes which occur in the part of axon distal to the site of injury are referred to as *anterograde degeneration* or Wallerian degeneration (after the discoverer A Waller, 1862). The degenerative changes occurring in the neuron proximal to the injury are referred to as *retrograde degeneration*. These changes take place in the cell body and in the axon proximal to injury.

Changes in the part of axon distal to injury

Degenerative changes in the part of axon distal to injury, also known as anterograde degeneration or Wallerian degeneration occur within few hours of injury. The changes take place in the entire length of this part of the axon simultaneously. The degeneration changes start within few hours of injury and continue for about 3 months and include the following (Fig. 2.1-25).

FIGURE 2.1-25 Degenerative changes (Wallerian degeneration) in distal part of a nerve fibre after injury (A–E) and subsequent regenerative changes (F–J).

Axis cylinder

Axis cylinder becomes swollen and irregular in shape within a few hours of injury. After a few days it breaks up into small fragments, the neurofibrils within it break down into granular debris and are seen in the space occupied by axis cylinder.

Myelin sheath

shows slow disintegration which starts on the 8th day and continues up to the 32nd to 35th day. In fact myelin sheath is converted into fat droplets containing cholesterol esters.

Neurilemmal sheath

is usually unaffected but the Schwann cells start multiplying rapidly.

Macrophages

invade the region and remove degenerating axons, myelin and cellular debris and thus the neurilemmal tube becomes empty.

Schwann cell's

cytoplasm proliferates rapidly and fills up the empty neurilemmal tube. These cells produce a large series of membranes that help to form numerous tubes which play a vital role in the regeneration of nerve fibres.

Changes in the cell body of neuron

Changes in the cell body of the injured neuron start within 48 h and continue up to 15–20 days. The changes are (Fig. 2.1-26):

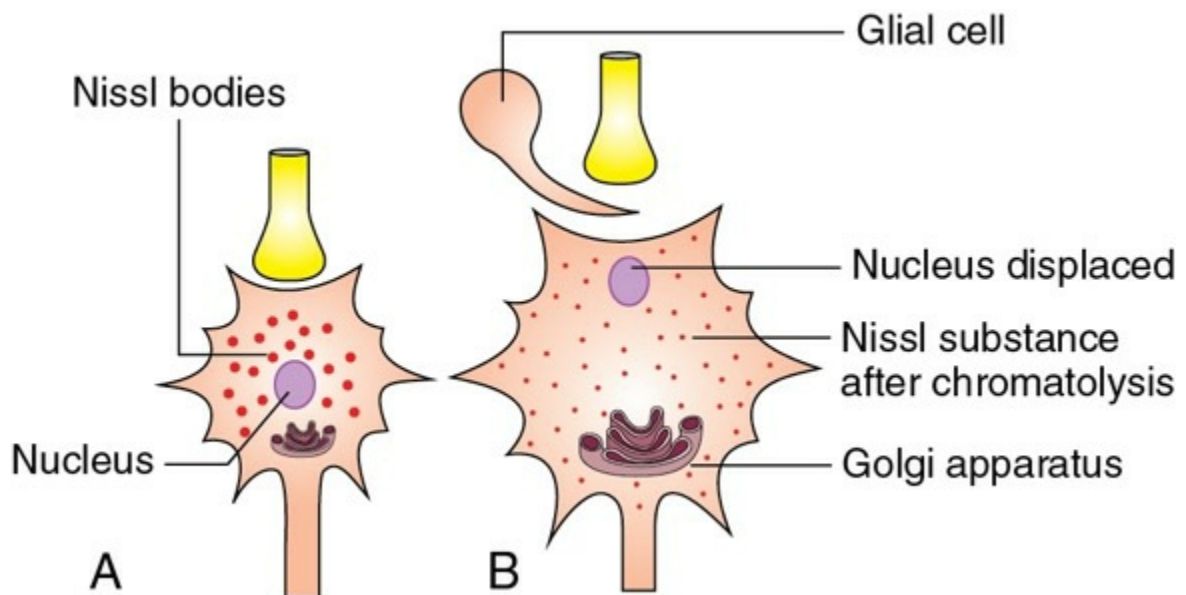

FIGURE 2.1-26 Changes in cell body of a neuron after injury (B) and normal cell body of a neuron (A).

Nissl substances

undergo disintegration and dissolution (*chromatolysis*). The process of chromatolysis starts around the nucleus and spreads in the periphery.

Golgi apparatus, mitochondria and neurofibrils

are fragmented and eventually disappear.

Cell body

draws in more fluid, enlarges and becomes spherical.

Nucleus

is displaced to the periphery (towards cell membrane). Sometimes, the nucleus is extruded out of the cell, in which case the neuron atrophies and finally disappears completely.

Severity of degenerative changes in the cell body

Severity of degenerative changes in the cell body is variable. The changes are more severe when the injury to the axon is near the cell body, and when the injury is caused by a forcible tear rather than a sharp cut. In some cases, the chromatolysis ends in cell death followed by degeneration of all its processes. If the cell survives, the changes described above are reversed after a period of time.

Changes in the part of axon proximal to injury

Changes in the part of axon proximal to injury occur only up to the first or second node of Ranvier near the injury and are similar to the changes seen in the distal part of the axon. Changes seen in the proximal part of axon along with those seen in the cell body of neuron constitute the *retrograde degeneration*.

Transneuronal degeneration

It is sometimes observed that changes resulting from axonal injury are not confined to the injured neuron, but extend to other neurons with which the injured neuron synapses. This phenomenon is referred to as *transneuronal degeneration*. The degeneration can extend through several synapses (as demonstrated in the visual pathway).

Stage of regeneration

The stage of degeneration is followed by stage of regeneration under favourable circumstances (listed below). It starts within 4 days of injury but becomes more active after 30 days and may take several months to one year for complete recovery.

Factors affecting regeneration

- Regeneration occurs more rapidly when a nerve is crushed than when it is severed and the cut ends are separated.
- Chances of regeneration of a cut nerve are considerably increased if the

two cut ends are near each other (gap does not exceed 3 mm); and if scar tissue does not intervene between them.

- Chances of regeneration are more if the two cut ends remain in the same line, and are not moved away from each other.
- Presence of neurilemma is a must for regeneration to occur. Therefore, axons in CNS once degenerated never regenerate as these nerve fibres have no neurilemma.
- Presence of nucleus in the neuron cell body is also a must for regeneration to occur. If it is extruded, the neuron is atrophied and the regeneration does not occur.

Regenerative changes

Anatomical regeneration

1. Changes in the axon

• Stage of fibres formation.

Axis cylinder from the proximal cut end of the axon elongates and gives out fibrils up to 100 in number in all directions. These branches grow into the connective tissue at the site of injury in an effort to reach the distal cut end of the nerve fibre (Fig. 2.1-25F and G).

• Stage of entry of fibrils into endoneural tube.

Strands of Schwann cells from the distal cut end of axon guide the regenerating fibrils to enter their axon endoneural tube and once the fibril enters the endoneural tube it grows rapidly within it. The rate of growth which is initially low (0.25 mm/day) increases rapidly once the regenerating axon enters the endoneural tube (3–4 mm/day). The axonal fibrils that fail to enter any one of the tubes degenerate. It often happens that more than one fibril (1–25) enters the same tube. Under such circumstances, the largest fibril survives and the rest degenerate.

• Stage of active growth.

The axonal fibril growing through the endoneural tube enlarges and establishes contact with an appropriate peripheral end organ. The new axon formed in this way is devoid of myelin sheath (Fig. 2.1-25H and I). The process of regeneration up to this stage takes about 3 months.

- **Stage of myelination.**

The myelin sheath is then formed by the cells of Schwann slowly. The myelination is completed in one year. Thus, there occurs a progressive increase in the thickness of nerve fibre. The regenerated nerve fibre, however, obtains only 80% of the original diameter.

Important Note

Axonal regeneration is promoted by growth promoting factor secreted by Schwann cell & adhesion molecules of immunoglobulin family (e.g. NgCAMK).

- In CNS the neurons do not require a growth promoting factor for regeneration.
- Events such as astrocyte proliferation, microglial activation, scar formation, inflammatory reaction following CNS injury are unfavourable for degeneration.

2. Changes in the cell body of neuron

- Nissl granules followed by Golgi apparatus appear in the cell body.
- The cell loses excess fluid and regains its normal size.
- The nucleus occupies the central position.

The above changes in some of the neurons start within 20 days of injury and are completed in 80 days. Regenerative changes in the cell body may occur, even when the axon does not regenerate.

Functional regeneration

The above-described regenerative changes constitute anatomical regeneration. The functional (physiological) recovery, however, occurs after a long period.

Complications following nerve injury

1. Complete atrophy

of the nerve fibre occurs in severe injuries where regeneration does not occur due to absence of favourable circumstances.

2. Functional complications

in the form of misinterpretation of sensations occur when the fibrils do not enter the appropriate tubes and thus there are faulty connections.

3. Neuroma formation

occurs if during regeneration the nerve fibrils growing from the proximal cut end of axon, do not find their way if the gap between two cut ends is too large. Under such circumstances, the fibrils turn round in search of the endoneural tube in a whorl-like mass known as *neuroma*, which may be quite painful.

Phantom limb

is a feeling sometimes perceived by a patient following amputation of the limb. Neuroma, developed at the site of amputation, when excited, causes the patient to feel like the lost limb is present (a feeling of phantom limb).

Factors promoting neuronal growth

Various factors affecting neuronal development, growth and survival have been isolated and studied. These can be broadly arranged into two groups:

- Neurotrophins, and
- Other factors affecting neuronal growth.

Neurotrophins

Neurotrophins are the proteins which provide trophic support to the neurons, i.e. they promote nerve growth and survival. They also have a role in neuronal plasticity.

Production.

The neurotrophins are produced by the muscles or other structures, especially the glands that the neurons innervate. Some of the neurotrophins are produced by the astrocytes.

Transport.

The neurotrophins produced by various structures innervated by a particular neuron, bind to the receptors present at the nerve ending. They

are internalized by endocytosis and then transported to the cell body by retrograde axoplasmic flow. After reaching the cell bodies the neurotrophins foster the production of proteins associated with neuronal development, growth and survival.

Established neurotrophins include:

- Nerve growth factor (NGF),
- Brain-derived neurotrophic factor (BDNF),
- Neurotrophin-3 (NT-3) and
- Neurotrophin 4/5 (NT-4/5).

1. Nerve growth factor.

Nerve growth (NGF) is probably the first neurotrophin recognized. It promotes the growth of *sympathetic nerves and* some sensory nerves.

- It is found in various tissues in human beings and many species of animals. NGF is particularly found in high concentration in the submaxillary salivary glands of the male mice.
- NGF is made up of 2α , 2β and 2γ subunits.
- The α subunits have trypsin-like activity.
- The β subunits are similar in structure to insulin and possess all the nerve-growth promoting activities.
- The γ subunits are serine proteases. Their functions are unknown.
- Receptor of NGF is TrkA (tyrosine kinase activity A)
- A low affinity NGF receptor called P 75^{NTR} forms a heterodimer with TrkA receptors, and increase the affinity and specificity for NGF. However, in absence of Trk receptors, it forms homodimer, that causes apoptosis.

- NGF is also present in the brain and appears to be responsible for the growth and maintenance of cholinergic neurons in the basal forebrain and striatum.
- Immunosympathectomy, i.e. complete destruction of the sympathetic ganglia is produced when antiserum against NGF is injected in a newborn animal.

2. Brain-derived neurotrophic factor

- It has a growth promoting role for peripheral sensory nerves, since it has been seen that BDNF-deficient mice lose peripheral sensory nerves and have severe degenerative changes in their vestibular ganglia.
- Receptor for BDNF is TrkB.

3. Neurotrophin-3

- The neurotrophin-3 (NT-3), plays a growth promoting role in cutaneous mechanoreceptors, since its disruption by gene knockout gives rise to marked loss of these receptors.
- Receptors for NT-3 are TrkC (mainly) and TrkA and B (to some extent).

4. Neurotrophin-4/5

- Receptors for neurotrophin-4/5 is TrkB.

Other growth-promoting factors

Factors, other than neurotrophins, which promote nerve growth include:

- **Ciliary neurotrophic factor (CNTF).**

It is produced by Schwann cells and astrocytes and plays a growth promoting role in lesioned and embryonic spinal cord neurons. It is believed that it may be of some value in treating human diseases in which motor neurons degenerate.

- *Leukaemia inhibitory factor (LIF),*
- *Insulin-like growth factor-I (IGF-I),*
- *Transforming growth factor (TGF),*

- *Fibroblast growth factor (FGF) and*
- *Platelet-derived growth factor (PDGF).*

Neuromuscular junction

STRUCTURE AT NEUROMUSCULAR JUNCTION

- Terminal button
- Presynaptic membrane
- Synaptic cleft
- Postsynaptic membrane

NEUROMUSCULAR TRANSMISSION

- Release of acetylcholine
- Effect of acetylcholine
- End plate potential
- Removal of acetylcholine

DRUGS AFFECTING AND DISORDERS OF NEUROMUSCULAR JUNCTION

- Drugs affecting neuromuscular junction
 - Neuromuscular blockers
 - Neuromuscular stimulators
- Disorders of neuromuscular junction
 - Myasthenia gravis
 - Lambert Eaton syndrome

Structure of neuromuscular junction

Neuromuscular junction refers to the intimate contact of the nerve endings with the muscle fibre to which they innervate. Characteristics of the nerve and muscle fibre at and near the neuromuscular junction are given in Fig. 2.2-1.

FIGURE 2.2-1 Structure of neuromuscular junction: **A**, the axon of the neuron loses its myelin sheath and divides into fine branches; and **B**, structure of terminal button and motor end plate.

Terminal button.

The axon of a neuron supplying a skeletal muscle loses its myelin sheath and divides into a number of fine branches that end in small swellings (knobs) called *terminal buttons* or end feet, which forms a neuromuscular junction at the centre of muscle fibre (Fig. 2.2-1A). The nerve terminal or

the so-called synaptic knob contains large number of vesicles (about three lakh) containing acetylcholine. Mitochondria are also present in the nerve terminal. The acetylcholine is synthesized by the mitochondria and is stored in the vesicles (Fig. 2.2-1B). The mitochondria contain adenosine triphosphate (ATP) which is the source of energy for synthesis of acetylcholine.

Presynaptic membrane.

This refers to the axonal membrane lining the *terminal buttons* of the nerve endings.

Synaptic cleft.

It is a 50–100 nm wide space between the presynaptic membrane and the postsynaptic membrane. It is filled by extracellular fluid with reticular fibres forming the matrix.

Postsynaptic membrane (fig. 2.2-1b).

This is the name given to the muscle fibre membrane (sarcolemma) in the region of neuromuscular junction. The muscle membrane in this region is thickened and depressed to form the *synaptic trough* in which the terminal button fits. This thickened portion of the muscle membrane is also called *motor end plate*. On each end plate only one nerve fibre ends (like other synapses there is no convergence of multiple inputs). Further, the postsynaptic membrane is thrown into large number of folds called *subneural clefts* or *pallisades*. These increase the surface area. The postsynaptic membrane, near the junction folds, contains *receptor sites* for acetylcholine called the *nicotinic–acetylcholine (ACh) receptors*. The matrix of subneural cleft contains the enzyme *cholinesterase* which can degrade acetylcholine.

Neuromuscular transmission

The skeletal muscle is stimulated only through its nerve. The neuromuscular junction transmits the impulses from the nerve to muscle. The *sequence of events* which causes transmission of impulse through neuromuscular junction are:

- Release of acetylcholine by the nerve terminals
- Effect of acetylcholine on postsynaptic membrane

- Development of end plate potential
- Miniature end plate potential
- Removal of acetylcholine by cholinesterase
- Initiation of the action potential in muscle fibre.

Release of acetylcholine by the nerve terminals.

When the nerve impulse (action potential) travelling in the nerve fibre (axon) reaches the terminal buttons, the voltage-gated Ca^{2+} channels present on the presynaptic membrane open up increasing its permeability to Ca^{2+} ions. Consequently, the Ca^{2+} ions present in the ECF of synaptic cleft enter the terminal buttons.

The elevated Ca^{2+} levels in the cytosol of terminal buttons bring about a fusion of vesicles (containing acetylcholine) with the presynaptic membrane and trigger a marked increase in exocytosis of vesicles releasing acetylcholine in the synaptic cleft. Each vesicle contains about 10,000 molecules of acetylcholine, and, at a time about 125 vesicles burst by exocytosis (Fig. 2.2-2).

FIGURE 2.2-2 Detailed structure of neuromuscular junction showing Ca^{2+} channels on presynaptic membrane and ACh

receptors on postsynaptic membrane.

Effect of acetylcholine on the postsynaptic membrane.

The acetylcholine so released diffuses in the synaptic cleft and binds to the nicotinic-ACh receptors located mainly on the junctional folds of the motor end plate (postsynaptic membrane).

Each receptor is actually *an acetylcholine-gated ion channel* (Fig. 2.2-3) made of a protein complex having molecular weight of 275,000 and is composed of five subunits (two alpha and one each of beta, delta and gamma). This protein complex penetrates all the way through the membrane forming a tubular channel which is kept closed (Fig. 2.2-4A).

FIGURE 2.2-3 Structure of acetylcholine receptor from below.

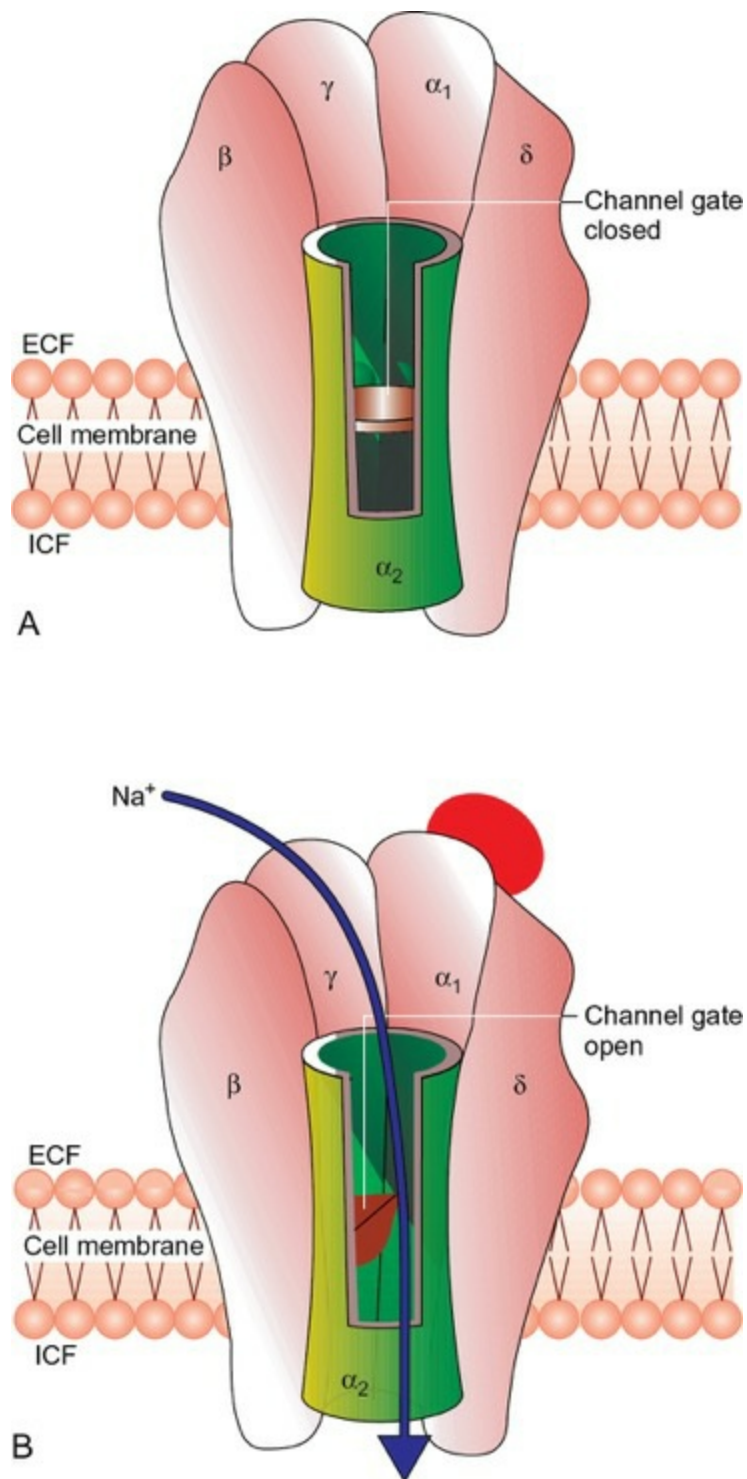

FIGURE 2.2-4 Acetylcholine-gated ion channels: **A**, closed state; and **B**, open state (conformational change occurred due to binding of two molecules of ACh to the binding sites).

When two molecules of acetylcholine get attached to the binding site of the receptors (i.e. two alpha units), there occurs a conformational change in the protein complex leading to opening up of the tubular channels (Fig. 2.2-4B). In other words, conductance to Na^+ and Ca^{2+} ions is increased at the motor end plate.

Development of end plate potential.

Due to opening of the acetylcholine-gated channels in the end plate membrane, a large number of Na^+ ions from the ECF enter inside the muscle fibre following the electrochemical gradient.

The resting membrane potential at the postsynaptic membrane is about -80 to -90 mV. When sodium ions enter inside carrying with them large numbers of positive charges, there occurs depolarization causing a local positive potential change inside the muscle fibre membrane called the *end plate potential*.

End plate potential (EPP)

is not the action potential. It is localized, nonpropagated, does not obey the all-or-none law and decays exponentially away from the plate.

The end plate potential is nonpropagative, but when a critical level of -60 mV is reached, it triggers the development of action potential in the muscle fibre (Fig. 2.2-5). The action potentials are generated on either side of the end plate and are conducted away from the end plate in both the directions along the muscle fibres thus causing muscle contraction.

FIGURE 2.2-5 End plate potential and development of action potential in muscle fibre: **A**, weak end plate potential (<60 mV); **B**, end plate potential triggers propagating action potential (>-60 mV); and **C**, miniature end plate potential.

Miniature end plate potential.

Even at rest, small quanta of acetylcholine are released randomly from the nerve terminal. Each quantum of acetylcholine produces a weak end plate potential about 0.5 mV in magnitude. This is called *miniature end plate potential*. The size of the quanta of acetylcholine released in this way varies directly with the Ca^{2+} concentration and inversely with the Mg^{2+} concentration at the end plate. The miniature end plate potential similar to that seen at the myoneural junction has been observed at other cholinergic synapses as well.

Removal of acetylcholine.

Acetylcholine released in the synaptic cleft is removed within 1 ms by two means (Fig. 2.2-6):

- Most of the acetylcholine is destroyed by the enzyme acetylcholinesterase which is present in the matrix of synaptic cleft.
- A small amount of the acetylcholine diffuses out of the synaptic space and is then no longer available to act on the muscle fibre membrane.

FIGURE 2.2-6 Removal of acetylcholine from the synaptic cleft of neuromuscular junction.

The acetylcholine is so potent that its stay in the synaptic space even for this short period of 1 ms is sufficient to excite the muscle fibre. It is important to note that the rapid removal of acetylcholine prevents the repeated excitation of muscle fibre.

Drugs affecting and disorders of neuromuscular junction

Drugs affecting neuromuscular junction

Neuromuscular blockers.

Neuromuscular blockers are the drugs that block transmission at the neuromuscular junction. Some of the common neuromuscular blockers, which are commonly used, in clinical practice and in research are:

1. Curare

or the active principle of D-tubocurarine prevents the neuromuscular transmission by combining with acetylcholine receptors. The acetylcholine released thus cannot combine with the receptors and so the end plate potential does not develop. The curariform drugs are called *receptor blockers* since they block the neuromuscular transmission by acting on acetylcholine receptors.

2. Bungarotoxin

found in the venom of deadly snakes also blocks neuromuscular transmission by binding with acetylcholine receptors.

3. Succinylcholine and carbamylcholine

act like acetylcholine and cause depolarization of the postsynaptic membrane. But these are not destroyed by cholinesterase and so the muscle remains in a depolarized state for a long time. Thus, these drugs block the myoneural junction by keeping the muscle in a depolarized state.

4. Botulinum toxin

is derived from the bacteria *Clostridium botulinum*. It blocks the transmission across the myoneural junction by preventing the release of acetylcholine from the terminal buttons of the nerve endings.

Neuromuscular stimulators

Drugs having acetylcholine-like action.

The drugs methacholine, carbachol and nicotine act like acetylcholine and produce end plate potential exciting the muscle fibre. However, these drugs are either not destroyed or are destroyed very slowly by the enzyme acetylcholinesterase. So they cause repeated stimulation and continuous action of muscle, thereby causing a state of muscle spasm.

Drugs that inactivate the enzyme cholinesterase (anticholinesterase).

The drugs like neostigmine, physostigmine and disopropylfluorophosphate (DFP) stimulate the neuromuscular junction by inactivating the enzyme acetylcholinesterase. Once this enzyme is inactivated, the acetylcholine released at the nerve terminal cannot be hydrolysed, this leads to repeated stimulation and continuous action of muscle.

The effect of neostigmine and physostigmine lasts for several hours while that of DFP lasts for several weeks. The DFP is thus a lethal poison which can cause death due to laryngeal spasm.

Disorders of neuromuscular junction

Myasthenia gravis.

Myasthenia gravis is a disorder in which the myoneural junction is unable to transmit signals from the nerve fibre to muscle fibres, thereby causing paralysis of the involved muscles. The worldwide incidence of this disease is 25–125 out of hundred million people. The disease is more common in females than in males. Myasthenia is probably an autoimmune disease. In this disease, antibodies are produced against the acetylcholine-gated channels (receptors) present on the motor end plate which destroy these channels. Thus, the acetylcholine released at the nerve terminal is not able to produce adequate end plate potential to excite the muscle fibre.

Clinical features.

The main clinical feature of the disease is muscle fatigue with sustained or repeated activity. It is usually presented in following forms:

- In one form, mainly extraocular, muscles are involved and in other form there is generalized weakness of skeletal muscles.
- In severe cases of myasthenia gravis, thymus may play a role by supplying helper T-cells sensitized against thymic protein that cross react with nicotinic–ACh-receptors and destroy them. Studies show that the number of receptors on motor end plates of affected muscle is reduced by 70–90%.

If the disease is intense enough, the patient dies of paralysis, particularly of respiratory muscles.

Treatment.

Weakness of the muscles improves after a period of rest or administration of ACh-esterase inhibitor. Thymectomy may also improve the symptoms.

Lambert–Eaton syndrome.

In this disease, antibodies are produced against the calcium channels present on the presynaptic membrane, which destroy the channels. Consequently, Ca^{2+} influx into the nerve terminal is markedly decreased and thereby release of acetylcholine is also reduced. Scanty amount of acetylcholine is not able to produce adequate end plate potential to excite muscle fibres, producing muscular weakness. A similar type of syndrome can also occur after the use of aminoglycoside antibiotics which impair the functioning of Ca^{2+} at nerve terminals.

Introduction

The muscle cell, like the neuron, is an excitable tissue, i.e. an action potential is generated when it is stimulated either chemically, electrically or mechanically. Further, the muscle is a contractile tissue with a chemically stored energy which can be transformed into mechanical energy.

There are three different types of muscles in the body: skeletal muscles, cardiac muscles and smooth muscles. Based on certain distinctive features the muscles can be grouped as:

Striated versus nonstriated muscles

Striated muscle cells show large number of cross striations at regular intervals when seen under a light microscope. Skeletal and cardiac muscles are striated.

Nonstriated muscle cells do not show any striations. Smooth muscles or the so-called plain muscles are nonstriated.

Voluntary versus involuntary muscles

Voluntary muscles can be made to contract under our will to perform the movements we desire. All skeletal muscles are voluntary muscles. These are supplied by somatic motor nerves.

Involuntary muscle's activities cannot be controlled at will. Cardiac and all smooth muscles are involuntary muscles. These are innervated by autonomic nerves.

Skeletal muscles

The skeletal muscles, as the name indicates, are attached with the bones of the body skeleton and their contraction results in the body movements. They constitute about 40% of the total body mass.

Functional anatomy and organization

Structural organization of muscle

Structurally, the skeletal muscle consists of a large number of muscle fibres and a connective tissue framework organized as (Figs. 2.3-1, 2.3-2):

- Each *muscle fibre* is surrounded by delicate connective tissue called *endomysium* which contains large quantity of elastic tissue arranged longitudinally.
- The muscle fibres are grouped into a number of bundles called *fasciculi*. Each fasciculus is surrounded by a stronger sheath of connective tissue called *perimysium*.
- All the fasciculi collectively form the *muscle belly*. The connective tissue that surrounds the entire muscle belly is called *epimysium*.
- At the junction of the muscle with its tendon, the fibres of endomysium, perimysium and epimysium become continuous with

the fibres of the tendon.

- *Tendons* are fibrous terminal ends of the muscles made up of collagen fibres.

FIGURE 2.3-1 Transverse section of skeletal muscle seen under light microscope.

FIGURE 2.3-2 Schematic diagram showing structural organization of skeletal muscle: **A**, muscle belly; **B**, muscle fibres grouped into fasciculi; **C**, muscle fibre; **D**, myofibril; and **E**, arrangement of thick and thin filaments.

Structure of a muscle fibre

Each muscle fibre is basically a long (1–4 cm), cylindrical (10–100 micron in diameter) multinucleated cell. Its cell membrane is called *sarcolemma* and the cytoplasm is called *sarcoplasm*. Like any other cell, in the

sarcoplasm are embedded many structures, the nuclei, Golgi apparatus, mitochondria, sarcoplasmic reticulum, ribosomes and glycogen and occasional lipid droplets. In addition, the sarcoplasm mainly contains number of *myofibrils* which form the main structure of a muscle fibre. The sarcolemma along with the sarcoplasmic reticulum forms the so-called *sarcotubular system* which will be described in detail later.

Myofibril

Each muscle fibre consists of a large number of myofibrils which are arranged parallel to each other and run along the entire length of the muscle fibre. Myofibril is about 1–2 μm in diameter and 1–4 cm in length depending upon the length of the muscle fibre.

Each myofibril consists of many thick and thin filaments (myofilaments) made up of a number of contractile proteins. Thick filaments are made up of myosin and are about 1500, while thin filaments are made of actin and about 3000 in number in each myofibril. The peculiar arrangement of these myofilaments when seen under a *light microscope* gives an appearance of alternate dark and light bands (striations) as described:

Striations of muscle fibres

The dark and light bands result from a difference in the refractive index of its different parts. The arrangement is as follows (Fig. 2.3-2D):

- The dark band is called *A band* (anisotropic to polarized light). It is 1.5 μm in length. In the area of A band, the thick (myosin) filaments line up the thin filaments.
- In the centre of each A band there is a lighter H-zone where thin filaments do not overlap the thick filaments (the word H either represents the discoverer, Henson or the hell which in German means light).
- In the centre of each H-zone is seen an M line, which is more pronounced during muscle contraction.
- The light band is called *I band*, because it is isotropic to polarized light. It is about 1 μm in length. This area contains only thin (actin) filaments.
- Each I band is bisected by a narrow dark *Z line* (the word Z has been

taken from Z Wischenscheibe which in German means between discs).

- The portion of myofibril between two successive Z lines is called a *sarcomere*. Thus, a sarcomere includes $\frac{1}{2}$ I band + A band + $\frac{1}{2}$ I band and is about 2.5 μm in length at rest. The sarcomere is the structural and functional unit of the muscle fibre. During muscle contraction, the sarcomere reduces in length to 1.5 μm and during stretching of the muscle it increases in length to 3.5 μm .

Thick and thin filaments

The thick and thin filaments (Fig. 2.3-2E) form the *contractile apparatus* of a striated muscle. These are made up of three types of proteins:

- *Contractile proteins* are *myosin* and *actin* which interact to generate the contractile force in a muscle.
- *Regulatory proteins*, also called relaxation proteins, include *tropomyosin* and *troponin*. These regulate the interaction between the myosin and actin.
- *Anchoring proteins*, as the name indicates, anchor the different proteins to each other as well as to the sarcolemma and the extracellular matrix. These include α -*actinin*, *titin*, *nebulin* and *dystrophin*.

The detailed structure of thick and thin filaments forming the myofibril as revealed by *electron microscopy* is described below:

Thick filament

Thick filaments are about twice the diameter of thin filaments. Each thick filament is surrounded by six thin filaments arranged in a regular hexagonal manner. A thick filament is made up of hundreds of molecules of a complex actin-binding contractile protein called *myosin*.

Structure of myosin molecule.

The myosin molecule has a molecular weight of 480,000 and is made up of six polypeptide chains, two heavy chains (each having molecular weight 200,000) and four light chains (each having molecular weight 20,000). The two heavy chains wrap around each other to form a double helix, which constitutes the *tail and body* of the myosin molecule (Fig. 2.3-3B). The light chains combine with the terminal part of the heavy chains to form the globular *head* of myosin molecule. The myosin molecule

present in the skeletal muscle has two heads and is called *myosin-II* (Fig. 2.3-3C) (single-headed myosin present in some other cells of the body is called myosin-I). These heads contain an *actin-binding site* and a *catalytic site* that hydrolyses ATP. During muscle contraction, the head forms the *cross-bridging* (described later). Digestion with trypsin generates two fragments of myosin molecules (Fig. 2.3-4):

- *Light meromyosin (LMM)* which comes from the tail part of the myosin. It does not have any ATPase activity or actin-binding ability (Fig. 2.3-4B).
- *Heavy meromyosin (HMM)* contains the globular head as well as part of the tail (Fig. 2.3-4B). HMM can be further split by papain into two parts (Fig. 2.3-4C): the *globular HMM-S1*, which has all the ATPase activity and actin-binding ability, and the fibrous, *HMM-S2*, which has none of it.

FIGURE 2.3-3 Myosin molecules: **A**, arrangement of myosin molecules in thick filament; **B**, structure of myosin molecule; and **C**, molecule of myosin II (with two heads).

FIGURE 2.3-4 Myosin molecule after digestion with trypsin and papain: **A**, before digestion with trypsin; **B**, after digestion with trypsin (form two fragments LMM and HMM); and **C**, heavy meromyosin fragment after digestion with papain.

Arrangement of myosin molecules in a thick filament

In a thick filament, half of the myosin molecules are oriented with their heads in one direction and the remaining half in the opposite direction (Fig. 2.3-3A). Because of this arrangement, the central portion of a thick filament is devoid of the head portions of the myosin molecules. This accounts for the comparatively lighter H-zone seen in the centre of dark A band. The central overlapping of the myosin molecules of each side creates a central bulge in each of thick filaments which accounts for the M line seen on light microscopy.

Thin filament

The thin filament has a head end (that extends into the A band) and a tail end that is anchored to the Z line (through a protein called α -actinin). Each thin filament is made up of contractile protein molecules (actin) and

two types of regulatory protein molecules (tropomyosin and troponin) (Fig. 2.3-5).

FIGURE 2.3-5 Structure of a thin filament.

Actin.

About 300–400 actin molecules are present in each thin filament. The actin molecules form a long double helix consisting of two chains of globular units. The globular molecules are *G-actin*, and the chain formed by them is designated as *F-actin*.

Tropomyosin.

About 40–60 tropomyosin molecules are present in each thin filament. Tropomyosin are long filaments that lie in the groove between the two chains of actin molecules. It covers the binding site of actin where the myosin head comes in contact with actin. Thus, it is a regulatory protein that prevents the interaction between actin and myosin filaments.

Troponin.

Troponin molecules are small globular units located at intervals along the tropomyosin molecule. The troponin molecule has three subunits:

- *Troponin-T* binds the other troponin components to tropomyosin.
- *Troponin-I* prevents the interaction of myosin heads with active sites on actin.
- *Troponin-C* contains binding site for Ca^{2+} that initiates muscle contraction. Each molecule of troponin-C binds to four molecules of Ca^{2+} ions.

Arrangement of anchoring proteins of contractile apparatus

The anchoring proteins of the contractile apparatus include α -actinin, titin, nebulin and dystrophin-associated glycoproteins. These are arranged as:

- **α -actinin**

cross links the actin filaments in the area of Z line (Fig. 2.3-6A).

FIGURE 2.3-6 Arrangement of anchoring proteins of the contractile apparatus: **A**, α -actinin (which cross link the thin

filament in area of Z lines) and titin (interconnects two Z lines), and **B**, dystrophin–glycoprotein (DG) complex associated with sarcoglycan (SG) complex of four glycoproteins α , β , γ and δ .

- **Titin**

earlier called as *connectin* or gap filament is a large elastic filament which interconnects the Z lines. It forms the *series elastic components* of the muscle.

- **Nebulin**

is an inextensible filament which is connected at one end to the α -actinin in the area of Z line and at another end to the tropomyosin–troponin complex of thin filaments at regular intervals.

- **Dystrophin–glycoprotein complex.**

The dystrophin–glycoprotein complex (Fig. 2.3-6B) forms the best known anchor protein complex, which provides structural support and strength to myofibril. As shown in Fig. 2.3-6B, the *dystrophin* molecule forms a rod that connects the thin actin filament to the two proteins (a and b dystroglycan) present in the sarcolemma which in turn are connected to the merosin subunit of *laminin* molecule present in the basal lamina matrix. The dystroglycans in turn associated with transmembrane glycoprotein complex made up of a, b, g and d sarcoglycans.

Important Note

The dystrophin–glycoprotein complex is of special importance because genetic defects in it are associated with many of the different forms of *muscular dystrophy*.

Sarcotubular system

The sarcolemma (cell membrane of muscle cell) along with the sarcoplasmic reticulum (the endoplasmic reticulum of muscle cell) forms a highly specialized system called sarcotubular system. This plays an important role in the internal conduction of depolarization within the muscle fibre. The sarcotubular system (which under an electron microscope appears as vesicles and tubules) is primarily formed by a transverse tubular system (T-system) and a longitudinal sarcoplasmic reticulum (Fig. 2.3-7).

FIGURE 2.3-7 Sarcotubular system showing transverse tubules and longitudinal sarcoplasmic reticulum.

Transverse tubular system (T-system)

The T-system of transverse tubules is formed by the through and through invagination of sarcolemma into the muscle fibre in the region of junction of A and I bands (Fig. 2.3-7). Since the T-tubules are formed by the invagination of sarcolemma, their lumen contains ECF which surrounds the muscle cell. These T-tubules facilitate the rapid transmission of the impulse in the form of action potential from sarcolemma to the myofibrils. The membrane of T-tubules contains voltage-gated Ca^{2+} channels called *dihydropyridine* receptors (as they get blocked by the drug dihydropyridine), through which they activate the longitudinal sarcoplasmic reticulum.

Longitudinal sarcoplasmic reticulum (L-tubules)

The longitudinal sarcoplasmic reticulum is the name given to the *sarcoplasmic* tubules of the sarcoplasmic reticulum which run along the long axis of the muscle fibre forming a closed tubular system around each myofibril. These L-tubules do not open to the exterior like T-tubules. The longitudinal sarcoplasmic tubules on either side of the T-tubule are dilated to form the so-called *terminal cisterns*. A T-tubule with the two terminal cisterns lying in close proximity (contiguity) constitutes a *triad* which is found at the junction of A and I bands. Thus, there are two triads in each sarcomere (Fig. 2.3-7).

The longitudinal tubules store a large quantity of calcium ions. When the action potential reaches the cisterns of L-tubules, these Ca^{2+} ions released are into the sarcoplasm through the calcium channels present on their membrane. The calcium channels are not voltage gated. These are called *ryanodine receptors*, as they are kept in open position by ryanodine alkaloid.

Process of muscle excitability and contractility

As we know, the muscle is an excitable tissue, i.e. when stimulated an action potential is produced (*electrical phenomenon*). The skeletal muscle responds to stimulus by contracting (*mechanical phenomenon*). The events that link the electrical phenomenon with the mechanical phenomenon is called *excitation–contraction coupling phenomenon*. These three phenomena which mark the excitability and contractility of the muscle when stimulated by the nerve innervating it are discussed.

Process of muscle excitation

It refers to electrical phenomenon and ionic fluxes in skeletal muscle fibres. As discussed in the transmission across neuromuscular junction (page 80), an end plate potential (EPP) is developed at the motor end plate by the nerve impulse travelling across the innervating axon. The end plate potential, as discussed earlier (page 81), is localized and nonpropagated. However, when EPP reaches a threshold level, it produces an *action potential* which propagates over muscle fibre surface and into the muscle fibre along the transverse tubules.

Essential features of electrical phenomena

Essential features of electrical phenomena which occur in the muscle fibre (resting membrane potential and action potential) are similar to those occurring in a nerve fibre. These have been described on page 60 (students are advised to revise them). However, there are some quantitative differences between the electrical phenomenon occurring in a skeletal muscle fibre and a nerve fibre which are summarized below:

1. Resting membrane potential

in a skeletal muscle fibre is about 290mV, while in a nerve fibre it is about -70 mV.

2. Initial excitation threshold level

for a muscle fibre is 30–40 mV, while that for a nerve fibre is about 15 mV.

3. Magnitude of action potential

produced in a muscle fibre is about 120–130 mV while that produced in the nerve fibre is about 100–105 mV.

4. Duration of spike potential

is longer in a muscle fibre (5 ms) than in a nerve fibre (0.4–2 ms).

5. Absolute refractory period

is also longer in a muscle fibre (1–3 ms) than in a nerve fibre (0.4–2 ms).

6. Maximum number of impulses

which can pass through a muscle fibre are much less (100–200/s) than the nerve fibre (1000/s).

7. The excitability

of the muscle is far less than that of the neuron, that is, *chronaxie* in a muscle fibre is longer while in a nerve fibre it is shorter.

8. Conduction velocity of action potentials

in a skeletal muscle fibre is low, 3–5 m/s. In a nerve fibre, the conduction velocity of an action potential is variable, being directly proportional to its diameter. In a myelinated nerve fibre, the conduction velocity can be as high as 120 m/s.

9. Equilibrium potential

for different ions in a skeletal muscle fibre and a nerve fibre is as shown in Table 2.3-1.

TABLE 2.3-1

Equilibrium Potential of Different Ions in Skeletal Muscle Fibre and Nerve Fibre

Ion	Equilibrium potential (mV)	
	Skeletal muscle fibre	Nerve fibre
Na ⁺	+65	+60
K ⁺	-95	-90
H ⁺	-32	-25
Cl ⁻	-90	-70
HCO ₃ ⁻	-32	-25

Process of excitation–contraction coupling

The process by which depolarization of a muscle fibre initiates contraction is called excitation–contraction coupling. The sequence of events by which an action potential in the plasma membrane of a muscle fibre leads to cross-bridge activity (excitation–contraction coupling) is as:

- Action potential initiated in the plasma membrane of a muscle fibre spreads rapidly on the surface as well as into the interior of the muscle fibre through the T-tubules.
- When the action potential reaches the tip of the T-tubule, it activates the voltage-gated channels called dihydropyridine receptors (DHP) which are located in the T-tubule membrane (Fig. 2.3-8).
- Activated DHP receptors in turn trigger the opening of Ca²⁺-release channels located on the terminal cisterns, the so-called *ryanodine receptor* (RYR). This is possible because the lateral cisterns are located very close to the tips of T-tubules and the protein channels of the cisterns (DHP and RYR) are mechanically interlocked. Thus, in short, when the DHP is activated by the depolarization of T-tubules, it undergoes conformational changes which result in the opening of RYR (being actually pulled open).
- Due to opening of calcium-release channels (RYR), calcium ions diffuse into the cytoplasm. The concentration of Ca²⁺ in the ICF is increased by some 2000 times, i.e. from 10⁻⁷ moles/L to 2 × 10⁻⁴ moles /L.

- The Ca^{2+} ions get attached to troponin-C and start a chain of events (discussed below) which produces contraction. Thus, the calcium ions act as a linking or coupling material between the excitation and the contraction of the muscle. Hence, the calcium ions are said to form the basis of excitation–contraction coupling.

FIGURE 2.3-8 Mechanism of release of calcium ions from terminal cistern of longitudinal tubules: **A**, in resting state Ca^{2+} -release channels (RyR) remain closed due to mechanical interlocking between DHP and RyR; and **B**, during activation state (depolarization of T-tubule). Conformational change in DHP results in opening of RyR and release of Ca^{2+} .

Process of muscle contraction

Molecular basis of muscle contraction

The process of muscle contraction is initiated by the calcium ions as discussed above. The molecular basis of muscle contraction describes the role of the contractile molecules myosin and actin play in the process of muscle contraction. AF Huxley and HE Huxley in 1954 put forward the *sliding theory* or *ratchet theory* to explain how the actin filaments slide over myosin filaments forming the actin–myosin complex during muscular contraction. This theory is called *walk-along theory* or the modern theory of muscular contraction. This theory explains that the sliding of filaments is brought about by a repeated cycle of formation of the *cross-bridges* between the head of myosin and actin molecules.

Steps of cross-bridge cycling

1. Initiation of cross-bridge cycling.

During the resting stage, troponin-I is lightly bound to actin and the tropomyosin molecules are located in the groove between the strands of actin filaments in such a way that they block the myosin-binding sites on actin. Thus, during resting stage, no actin–myosin cross-bridges are formed. Thus, the *troponin–tropomyosin complex*, so-called *relaxing proteins*, inhibits the interaction between actin and myosin (Fig. 2.3-9A). When activation takes place, the Ca^{2+} ions released into the cytosol from the terminal cisterns of the sarcoplasmic reticulum get attached to *troponin-C* subunit of the protein troponin. It results in a conformation change which causes the tropomyosin molecule to move laterally, uncovering the binding sites on the actin molecules for head of the myosin molecules. Seven myosin-binding sites on the actin filament are uncovered for each molecule of troponin that binds a Ca^{2+} ion. Thus, the cross-bridge cycle is switched on (initiated) by the lateral movement of tropomyosin (Fig. 2.3-9B).

FIGURE 2.3-9 Initiation of cross-bridge cycling: **A**, resting state (myosin-binding site on actin is covered by troponin–tropomyosin complex); and **B**, on activation, Ca^{2+} binds to troponin-C subunit and this results in conformational change and lateral displacement of tropomyosin (causing uncovering of binding site for myosin (head of myosin) on actin (initiation of cross-bridge cycle)).

2. Formation of actin–myosin complex (i.e. attachment of myosin head to active site of actin filament).

The head of myosin molecule binds with ATP. The ATPase activity of myosin head immediately causes breaking of ATP to ADP and Pi cleavage products which remain bound to myosin head. The head of

myosin therefore becomes energized. The activated myosin head extends perpendicularly (at 90° conformation) towards the actin filament and gets attached to the actin filament (Fig. 2.3-10) (Stages I and II). The reaction occurs as:

FIGURE 2.3-10 Stages of cross-bridge cycling (for details see text).

3. The power stroke.

Formation of the *actin–myosin-ADP Pi* complex triggers simultaneously the following two events:

- Release of the Pi and ADP from the complex, and
- A conformational change in the myosin head causing it to flex towards the arm of the cross-bridge. The flexion of the myosin head from the high-energy 90° conformation to low-energy 45° conformation generates mechanical force (the power stroke). The power stroke has either or both of the following effects:
 - *If the load on the muscle is small*, then the actin filament slides over the myosin filament, producing muscle shortening (Fig. 2.3-10) (Stage III).
 - *If the load on muscle is large*, then the actin filaments are unable to slide over the myosin filament; under such circumstances, the flexion of the myosin head will produce stretching of the elastic neck of myosin molecule.

Thus, the energy stored in head of myosin cross-bridge is utilized for the power stroke. The reaction occurs as:

A.M. ADP. Pi $\xrightarrow{\text{bridge movement}}$ A.M. + ADP + Pi myosin head still remains attached to active site of actin filament at 45° position but stops sliding.

4. Detachment of head of a cross-bridge from active site of actin filament.

The release of ADP and Pi allows a fresh ATP molecule to bind to the myosin head. The *myosin ATP complex* has a low affinity for actin, and therefore, it results in the dissociation of myosin head from the actin filament (Fig. 2.3-10) (stage IV). The reaction is as:

5. Reactivation of myosin head.

The freshly bound ATP molecule splits again, and the myosin head is reactivated for the next cycle to begin. The energized head extends perpendicularly towards the actin filament and gets attached to the new active site for repeating the cycle. This reaction occurs as:

Thus with each cross-bridge cycle, there is movement of the actin filament towards the centre of myosin to a small degree. Repeated cross-bridge cycling causes the movement of actin filaments of either side towards the centre of myosin filament of the sarcomere leading to muscle contraction (Fig. 2.3-10) (stage V).

Steps in muscle relaxation.

Within a few milliseconds of the action potential, the calcium pump transports Ca^{2+} ions present in sarcoplasm during contraction back into the longitudinal portion of the sarcoplasmic reticulum, from where the Ca^{2+} ions are discharged into the terminal cistern for storage (Fig. 2.3-11).

FIGURE 2.3-11 Transport of Ca^{2+} from sarcoplasm into longitudinal tubules by Ca^{2+} pump.

Removal of calcium from troponin restores blocking action of troponin–tropomyosin complex. Myosin cross-bridge cycle closes and muscle relaxes.

Functions of ATP in skeletal muscle contraction and relaxation

1. *Hydrolysis of ATP* by myosin energizes the cross-bridges providing the energy for force generation.
2. *Binding of ATP to myosin* causes dissociation of cross-bridges, allowing the bridges to repeat their cycle of activity.
3. *Hydrolysis of ATP by Ca^{2+} ATPase* in the sarcoplasmic reticulum provides the energy for active transport of calcium back into the cisternae, lowering cytoplasmic calcium, ending the contraction and allowing muscle fibre to relax.

Applied Aspects

Rigor mortis refers to shortening and rigidity of all the body muscles which occurs some hours after death. The rigidity occurs because of fixation of cross-bridges of myosin head to actin filaments in an abnormal and resistant manner due to loss of all the ATP (which is normally required for detachment of cross-bridges of myosin heads from the actin filaments cause relaxation). Depending upon the environmental temperature and other factors, the rigidity disappears after some hours due to destruction of the muscle proteins by enzymes released from cellular lysosomes. The appearance and disappearance of rigor mortis is used by the forensic experts in fixing the time of death.

Changes produced by sliding of thin filaments over thick filaments during muscle contraction

Fig. 2.3-12 shows the following changes produced by sliding of thin filaments over thick filaments during muscle contraction.

1. The width of A band remains constant,
2. H-zone disappears,

3. I band width decreases,
4. The Z lines move closer,
5. The sarcomere shortens and
6. The actin filaments from the opposite end of the sarcomere approach each other, and when the muscle shortening is marked, these filaments apparently overlap.

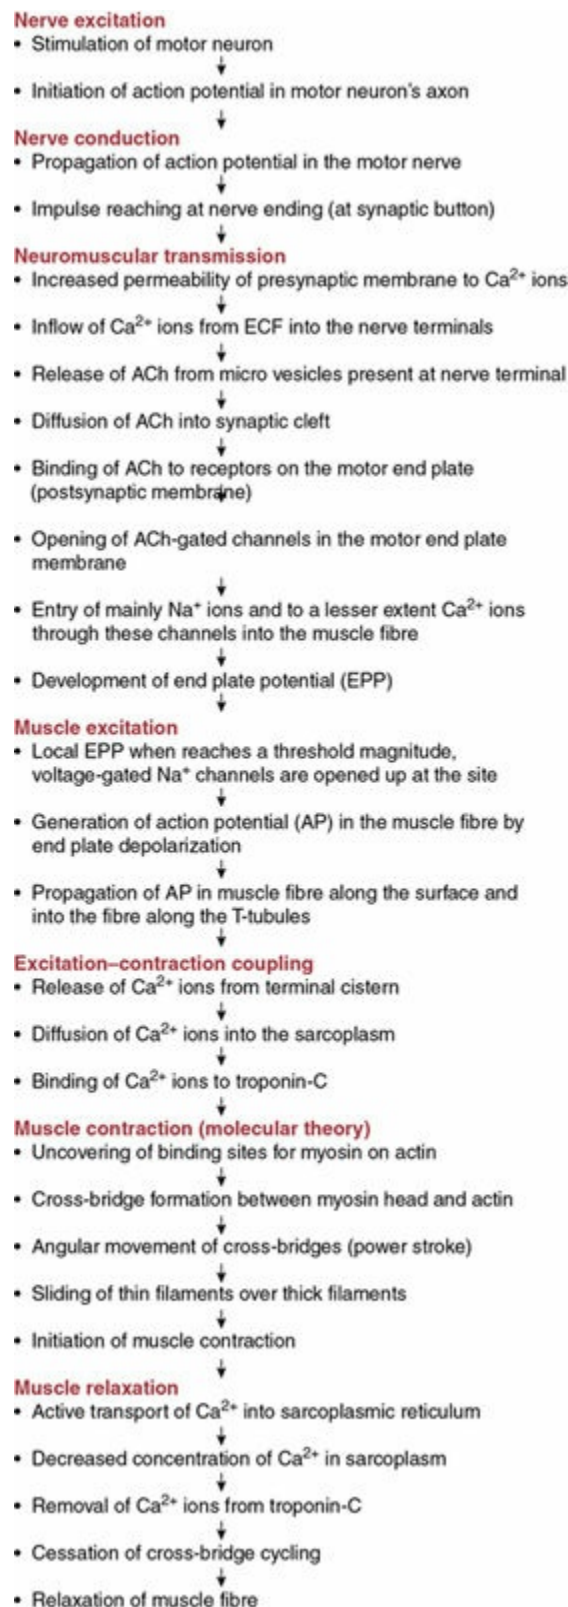

FIGURE 2.3-12 Changes produced in a sarcomere by sliding of thin filament (actin) over thick filament (myosin) during muscle contraction: **A**, relaxed state; and **B**, contracted state.

Sequence of events during muscle contraction

and relaxation when stimulated by a nerve

The events that occur during contraction and relaxation in a skeletal muscle when excited by a nerve are summarized sequence wise:

Characteristics of muscle excitability and contractility

Excitability

Excitability is the property by which tissues respond to stimuli. The skeletal muscles respond by undergoing depolarization (development of action potential).

Characteristics of electrical phenomenon in a skeletal muscle

The essential features of the resting membrane potential (RMP) and action potential (AP) of skeletal muscles are similar to those of a nerve (see page 60). The quantitative differences between the electrical phenomenon occurring in a skeletal muscle fibre and a nerve fibre are summarized on page 88.

Characteristics of skeletal muscle fibre excitability vis-à-vis characteristics of the stimulus

The skeletal muscle fibres exhibit some peculiar characteristics of the excitability depending upon the strength and duration of the stimulus used and the electrogenic state of the muscle fibre when stimulus is applied. Some of the important excitability characteristics are described:

Strength–duration curve

The essential features of strength–duration curve plotted for a skeletal muscle are similar to that plotted for a nerve (see page 64), except that the chronaxie value of skeletal muscle fibre is longer than that of nerve fibre (Figs. 2.1-13 A and B).

- Chronaxie value in frog's skeletal muscle is about 3 ms.
- Normal value of chronaxie in human skeletal muscles varies from 0.08 to 0.32 ms.
- Chronaxie is 10 times more in skeletal muscles of infants than in adults.

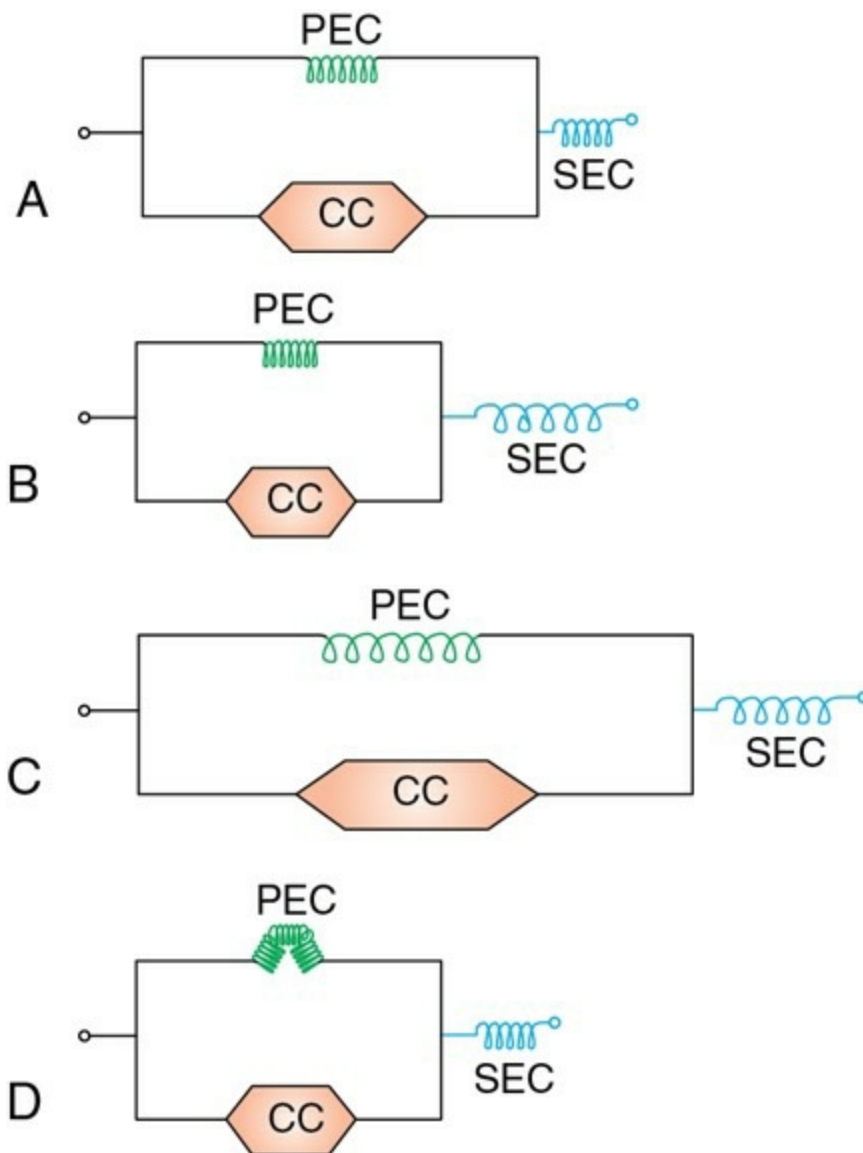

FIGURE 2.3-13 Three-component model of skeletal muscle consisting of contractile component (CC), series elastic component (SEC) and parallel elastic component (PEC): **A**, when muscle is at normal length; **B**, during isometric contraction; **C**, when muscle is passively stretched; and **D**, in isotonic contraction.

Contractility

To understand contractile response and its characteristics after discussing the process of muscle excitability and contraction, it is essential to have a knowledge about the following elementary aspects in relation to skeletal muscle:

- Contractile and elastic components of a muscle,

- Muscle length,
- Type of muscle fibres and
- Motor unit.

Contractile and elastic components of a muscle

To understand certain facts associated with muscle contraction such as shortening, contraction without shortening and effect of passive stretch, a *three-component model* has been proposed. According to this model, the skeletal muscle as a whole consists of three components (Fig. 2.3-13A):

- Contractile component,
- Series elastic component and
- Parallel elastic component.

1. Contractile component

The contractile component (CC) represents the thick (myosin) and thin (actin) filaments present in the myofibrils. It is considered to be viscous in nature, i.e. it offers no resistance to stretch and is unable to return to its original length after it has shortened. The contractile component comprises 60% (3/5th) of the total muscle proteins.

2. Series elastic component

The series elastic component (SEC) refers to that elastic tissue of the muscle which is present in series with the contractile component (CC) of the muscle. It consists of the elastic tendon of the muscle. In resting condition, the SEC offers resistance to passive stretch and explains how muscle is able to contract even when its external length does not change, i.e. isometric contraction (Fig. 2.3-13B). It also explains how the muscle regains its original length after contracting isometrically.

3. Parallel elastic component

The parallel elastic component (PEC) refers to the elastic tissue of the muscle which is attached parallel to the CC. The PEC is represented by the structural elastic tissue of the muscle such as connective tissue sheaths of the muscle, sarcolemma and gap filaments. Presence of this component explains why the muscle regains its original length after it is passively stretched (Fig. 2.3-13C and D). In an isotonic contraction, this

component gets folded up. It also offers some resistance to passive stretch.

The SEC and PEC combinedly form 40% (2/5th) of total muscle proteins.

Concepts about muscle length

The following concepts about muscle length will be useful in understanding certain characteristics about muscle contraction:

- *Optimum length* refers to that length of the muscle at which it will develop *maximum active tension*.
- *Resting length* of a muscle represents the length of the muscle during relaxed state under natural conditions in the body. The resting length of many muscles in the body is optimum length.
- *Equilibrium length* refers to the length of a relaxed muscle cut free from its bony attachments.
- *Initial length* is the length of the muscle before it contracts.

Motor unit

Motor unit is the functional unit of muscle contraction in the intact body. It consists of the single motor neuron cell body, its axon fibres, and the muscle fibres innervated by it (Fig. 2.3-14). The cell bodies of the motor neurons (α motor neuron) supplying the skeletal muscle fibres lie in the ventral horn of the spinal cord or the motor cranial nerve nuclei.

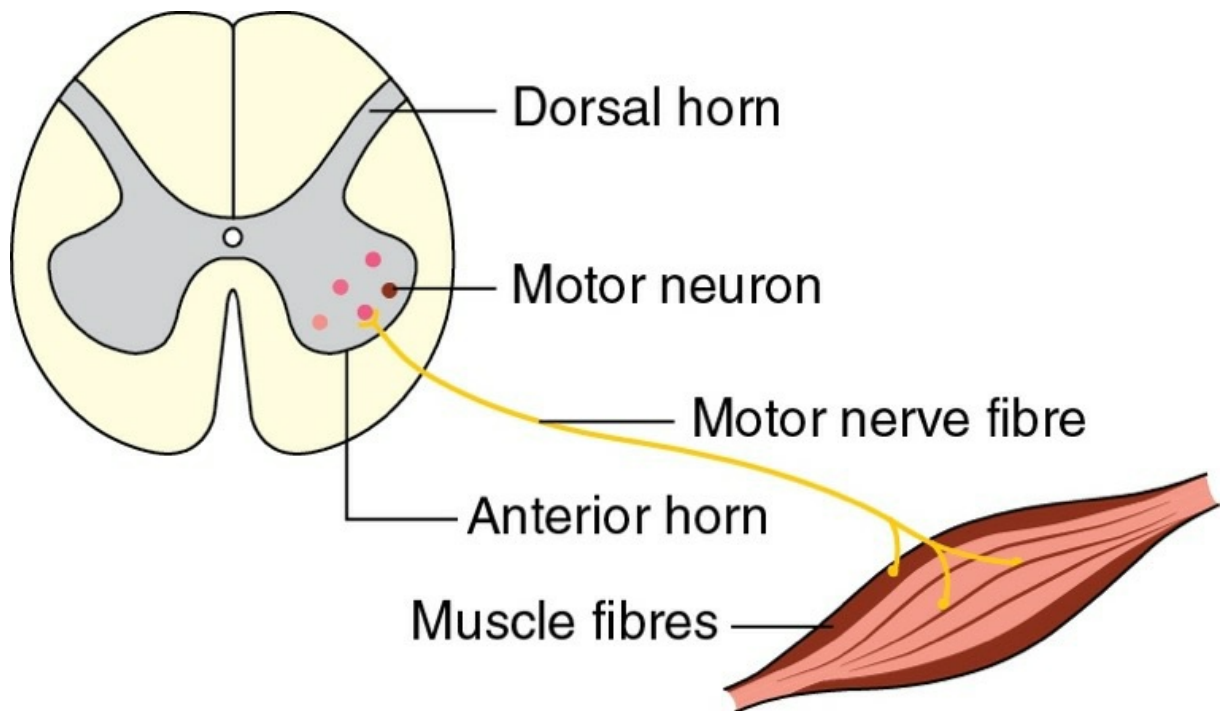

FIGURE 2.3-14 Structure of a motor unit.

Characteristic features of motor unit

Innervation ratio.

The number of muscle fibres supplied by single neuron constitutes the innervation ratio or the size of the motor unit. The innervation ratio of a motor unit varies with the precision of the movement to be produced by the muscle supplied. For example, in extraocular muscles (concerned with the eye movements) and hand muscles (for fine movements) the innervation ratio is only 3–6 muscle fibres per motor unit. Whereas in gastrocnemius muscle and in muscles of the back (concerned with posture maintenance), the innervation ratio is up to 2000 muscle fibres per motor unit.

Motor neuron pool.

All the motor neurons for a given muscle make up the motor neuron pool.

Recruitment of motor units.

The force of contraction is graded by recruitment of additional motor units (size principle). The *size principle* states that as additional motor units are recruited, more motor neurons are involved and more tension is generated.

Motor unit territory.

The motor unit territory is the term used for the area occupied by a single motor unit in a transverse section of a muscle. For example, in biceps muscle, the motor unit territory ranges from 2 to 5 mm in diameter. The muscle fibres of each motor unit are not bunched together in the muscle, but are scattered and overlap with other motor units. In other words, there is overlapping of motor units territories (Fig. 2.3-15). The intermingling of motor fibres from different motor units results in smooth muscle movements. The importance of overlapping of motor units will be discussed later in detail.

FIGURE 2.3-15 Motor unit territory of four motor units (I to IV) along with their central overlapping area seen in a schematic cross-section.

Type of motor units.

Each motor neuron innervates only one type of muscle fibre. In other words, in a single motor unit the muscle fibres supplied by it are of the same type. Therefore, depending on the type of muscle fibres, the (fast or slow type) motor units are also of two types:

- **Type I** (red or slow) motor units, and
- **Type II** (white or fast) motor units. The characteristic features of each type of motor units are given in [Table 2.3-2](#).

TABLE 2.3-2

Characteristic Features of Type I and Type II Motor Units

Characteristics	Motor unit type I	Motor unit type II
1. Muscle fibre type:	The muscle fibres of type I motor unit are: slow, red and involved in tonic activity	The muscle fibres of type II motor units are: fast, white and involved in phasic activity
2. Motor unit innervation ratio:	High (120–160 muscle fibres/axon), e.g. postural muscles	Low (<6 muscle fibres/axon), e.g. extraocular muscles
3. Metabolism	Aerobic, low glycolytic and high oxidative capacity	Anaerobic, high glycolytic and low oxidative capacity.
• Mitochondria number	High	Low
• Glycogen contents	Low	High
• Capillary density	High	Low
• Blood supply	High	Normal
• Myoglobin content	High	Low
• Enzymes:	Low	High
NADH dehydrogenase	Small	High
Phosphorylase activity	Long	Large
Myosin ATPase activity	Small	Fast
4. Axon diameter	These are adapted for tonic contraction, i.e. for posture maintenance and are first to be recruited during muscle contraction	Brief
5. Axon conduction velocity		Large
6. Twitch duration of the muscle		These are adapted for phasic contractions, e.g. fine and skilled movements, and these remain inactive during contraction and are recruited only when brief and powerful contraction is required

7. Tetanic tension 8. Type of movements		
9. Fatiguability	Fatigue resistant	Easily fatiguable
10. Further types	–	Type II motor units are further of four types: IIa, IIb, IIc and IIm. IIa: are fast, fatigue resistant and glycolytic. IIb: are fast, fatiguable and glycolytic. IIc: contain muscle fibres found in fetal stage. IIm: are superfast, having unique myosin structure and present mainly in the jaw muscles.

Contractile response

Contractile response is the characteristic feature of a skeletal muscle. When stimulated, an action potential is developed in the muscle fibres, which is followed by the muscle contraction. The muscle contraction is manifested by either shortening (*isotonic contraction*) or development of tension (*isometric contraction*) or both. The contractile response can be studied in an *isolated nerve muscle preparation*. In experimental studies, frog's gastrocnemius-sciatic nerve preparation is used to demonstrate the different characteristics of the contractile response. The contractile response of a muscle to a single stimulus through its nerve can be recorded using a suitable lever system on kymograph or physiograph.

A typical contractile response consists of a brief contraction followed by relaxation, and is referred to as *single muscle twitch*. The contractile response of a skeletal muscle can be discussed under the following headings:

- Isometric versus isotonic contraction,
- Single muscle twitch and
- Factors affecting force of contraction.

Isometric versus isotonic contraction

Isometric contraction.

As the name indicates (iso = same, metric = measure, i.e. length), in this type of contraction, the length of muscle remains same but tension is developed in the muscle. Thus, there is no movement of the object. Since work done is the product of *force* × *distance*, therefore, in isometric contraction *no external work is done*.

How the muscle length remains same in isometric contraction is depicted in

Fig. 2.3-13B. As shown in this figure, the shortening produced by *contractile component (CC)* of the muscle is compensated by the stretching of the *series elastic component (SEC)*.

Examples of isometric contraction of muscles

- Contraction of muscles which help in maintaining posture against gravity, and
- Contraction of arm muscles when trying to push a wall.

Isotonic contraction.

As the name indicates (*iso* = same, and *tonic* = tone or tension), in this type of contraction, the tension in the muscle remains same whereas its length decreases. Since the muscle length is shortened, so the *external work is done* in isotonic contraction. As shown in **Fig. 2.3-13D**, in isotonic contraction, the *contractile component (CC)* and *parallel elastic component (PEC)* are shortened, but the *series elastic component (SEC)* does not stretch further, producing a visible shortening of the muscle.

Examples of isotonic muscle contraction

- Contraction of leg muscles during walking and running,
- Contractions of muscles while lifting a weight and
- Contraction of muscles during flexion of arm.

Single muscle twitch

As mentioned earlier, the single muscle twitch or also known as the simple muscle twitch refers to the typical contractile response of a skeletal muscle to the single stimulus.

Recording of single muscle twitch.

For experimental demonstration, the single muscle twitch is recorded using frog's *gastrocnemius-sciatic nerve preparation*. Ideally, the single muscle twitch should be recorded in isotonic conditions. Technically speaking, to get a perfect isotonic contraction is impossible, but practically near isotonic contraction can be recorded by using a very light isotonic lever. **Fig. 2.3-16** shows the arrangement for recording the isotonic contraction. In this, one end of the muscle is tied and the other

end is kept free to allow shortening and is connected to the isotonic lever which is moved easily by the muscle.

FIGURE 2.3-16 Arrangement for recording isotonic contraction.

Phases of single muscle twitch.

A single muscle twitch recorded under isotonic conditions from a frog's gastrocnemius-sciatic preparation. It shows (Fig. 2.3-17):

- *Point of stimulation (PS)* denotes the time when the stimulus is applied,
- *Point of contraction (PC)* refers to the starting point of muscle contraction,
- *Point of maximum contraction (PMC)* denotes the highest point of muscle contraction and
- *Point of maximum relaxation (PMR)* refers to the point where relaxation is completed.

FIGURE 2.3-17 Typical single muscle curve recorded from frog's gastrocnemius-sciatic nerve preparation. PS: point of stimulation, PC: point of contraction, PMC: point of maximum contraction, PMR: point of maximum relaxation, CP: contraction period and RP: relaxation period.

The total duration of the muscle twitch is 0.1 s and it shows three phases: latent period, contraction phase and relaxation phase.

1. Latent period (LP).

As shown in Fig. 2.3-17, the contraction occurs after a brief gap of stimulation. This time interval of 0.01 s between the point of stimulation (PS) and the point of start of contraction (PC) is called the latent period.

The latent period includes:

- Time taken by the impulse to travel from point of stimulation on the nerve to the neuromuscular junction,
- Time taken by the impulse for neuromuscular transmission,
- Time taken by excitation–contraction coupling phenomenon,
- Time taken by chemical events to cause muscle contraction (sliding phenomenon),
- Time taken for development of tension in the muscle and
- Time taken by inertia of recording lever.

Factors affecting latent period

- Latent period is longer when the distance between the point of stimulation on nerve and the neuromuscular junction is more and vice

versa.

- Latent period is more if the load on muscle is heavier.
- It decreases with increase in temperature and vice versa.

2. Contraction phase (CP).

Contraction phase of about 0.04 s extends from the point of start of contraction (PC) to the point of maximum contraction (PMC) and is recorded as upward movement of the lever. During this phase, the muscle shortens by about 20% of its resting length. The magnitude of contraction is affected by many factors (see factors affecting force of contraction at page 97).

3. Relaxation phase.

The contraction phase is followed by the relaxation phase of about 0.05 s during which the muscle is stretched back to its original length by the dead-weight suspended from the recording lever. It is recorded as downward movement of the recording lever system. The relaxation period is prolonged when the dead-weight is lighter. In general, the relaxation phase is longer than the contraction phase.

Duration of twitch. The total duration of twitch (*contraction time*) varies with the *type of muscle fibres*:

- *Fast (white) muscle fibres* (e.g. extraocular muscles and muscle of hands for fine movements) have shorter contraction time (about 0.025 s).
- *Slow (red) muscle fibres* (e.g. back muscles) have longer contraction time (0.1 s).

The total duration of twitch also varies from species to species. In human skeletal muscle, the duration of twitch is 30–50 ms in comparison to 100 ms in frog's (amphibian's) muscle.

Relation between electrical and mechanical events of single muscle twitch.

Fig. 2.3-18 shows the electrical events (action potential) and mechanical response (simple muscle twitch curve) plotted on the same time scale after being recorded separately. From this relationship graph, it can be concluded that:

- The twitch starts about 2 ms after the start of depolarization of the membrane but always before the repolarization is completed, and that
- The refractory period (absolute refractory period) is very short and lies in the first half of the latent period of the single muscle twitch.

FIGURE 2.3-18 Electrical (A) and mechanical (B) responses of mammalian skeletal muscle fibre to a single maximum stimulus plotted on same time scale.

Factors affecting contractile response

The factors that can affect the contractile response (force of contraction) of a skeletal muscle are:

- Strength of stimulus,
- Frequency of stimulus,

- Load on the muscle (preload and after-load),
- Initial length of muscle and
- Temperature.

Strength of stimulus.

A single muscle fibre

obeys the all or none law, i.e.

- A subthreshold stimulus evokes no response, and
- With threshold, maximal and supramaximal stimuli the contractile response remains constant.

The whole muscle,

however, when stimulated with different intensity stimuli the response obtained (force of contraction) is a graded one. This fact can be well demonstrated in an isolated nerve muscle preparation.

In the isolated nerve-muscle preparation.

The graded response is obtained when stimuli of different intensities were applied through the nerve in a nerve-muscle preparation (Fig. 2.3-19). The whole muscle responds to the stimuli as:

- *Subthreshold stimuli* do not evoke any response.
- *Threshold stimulus*, i.e. a stimulus just sufficient to elicit response and produces minimal contraction.
- *Suprathreshold stimuli* produce a graded response (i.e. the force of contraction goes on increasing with the increase in strength of stimulus till a maximum limit is reached). This is because, as the strength of stimuli is increased, more and more muscle fibres are recruited into activity. This phenomenon is called *quantal* or *multi fibre summation*. The graded response achieved by suprathreshold stimuli is called *submaximal response*.
- *Maximal stimulus* is that stimulus which produces the maximal response (i.e. the maximal stimulus excites all the motor units).

- *Supramaximal stimulus* refers to the stimulus which exceeds the maximal value. Supramaximal stimuli do not increase the response beyond the maximal response. This is because, at the maximal stimulus, all the motor units are already contracting to their maximum extent and thus any further increase in the strength of stimuli (supramaximal stimulus) has no effect in increasing the force of contraction.

FIGURE 2.3-19 Effect of strength (intensity) of stimulus on an isolated nerve muscle preparation of frog.

In the intact body.

In the intact body, the whole muscle gets stimulus from the activity of anterior horn cells through their axons to the muscle fibres supplied by that particular neuron, i.e. by *recruitment of motor units*. With minimum activity, only a few motor units are recruited for activity. With increasing activity, more and more motor units (from the motor neuron pool of a muscle) are recruited into activity. This phenomenon is called *multiple motor unit summation*.

Thus, in an intact body, the relationship between the number of motor units recruited and the mechanical response achieved in terms of type of stimulus can be interpreted as below:

- *At subthreshold stimulus*, no motor units are recruited and hence no response is achieved.
- *At threshold stimulus*, the minimum number of motor units (say 1 or 2) are recruited which are just sufficient to excite minimal response.
- *At suprathreshold stimuli*, more and more motor units are recruited producing progressively increasing response.
- *At maximal stimulus*, all the motor units are recruited producing the maximal response.
- *At supramaximal stimuli*, no further motor units are left to be recruited, and hence the response achieved is not more than the maximal response.

Frequency of stimulus

The effect of repeated stimuli on the contractile response of a skeletal muscle depends upon the number of stimuli (frequency). The effect of number of stimuli can be better understood by keeping the strength of stimuli constant and varying the time interval between the successive stimuli.

Effect of two successive stimuli.

Depending upon the length of interval between the two successive stimuli, following types of effects are observed:

- No response,
- Summation,
- Superposition and
- Beneficial effect.

i. No response.

When the second stimulus is applied during first half of the latent period,

no response is obtained to the second stimulus as this period corresponds with the absolute refractory period (ARP) of the muscle. The muscle responds only to the first stimulus and the curve obtained is similar to a simple muscle twitch (Fig. 2.3-20A).

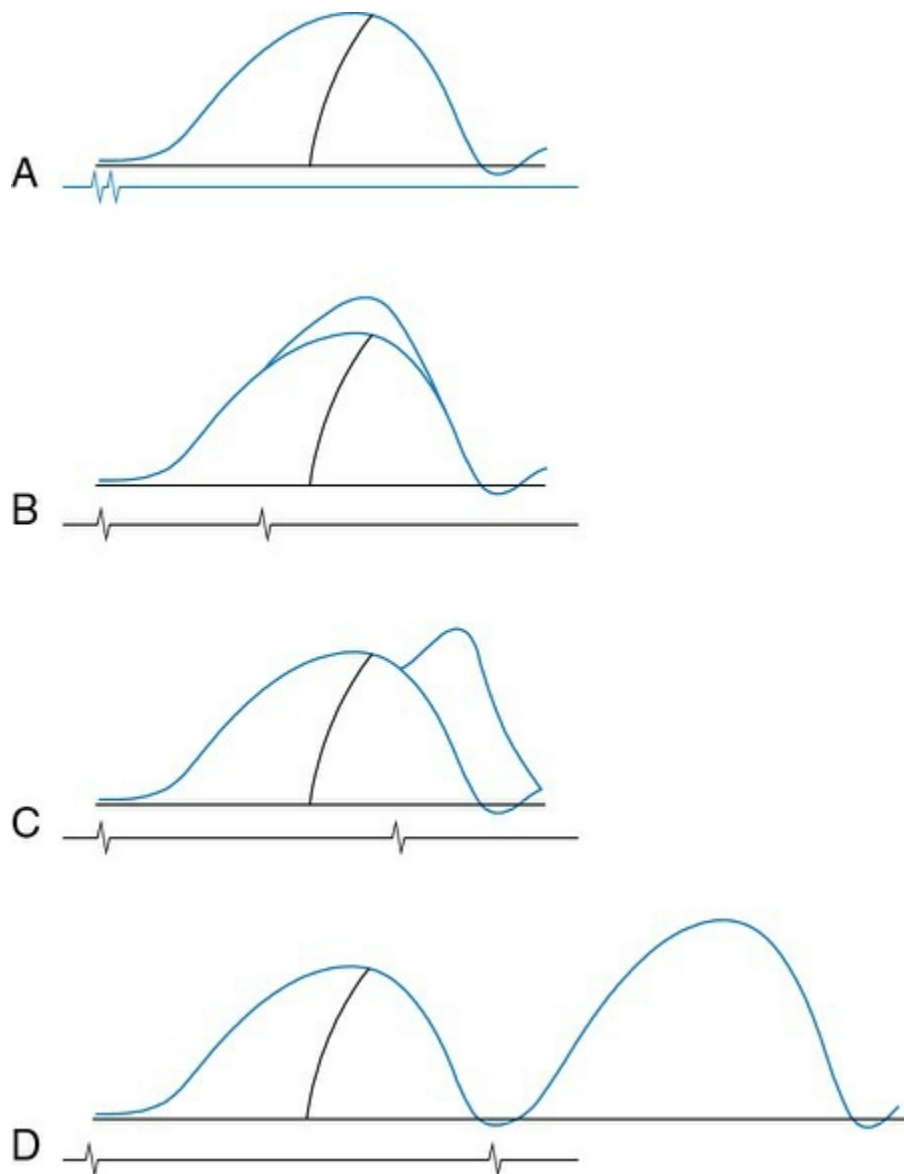

FIGURE 2.3-20 Effect of two successive stimuli in an isolated gastrocnemius-sciatic nerve preparation: **A**, no response (when second stimulus applied in absolute refractory period of the first response); **B**, summation effect; **C**, superposition (incomplete summation); and **D**, beneficial effect.

ii. Summation.

When the second stimulus is applied from second half of the latent period to the contraction phase, the effect of two stimuli is summed up

and a single curve is achieved. This phenomenon is called *complete summation*. The graph obtained shows an increase in the force of contraction—an effect called *summation of contractions* or *wave summation*. This is due to the *beneficial effect* which will be discussed later. Thus, the summation curve (Fig. 2.3-20B) so obtained is different from the simple muscle curve by having:

- A greater amplitude, and
- A broader base.

iii. Superposition.

When the second stimulus is applied during relaxation phase of the curve due to first stimulus, the relaxation phase is cut short and another contraction occurs. The second curve is superimposed over the first curve (Fig. 2.3-20C). This is called phenomenon of *superposition* or *incomplete summation* of waves. The amplitude of the second curve is more than that of the first curve. This is also due to the beneficial effect, which is explained below.

iv. Two separate curves with beneficial effect.

When the second stimulus is applied soon after the relaxation phase of the curve due to first stimulus, another complete curve is obtained. However, the force of second contraction is greater than that of the first contraction (Fig. 2.3-20D). The increase in the force of contraction of second curve is due to the beneficial effect.

Beneficial effect and its causes.

As discussed above, when second stimulus is applied at any stage after the first half of the latent period (i.e. at any time after the absolute refractory period), the force of second contraction is more than that of the first one. In other words, the contraction produced by first stimulus proves beneficial for the second one. This is called *beneficial effect*.

Causes.

of beneficial effect are:

- Some of the *calcium ions* released from the terminal cisterns into the sarcoplasm during first contraction are also available in addition to those released by the second stimulus when the two stimuli are applied successively. These additional Ca^{2+} ions increase the duration

of active state of second stimulus. The prolonged active state in turn increases the amount of stretch on the series elastic component of the muscle and so more force is transmitted to the recording lever (or to the bones in the intact body), thus increasing the height of the curve.

- *Viscosity of the muscle* and thus the elastic inertia of the muscle is decreased to some extent by the first contraction, which contributes to the beneficial effect for the second contraction.
- *Increase in H^+ ion concentration* due to the first contraction also adds to the beneficial effect for the second contraction.
- *Increase in the temperature* due to first contraction decreases the viscosity of the muscle and thus contributes to the beneficial effect.

Effect of multiple stimuli.

The effect of multiple successive stimuli on the contractile response of a skeletal muscle depends upon the total duration of twitch and the frequency of stimuli. The basic principle that governs the effect of multiple stimuli is the same that explains the effect of two successive stimuli. That is the response obtained will depend upon whether the next stimulus falls:

- After the first twitch, or
- On relaxation phase of first twitch or
- On contraction phase or to second half of latent period of first twitch.

Based on the above facts, following types of responses are observed due to multiple stimuli:

- Discrete responses,
- Incomplete tetanus and
- Complete tetanus.

i. Discrete responses.

If the frequency of stimulation is such that the next successive stimulus falls after completion of relaxation phase of the previous twitch, then the succeeding contractions obtained, with brief intervals between them, are

complete individual twitches (with contraction and relaxation phases). Such a response is called a *discrete response*. Further, each successive twitch has increased force of contraction (due to beneficial effect of previous twitch) till a maximal beneficial effect is achieved (Fig. 2.3-21A). This phenomenon is called the *staircase effect* or *treppe* (a German word for staircase).

FIGURE 2.3-21 Effect of multiple stimuli in an isolated gastrocnemius-sciatic nerve preparation: **A**, discrete

responses; **B**, incomplete tetanus (clonus); and **C**, complete tetanus (sustained contraction).

Thus, if the total duration of a twitch is 100 ms, then frequencies less than 10/s (i.e. each stimulus coming after every 100 ms) will produce discrete responses with a staircase effect.

ii. Incomplete tetanus or clonus.

When the frequency of multiple stimuli is such that the next successive stimulus falls on the relaxation phase of the previous twitch, then the succeeding contraction obtained will be superposed over the previous twitch due to incomplete summation of waves. The record so obtained shows a progressive increase in amplitude up to a certain level beyond which there is no further increase. This phenomenon, as already mentioned, is called *staircase effect* or *treppe*. On stoppage of stimulation, the lever returns to normal (Fig. 2.3-21B). The series of jerky contractions of the muscle, with period of incomplete relaxation in between, so obtained is referred to as state of *subtetanus* or *incomplete tetanus* or *clonus*.

Thus, when the total duration of a twitch is 100 ms, then frequencies between 10 and 20/s (i.e. each stimulus coming after every 50 ms but before 100 ms) will fall on the relaxation phase of previous twitch and produce incomplete tetanus.

iii. Complete tetanus.

When the frequency of multiple stimuli is such that the next successive stimulus falls in the second half of latent period to the contraction phase of the previous twitch (i.e. before relaxation begins), then due to complete summation effect, the muscle will remain in a state of sustained, smooth and forceful contraction called *tetanus* or tetanic contraction (Fig. 2.3-21C). The graph shows an increasing slope of the uninterrupted tracing, which exceeds the peaks of single twitches. When the stimulation is stopped, the muscle relaxes immediately. However, if the stimulation is continued further, a plateau is maintained until the muscle begins to fatigue, after which it relaxes gradually. During complete tetanus, the tension developed in the muscle is four times greater than that developed during the individual muscle twitch.

Thus, when the total duration of twitch is 100 ms, then frequencies more than 20/s (i.e. each stimulus coming before 50 ms) will fall on the contraction phase of previous twitch and produce complete tetanus. The rate of stimulation at which there is complete fusion of individual

contraction to produce tetanus is called the *tetanizing* or *fusion* frequency.

Ionic Basis of Tetanus. The Ca^{2+} ions released in sarcoplasm during single twitch are removed quickly and relaxation occurs. When the muscle is stimulated in rapid succession, there occurs a progressive accumulation of Ca^{2+} ions in the sarcoplasm. The longer stay of Ca^{2+} ions in the sarcoplasm increases the duration of active state (due to continuous recycling of myosin heads). This increases the amount of stretch on the series elastic component (SEC) and the tension developed rises to tetanic levels.

Effect of load

Load is the force exerted by the weight of an object on the muscle. The force exerted by the contracting muscle on the object is known as *muscle tension*. Thus, muscle load and muscle tension are two opposing forces. The load acting on the muscle is of two types: free-load (or preload) and after-load.

Effect of free-load.

A load that starts acting on a muscle before it starts to contract is called free-load (or preload). Example of a free-load on the muscles in an intact body is filling water from a tap by holding a bucket in the hand. The free-load increases the force of contraction and work efficiency of the muscle. The free-load stretches the muscle passively producing a *passive tension* across the muscle. This passive tension increases the force of muscle contraction in two ways:

- By increasing the initial length of the muscle to its resting length at which maximum force is generated, and
- By adding an elastic recoil force to the muscle during its contraction.

Effect of initial length on force of contraction.

According to Starling's law, the force of contraction is a function of the initial length of muscle fibres. Therefore, up to physiological limits, the greater the initial length, greater is the force of contraction.

Length–tension relationship.

When a muscle is removed from the body, it shortens because muscles in the body are in a state of slight stretch. The length of the muscle when it is detached from its bony attachments is called *equilibrium length*.

The *length–tension relationship graph* can be plotted by measuring isometric tension at different muscle lengths in an isolated muscle preparation. For this, the isolated muscle is attached to an *isometric lever*, which does not allow the shortening of muscle to occur. The tension developed is recorded through the force transducer (Fig. 2.3-22). The length of the muscle is varied by changing the distance between its two attachments and the recording is made as:

- First, at each length, the *passive tension* is measured. The passive tension is due to stretching of parallel and series elastic components of the muscle (PEC and SEC).
- The muscle is then electrically stimulated at each length and the tension developed is recorded. The *total tension* so recorded includes both the passive tension and the active tension developed due to contraction of the contractile component (CC) of the muscle.
- The *active tension* is thus denoted by the difference between the total tension and passive tension at any length.

FIGURE 2.3-22 Arrangement for recording isometric contraction in an isolated nerve-muscle preparation.

Length–tension relationship graph is then plotted with increase in muscle length (in cm) along horizontal axis and tension (in kg) along the vertical axis (Fig. 2.3-23). The following inferences can be drawn from this graph:

- *Passive tension* due to elastic components (PEC and SEC) of the muscle increases with the passively increased muscle length.
- *Active tension* developed is maximum at the *optimum length* of the muscle (position B in Fig. 2.3-23) which is equivalent to the *resting length* in intact body.
- *Total tension* is contributed by active tension and passive tension at different muscle lengths as below:
- At muscle length less than optimal level, the total tension is mainly due to active tension (position A in Fig. 2.3-23). Because at such a lower initial length there

is no stretch on the muscle and so passive tension fails to develop.

- At a muscle length twice the optimal length, the total tension is mainly due to passive tension (position D in Fig. 2.3-23). Because at this muscle length the contractile tissue cannot contract and so the active tension is at zero level.
- At a muscle length one and a half times the optimal length, the total tension is equally contributed by the active and passive tension (position C in Fig. 2.3-23).

FIGURE 2.3-23 Length–tension relationship graph.

Molecular basis of length–tension relationship.

During isometric contraction, the tension developed in the muscle is proportional to the cross-bridges formed between actin and myosin filaments. The effect of muscle length on the tension produced during

contraction can be explained by the sliding filament theory of muscle contraction as:

- *At optimum length* (position B in Fig. 2.3-24), there is optimum overlapping between the actin and myosin filaments, so maximum cross-bridges are formed between them.
- *At muscle length shorter than optimum length* (at position A in Fig. 2.3-24), the thin filaments overlap each other and thus reduce the cross-bridges between actin and myosin filaments and so the active tension produced is less.
- *When the muscle is overstretched* (position C in Fig. 2.3-24), the Z lines are pulled apart and the overlapping between the actin and myosin filaments is markedly reduced and so no active tension is developed at this level.

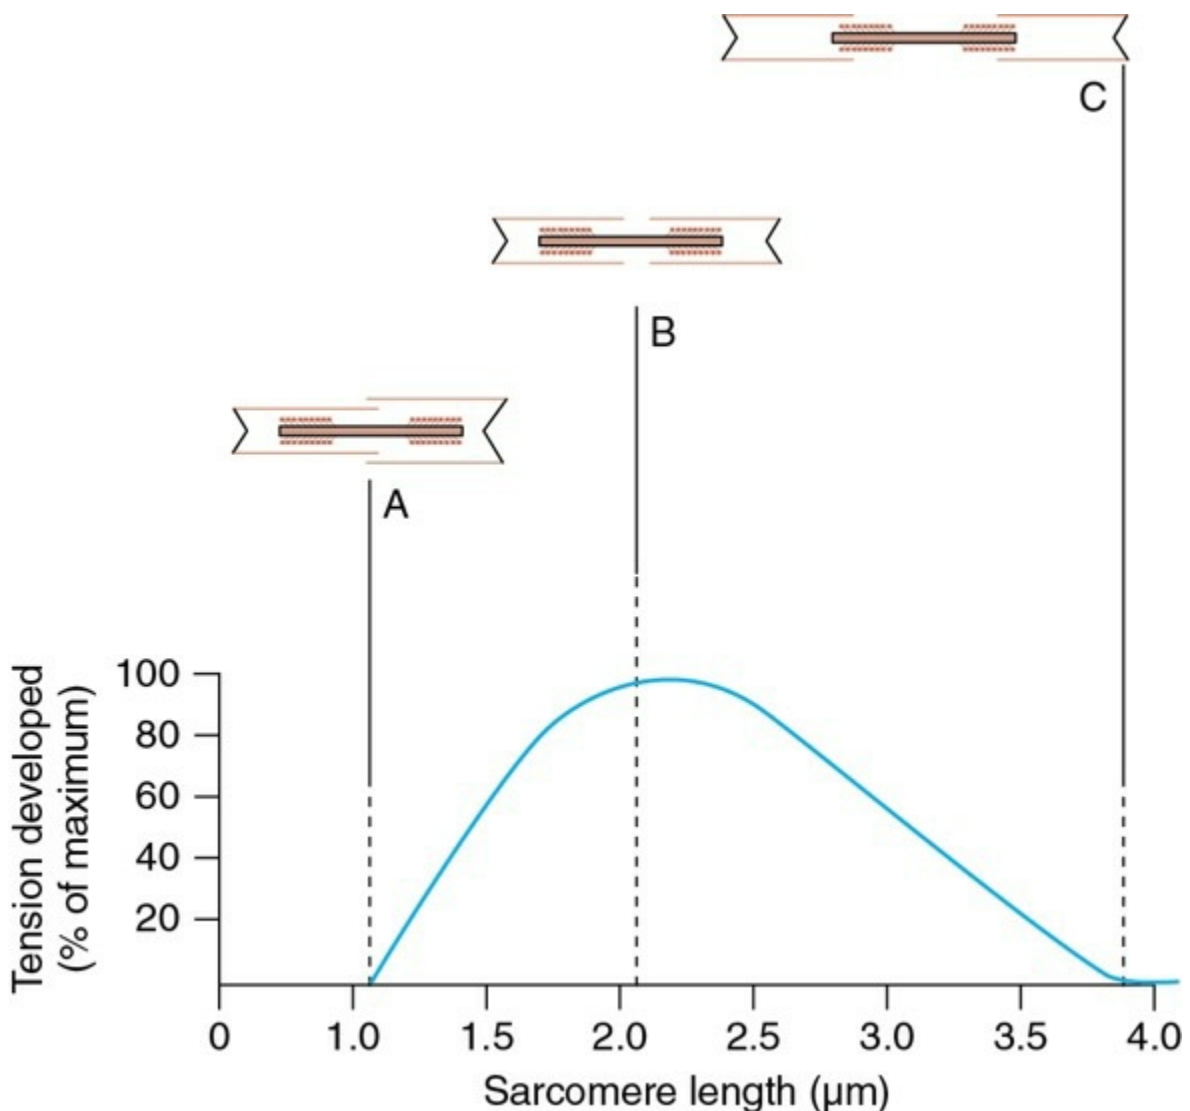

FIGURE 2.3-24 Molecular basis of length–tension relationship.

Effect of after-load.

After-load refers to the load which acts on the muscle after the beginning of muscular contraction. Thus, the after-load opposes the force produced by muscle contraction. The work done in an after-loaded muscle is less than that of a free-loaded muscle. An example of after-load in an intact body is lifting any object from the ground. The load acts on the muscles of arm only after lifting the object off the ground, i.e. only after beginning of the muscular contraction.

Phases of muscle contraction with after-load.

Experimentally, the effect of after-load can be studied by subjecting the muscle to *after-load preparation*; when a muscle contracts against a load it shows three phases:

- i. *Initial isometric contraction phase*. In this phase of muscular contraction, as the name indicates, there occurs no shortening of the muscle. The contraction of contractile components (CC) stretches the series elastic component (SEC) and there occurs a rise in the tension (Fig. 2.3-25B). The rise in tension continues till it equals the load. This is the end point of isometric phase.
- ii. *Intermediate isotonic contraction phase* starts when the muscle tension exceeds the load and load starts moving. There occurs shortening of the muscle without further stretching of SEC (Fig. 2.3-25C).
- iii. *Terminal isometric phase*. After the muscle becomes shorter than the resting length, any further shortening is associated with a decrease in the tension. And, when the tension generated equals the load, the muscle once again starts contracting isometrically.

FIGURE 2.3-25 Phases of muscle contraction in after-loaded condition: **A**, resting state; **B**, initial isometric contraction; and **C**, intermediate isotonic contraction which gradually slows down and tension decreases and becomes equal to load and no further shortening (terminal isometric phase).

Effect of increasing load in after-loaded condition.

Fig. 2.3-26 is the graph depicting effect of progressively increasing weight in after-loaded muscle preparation. It shows that:

- As the load increases, the latent period increases due to lever inertia.
- The amplitude of contraction decreases progressively as the muscle has to lift greater load.
- Contraction period decreases due to decrease in the duration of active state.
- Relaxation period also decreases, since the load hastens the return of the lever to the baseline.

- a 10 gram weight
- b 20 gram weight
- c 30 gram weight

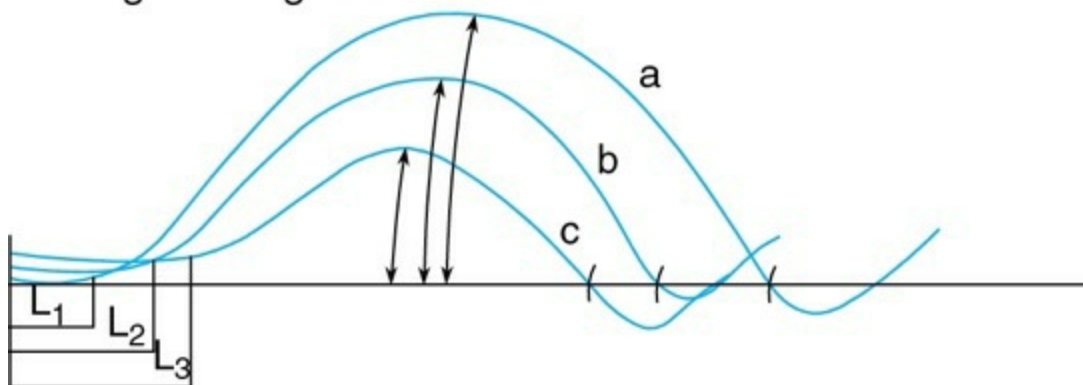

FIGURE 2.3-26 Effect of increasing load in after-loaded condition in an isolated muscle-nerve preparation.

Comparison of the muscle curves

recorded in an isolated nerve-muscle preparation in preloaded and after-loaded conditions (Fig. 2.3-27) depict the following differences:

- *Latent period* is less in preloaded as compared to after-loaded condition.
- *Height of contraction* is more in preloaded as compared with after-loaded curve.
- *Duration of twitch* is less in preloaded and more in after-loaded condition.

FIGURE 2.3-27 Comparison of muscle curves recorded

during preloaded and after-loaded conditions using 10 g weight.

Force–velocity relationship.

The force–velocity curve (Fig. 2.3-28) is plotted by noting the velocity of shortening of muscle with progressively increasing load on the muscle. Following inferences can be drawn from the force–velocity curve:

- When load is zero, the muscle contracts rapidly and the velocity of muscle shortening is maximum (V_{\max}).
- As the load increases, the velocity of shortening decreases. With further increase in the load, a stage comes when the muscle is unable to lift the load. At this point, the muscle contracts isometrically.
- Between the two extremes of zero load and immovable load, all contractions have variable durations of isometric and isotonic contractions.
- In the force–velocity curve, mt is the point of maximum efficiency of the muscle. It lies about 1/3rd of the abscissa and 1/3rd from the ordinate.

FIGURE 2.3-28 Force–velocity curve plotted by recording velocity of shortening of skeletal muscle with progressively increasing load.

Calculation of work done by muscle

The work done by the muscle is calculated in both the free-loaded and after-loaded contractions, utilizing the following data (Fig. 2.3-29A):

- Height of the muscle contraction curve for each weight (H),
- Length of long arm of the lever between fulcrum and the writing point (L),
- Length of short arm of the lever between fulcrum and point where weight is added (l) and
- Actual height up to which the weight is lifted (h).

FIGURE 2.3-29 Work done by the muscle: **A**, calculation of work done by finding actual height of contraction; and **B**, graphical representation of work done by the muscle in preloaded and after-loaded conditions.

Calculations

- Actual height (h) is calculated taking into consideration the magnification factor (which is equal to L/l):

$$\frac{h}{H} = \frac{l}{L}, h = H \times \frac{l}{L}$$

Work done is then calculated as:

Work done $W = w$ (weight in g) $\times h$ (actual height in cm)

$$W \text{ (gm/cm)} = w \times \frac{l}{L} \times H$$

- To express the work done in ergs, the above reading is multiplied by 981.
- A graph is then plotted, indicating the weight on the abscissa and the work done on the ordinate (Fig. 2.3-29B).

Effect of temperature

The contractile response is altered due to the effect of temperature. The effect of temperature can be studied by changing the temperature of the Ringer's solution in which muscle-nerve preparation is immersed. The effect of temperature noted on the amplitude of contraction, and its various periods is given below:

At room temperature,

a normal simple muscle is recorded as shown in Fig. 2.3-30A.

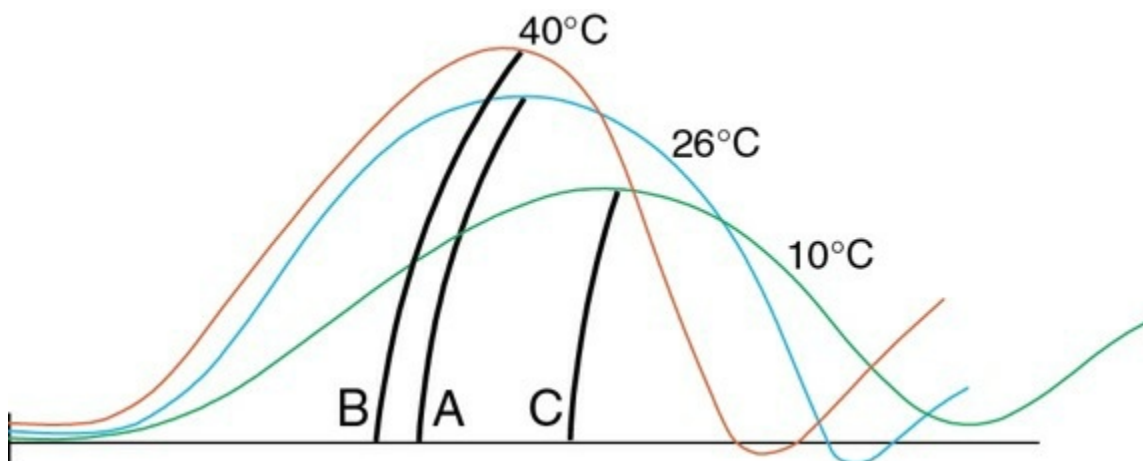

FIGURE 2.3-30 Effect of temperature in an isolated nerve-muscle preparation: A, at room temperature (26°C); B, at moderately high temperature (40°C); and C, at cold

temperature (10°C).

At moderately high temperature

(say 40°C), there occurs:

- Faster diffusion of Ca^{2+} ions from sarcoplasmic reticulum to sarcoplasm leading to:
- An increase in the muscle excitability,
- Acceleration of the chemical processes involved in muscle contraction and
- A decrease in muscle viscosity.

Because of the above effects of temperature, the following changes are noted in an isotonic muscle twitch (Fig. 2.3-30B):

- Total duration of the twitch is decreased with shortening of all the periods,
- Speed of contraction increases, as is evident from the steep slope of contraction phase,
- Relaxation is also faster and
- An increase in amplitude of muscle curve occurs due to increase in isotonic shortening of muscle. This occurs due to decrease in the internal viscoelastic resistance.

At low temperature

(say 5–10°C), the reverse changes occur, i.e.

- A decrease in the muscle excitability,
- Slowing down of chemical processes involved in muscle contraction and
- An increase in the muscle viscosity. Because of the above effects of cold, there occurs (Fig. 2.3-30C):

- A decrease in the force of contraction, and
- Prolongation of all the periods.

However, the effects of cold are reversible. So, if the muscle is gradually rewarmed, excitability is regained.

At high temperature

(above 50–60°C), there occurs coagulation of the muscle proteins leading to stiffness and shortening of the muscle fibres. This condition is called *heat rigor*. It is an irreversible phenomenon.

Other types of rigors.

Some other types of rigors (other than the heat rigor) are also described here because of the similar changes:

- *Cold rigor*. It occurs following exposure to severe cold. It is a reversible phenomenon.
- *Calcium rigor*. It occurs due to increased calcium content. It is also a reversible phenomenon.
- *Rigor mortis* (see page 91).

Some characteristics of the skeletal muscles in the intact body

- Muscle tone
- Nature of muscle contraction in the intact body
- Gradation of muscular activity
- Muscle fatigue
- Mechanics of muscles

Muscle tone

Muscle tone is the state of slight contraction with certain degree of vigour and tension. All the skeletal muscles exhibit muscle tone. However, it is more marked in the antigravity muscles, viz. extensors of the lower limbs, trunk muscles and muscles of the neck.

Maintenance of muscle tone.

Muscle tone is a state of partial tetanus of the muscle maintained by asynchronous discharge of impulses from gamma motor neurons in the anterior grey horn of the spinal cord concerned with the motor nerve supply of the muscles. The gamma motor neurons in turn are controlled by some higher centres in the brain (see page 1063).

Abnormalities of the muscle tone

include:

- *Hypertonic state* or the spastic paralysis of the skeletal muscles that occurs in upper motor neuron lesions. Spasticity results due to exaggerated activity of lower motor neurons following or loss of inhibitional activity of upper motor neurons.
- *Hypotonic state* or the flaccid paralysis of the muscles that occurs in lower motor neuron lesions. The tone of the affected muscles is decreased or totally lost and ultimately the muscles undergo wasting.

Nature of muscle contractions in the body

A simple muscle twitch is not a physiological event. Basically, all contractions in the body are tetanic in nature. Weak contractions result from low frequency of firing (5–10/s) of the motor units. The expected jerkiness and the disadvantage of incomplete tetanus are overcome by the asynchronous discharge (out of step firing) of groups of motor units. When one group is firing, the others are silent, and vice versa. Algebraic summation occurs, the individual variations are evened out and a smooth contraction results. The degree to which the motor neuron discharge is asynchronous is related both to the force and duration of contraction. (In a subtetanus experiment, the muscle fibres contract and relax at the same time in response to the low-frequency stimulation). Such a situation does not occur in the body.

With increasing firing rates and, of course, with more recruitment of motor units, contractions become stronger until, at and beyond the tetanizing rate, sustained and powerful contractions result.

Gradation of force of muscle contraction in the intact body

For performing different kinds of work, e.g. picking up a pen from the table, or lifting a 10 kg weight, same muscles are involved but in these different situations, muscles can generate different degree of power. This property of skeletal muscles is known as gradation of force of contraction. Gradation of muscle power in muscles is made possible by certain factors which affect the force of contraction. These are:

1. Recruitment of motor units.

The force of contraction produced in a muscle depends upon the number of motor units recruited. When minimal activity is required, only a few motor units are recruited. With increasing effort, more and more motor units from the *motor neuron pool* of a muscle are recruited into activity. This phenomenon is called multiple motor unit summation.

2. Frequency of nerve impulses.

The motor control system in the brain can vary the force of contraction by varying the frequency of nerve impulses stimulating the muscle. As the impulse frequency increases, its effects are summated (*wave summation*) and the muscle tension increases.

3. Synchronization of impulses.

At any one time, the motor units are in different phases of activity, i.e. some are contracting and others are relaxing. Due to algebraic summation, the muscle gives a steady but weak pull. With increasing synchronization of the motor units, the force of contraction increases.

4. Effect of initial length of muscle fibre.

According to Starling's law, up to an optimal limit, the greater the initial length of the muscle fibres, greater is the force of contraction. This, however, is not the usual method of varying the force of contraction in the intact body.

5. Warming up.

Warming up is the term used in the parlour of sports persons for the exercises performed before actually participating in any game event. These pregame 'warm up' due to beneficial effects of the exercise increase the muscle performance when the person takes part in the actual

event.

Muscle fatigue

Failure of a muscle to maintain tension as a result of previous contractile activity is known as muscle fatigue. If the muscle is allowed to rest after the onset of fatigue it recovers its ability to contract. Muscle fatigue is discussed under two separate situations:

- Fatigue in an isolated muscle, and
- General fatigue.

Fatigue in isolated nerve-muscle preparation

In an isolated nerve-muscle preparation, when the muscle is repeatedly stimulated through its nerve, the graph (Fig. 2.3-31) obtained shows the following features:

- The first few contractions increase in amplitude due to beneficial effect.
- As stimulation is continued, there occurs a progressive increase in the latent period, and a decrease in the amplitude. The rise of tension becomes slower, relaxation becomes more gradual and incomplete, and finally the muscle fails to contract altogether, and the recording lever does not return to the base line, i.e. the muscle remains in a state of partial contraction called *contraction remainder* or *contracture*. This failure of response, after repeated stimuli, is called fatigue.

FIGURE 2.3-31 Phenomenon of fatigue in an isolated muscle-nerve preparation.

Site and cause of fatigue.

The *site of fatigue*, when the muscle has undergone fatigue through stimulation of its nerve, is *neuromuscular junction*, because the muscle responds briskly on direct stimulation. The *cause of fatigue* is depletion of acetylcholine from the motor nerve endings and interference with neuromuscular transmission by substances like pyruvic and lactic acids, and breakdown products of ATP.

The repeated stimulation of muscle itself leads to actual muscle fatigue and is due to depletion of muscle glycogen.

General fatigue

General fatigue refers to the fatigue of most of the muscles that develops after prolonged general exercise such as marathon running and competitive football match playing.

Onset and recovery of fatigue depends on:

- Intensity and duration of exercise, and
- Type of muscle fibres. Fast glycolytic fibres fatigue early and also

recover rapidly from fatigue. Slow oxidative fibres do not fatigue early but they also require longer time of rest (up to 24 h) for complete recovery.

Site, causes and mechanism of fatigue.

In the human body, the sites of fatigue are in the following order:

- Fatigue of *synapses of central nervous system* due to slight hypoxia occurs first of all. It is particularly of so high intensity in short-duration exercises.
- The second site of fatigue is *motor neurons* (anterior grey horn cells) of spinal cord.
- *Motor end plate* in the neuromuscular junction may also be fatigued.
- Changes in muscles also contribute to development of fatigue:
- In short-duration high-intensity exercises such as weight lifting and short distance running, there occurs increased acidity in the muscle cells which accompanies rise in lactic acid (formed due to anaerobic glycolysis). H^+ ion concentration directly inhibits cross-bridge cycles and therefore force generated by them. The second cause is decrease in release of Ca^{2+} ions from the sarcoplasmic reticulum.
- In long-duration low-intensity exercises such as marathon race, depletion of muscle glycogen is an important contributing factor.

Psychological fatigue

Lack of motivation due to failure of cerebral cortex to send excitatory signals to motor neurons causes an individual to stop exercising. The psychological fatigue (feeling of weariness) is different from *physiological fatigue* of the muscles. The muscles are actually not fatigued (therefore, it is not a true muscle fatigue). An athlete's performance, therefore, depends not only on the physical status of appropriate muscle but on

psychological fatigue also.

Muscle mechanics

Common terms used in muscle mechanics

Strength of the muscle.

Strength of the muscle can be defined as the maximal contractile force produced per square centimetre of the cross-sectional area of the skeletal muscle. On an average, the normal force produced by a muscle is about 3–4 kg/cm² area of the muscle. Thus, strength of a muscle is directly proportional to the size of the muscle. The size of the muscle can be increased by regular exercise.

The strength of the muscle is of two types:

1. Contractile strength

of the muscle is exhibited during actual shortening (isotonic contraction) of the muscle. For example, the strength developed in the leg muscles during taking off the body from the ground while jumping is the contractile strength.

2. Holding strength

refers to the force produced while stretching the contracted muscles. For example, the force developed in the leg muscles while landing after jumping is the holding force. The holding strength of a muscle is greater than the contractile strength.

Power of the muscle.

Power of the muscle refers to the amount of work done by the muscle in a given unit of time. It is expressed in kilogram-metre per minute (kg-m/min). Thus, the muscle power is the product of strength and speed. The power output of a muscle is determined by the energy input per second and its mechanical efficiency.

Endurance of the muscle.

Endurance of the muscle refers to its capacity to withstand the power produced during activity. In other words, it is the ability of the muscle to contract repeatedly over time. The muscle endurance depends mostly on the nutrition to the muscle.

Muscle tension and excursion.

When a muscle contracts, the external work done is observable as the force generated by the muscle, which is known as *muscle tension*, and/or a change in the muscle length, which is known as *muscle excursion*. Muscle length usually shortens during isotonic contraction. However, due to simultaneous passive stretching the muscle length may increase under certain circumstances. In such situations the work done is negative.

Muscle action.

When a muscle or group of muscle contracts, a movement is produced in the associated part of the skeletal lever system of the body; such a resultant movement is referred to as the action of that muscle. For example, flexion or extension produced at some joint in the body is the action of the concerned muscles.

Certain facts about muscle mechanics

Certain facts about the muscle mechanics in human body are as follows:

1. Skeletal lever system.

In our body, the muscle, bones and joints form a system of lever. At most places in the body, the anatomical system provides third class levers. According to principles of physics, with third class levers, much greater force is required to lift the same load, although the speed of lifting is faster. Therefore, speed of action with human muscle is fast but requires greater force.

2. Advantage of resting length.

Attachments of most of the muscles in the body are such that many of them are normally at or near their resting length when they start to contract, and thus force of contraction produced is more.

3. Situations for isometric contractions.

In muscles that extend over more than one joint, movement at one joint may compensate for movement at another in such a way that relatively little shortening of the muscle occurs during contraction. Such situations, for nearly isometric contraction, permit development of maximal tension per contraction. For example, in the case of hamstrings muscles which extend over the hip as well as knee joint, the lengthening of the muscles across the hip joint compensates the shortening across the knee joint.

4. Peculiar integration of momentum and balance into the body movements.

This makes a possible maximal motion with minimal muscular exertion. Due to such integration, the stress put on the tendon and bones is rarely over 50% of their failure strength, protecting them from damage. For example, during walking each limb passes rhythmically through two phases: the support or *stance phase* (when the foot is on the ground) and the *swing phase* (when the foot is off the ground). The support phases of the two legs overlap, so that there are two periods of double support during each cycle. There is a brief burst of activity in the leg flexors at the start of each step, and then the leg is swung forward with little more active muscular contraction. Thus, in this way, the muscles are active for only a fraction of each step. Therefore, walking for long periods causes relatively little fatigue.

5. Integrated muscle action.

The muscles may play a functional role as an agonist, antagonist or synergist during a particular movement. These relationships are not absolute, but vary with the activity, position of the body and the direction of the resistance that the muscle must overcome.

- **Agonist**

refers to a muscle (or group of muscles) which on contraction acts as the principal muscle producing a joint motion.

- **Antagonists**

refer to those muscles which have actions opposite to the agonist. Antagonists do not contract during a particular movement, but passively elongate or shorten to permit the motion to occur.

- **Synergists**

refer to those muscles which contract along with the agonist to produce a motion. The synergist may act as an assistant mover, neutralizer or a stabilizer.

- **Assistant mover**

is the muscle which aids the prime mover (agonist) in performing a particular motion.

- **Neutralizers**

are the muscles which neutralize the action of those muscles which prevent the agonist to produce a particular movement. For example, the extensors of the wrist neutralize the wrist flexors and these allow the long flexors of the fingers to contract and close the fist.

• Stabilizers

refer to those muscles which stabilize a proximal joint so that another muscle may act effectively at a distal joint. For example, the wrist extensors stabilize the wrist joint, so that the hand can be used effectively.

6. Active and passive insufficiency.

This phenomenon is seen in muscles which extend over two joints. Failure to produce a tight fist by the finger flexors when the wrist is in flexion is an example of active insufficiency. Passive insufficiency of rectus femoris occurs due to excessive stretching when there is knee flexion with hip extension.

Electromyography and common disorders of muscles

Electromyography

Electromyography refers to the technique of recording the total electrical activity of the motor nerve and the muscle under study. The machine used to record the said electrical activity is called *electromyograph* and the record obtained is called the *electromyogram*.

Recording technique

The basic recording unit of the electromyograph is a cathode ray oscilloscope. The electromyography can be recorded using two types of electrodes:

1. *Surface electrodes* or skin electrodes are placed on the skin above the surface of the muscle to be studied. They are convenient but are not precise, so they are not commonly used.
2. *Needle electrodes* are inserted into the muscle under study. The commonest inserted electrode used in EMG is the *bipolar concentric needle*

electrode. It consists of an insulated stainless steel hypodermic needle which contains an insulated fine wire in its barrel: the wire and the needle have bared tips. With needle electrodes, it is usually possible to pick up the activity of a single muscle fibre.

Protocol for recording EMG

For recording of EMG, the patient is made to lie comfortably in a quiet room. The needle electrode is inserted into the muscle and a ground lead is attached to the same limb to which the muscle under study belongs. The recordings are then taken as:

- ***At rest***, the muscle is explored systematically for presence of any *spontaneous activity*.
- ***During slight muscle contraction***, the recording is made from different sites to assess the size and duration of activity of different motor units (*motor unit potentials*).
- ***During maximal muscle contraction (against resistance)*** to record the *interference pattern*, which helps in determining the abnormal recruitment of motor units, if any. Observations made help in differentiating whether the problem is myogenic or neurogenic.

Electromyogram

Components of a normal electromyogram along with the common abnormalities which can be detected are given:

Spontaneous activity at rest

Normally, at rest, there is complete electrical silence and no spontaneous activity is recorded, except for:

1. The insertion activity.

When a needle electrode is inserted into a muscle it evokes a discharge of action potentials (due to mechanical stimulus). These potentials are of short duration and small amplitude (Fig. 2.3-32A). The insertion activity is:

- Prolonged in denervated muscle, and
- Absent when muscle tissue is not viable.

FIGURE 2.3-32 Electromyogram showing spontaneous activity at rest: **A**, complete silence followed by insertion activity; and **B**, end plate potential noise.

2. End plate noise.

After the cessation of insertion activity, no other spontaneous activity is seen but for a monophasic negative potential in the end plate region called *end plate noise* (Fig. 2.3-32B). These potentials correspond to the miniature end plate potential (MEP) of the neuromuscular junction.

Voluntary activity during muscle contraction

The potential change recorded during muscle contraction is called *motor unit potential* (MUP). The motor unit potential is the compound potential which represents the sum of the individual action potentials generated in the few muscle fibres of the motor unit that are within the pick-up range of the recording electrode. Since fibres of several motor units intermingle singly, each EMG electrode records the activity of more than one motor units. The electromyographic records obtained *during different grades of muscle contraction* have the following characteristics:

1. On minimal voluntary contraction.

only a single or two smaller motor units in the vicinity of needle electrode give off electrical discharge. The MUP recorded has the following features (Fig. 2.3-33A):

- It has a regular rhythmic fashion.
- Frequency is low (5–10/s).
- Amplitude of MUP is usually between 200 μV and 3 mV and is determined largely by the distance between the recording electrode and the active fibres that are closest to it.
- Duration of each spike of MUP normally varies between 2 and 15 ms and is related to the anatomic scatter of end plates of these muscle fibres in the motor units that are within the pick-up zone of the recording electrode.

FIGURE 2.3-33 Electromyogram during voluntary muscle activity: **A**, on minimal contraction, **B**, on moderate contraction (recruitment pattern); and **C**, on maximum contraction (normal interference pattern).

2. With the progressive increase in the voluntary contraction.

the firing rate of small units increases until it reaches a certain frequency, when larger units are recruited. Fig. 2.3-33B shows the recruitment pattern with moderate force of contraction.

3. During maximal contraction.

so many motor units are recruited and thus the so many rhythmically recurring motor unit potentials become superimposed upon one another on the oscilloscope screen that it is impossible to determine their individual characteristics. The resulting appearance of the EMG is designated as *normal interference pattern* (Fig. 2.3-33C).

Interpretation of emg record taken during muscle contraction

Features to be noted while analysing the EMG record taken during voluntary muscle contraction include:

- *Onset frequency*, i.e. the frequency when the MUPs first appear,
- *Recruitment frequency*, i.e. the frequency at which a particular unit must fire before another is recruited and
- *Density of the interference pattern*, i.e. the frequency of MUPs at maximal contraction.

Abnormal spontaneous activities

Abnormal spontaneous activities which can be recorded during resting phase are:

1. Fasciculation potentials

resemble MUPs and represent the involuntary contraction of muscle fibres of a single motor unit. The fasciculation (jerky, visible twitching of a group of muscle fibres) occurs in patients with chronic partial denervation especially due to spinal cord lesions.

2. Fibrillation potentials

are of very short duration (0.5–2 ms) and low amplitude (25 and 100 μV). They occur at a regular rhythm (2–10/s) and always have an initial positive phase and a secondary negative phase (Fig. 2.3-34).

FIGURE 2.3-34 Fibrillation potential recorded from denervated muscle.

The fibrillation potentials are produced due to involuntary contraction of the single muscle cells which have been dissociated from nervous control following denervation.

Abnormalities during voluntary activity

Abnormalities of MUP frequency and amplitude detected during voluntary activity are as follows:

1. Decrease in the density of the interference

or the so-called *sparse interference pattern* is seen in patients with *neurogenic weakness* of the muscle when the number of functional motor units is reduced and thus the MUP frequency during maximal contraction is decreased. The amplitude of MUP record is however normal, since the number of muscle fibres in each unit are normal. In severe cases, the interference pattern may be completely lost.

2. Low amplitude of MUP

is observed in patients with *myogenic causes* of muscle weakness due to reduction in the number of muscle fibres per motor unit. However, the interference pattern during maximal contraction remains normal since the number of motor units available for recruitment is not reduced.

3. High amplitude of MUP

is recorded from the denervated muscles that have subsequently got reinnervated. It is because of the fact that during reinnervation, the number of muscle fibres in each motor unit is increased (since the muscle fibres which have lost their innervation get innervated by the axonal branches of the neighbouring motor unit).

Disorders of skeletal muscles

1. Muscular dystrophy

Muscular dystrophy is a syndrome which occurs due to genetic mutation and is characterized by progressive muscle weakness.

Duchenne's muscular dystrophy

is caused by mutations of the dystrophic gene that cause dystrophin to be absent from the muscles. It is an X-linked disorder occurring in about 1 of every 3000 male infants. It causes great disability and eventually proves fatal by the age of 30 years.

Becker's muscular dystrophy

is an autosomal recessive disorder occurring due to a mutation in the gene for sarcoglycan or other components of dystrophin–glycoprotein

complex. It is a milder form of the disease in which the dystrophin is present but is either altered or reduced in amount.

Malignant hyperthermia

is also related to dysfunction of muscle ion channels due to mutation in gene for ryanodine receptors for Ca^{2+} -release channels in the sarcoplasmic reticulum. This mutation results in dysfunction of Ca^{2+} channel to shut down after stimulation, thus more availability of Ca^{2+} causes increase in contractility of muscles leading to more production of heat.

2. Myotonia

Myotonia is a disorder that occurs due to abnormalities of the sodium and chloride channels caused by abnormal genes on chromosomes 7, 17 or 19. It is characterized by an abnormally prolonged muscle relaxation after voluntary contraction.

3. Myasthenia gravis

It is a disorder of the neuromuscular junction, characterized by a grave weakness of the muscles (see page 83).

4. Abnormal muscle tone

The normal muscle tone of a muscle may be increased or decreased constituting an abnormal muscle tone (see page 104).

5. Metabolic myopathies

Metabolic myopathies occur due to mutation of genes that code enzymes involved in carbohydrate and protein metabolism of the muscles for the production of ATP (McArdle syndrome). Metabolic myopathies usually present as intolerance to exercise.

6. Fibrillation and denervation hypersensitivity

The denervation of skeletal muscles in lower motor neuron lesions causes flaccid paralysis of the muscle, fibrillation and denervation hypersensitivity.

• Fibrillation

is characterized by fine, irregular contractions of individual muscle fibres.

• Denervation hypersensitivity

refers to when the muscle becomes highly sensitive to acetylcholine.

Source of energy and metabolic phenomenon during muscle contraction

- Chemical composition of muscle
- Energy source for muscle contraction
- Oxygen consumption, demand and debt
- Changes in pH during muscle contraction
- Thermal changes during muscle contraction

Chemical composition of muscle

Chemical composition of a skeletal muscle is as follows:

1. *Water*. It constitutes the major bulk of (75%) the muscle weight.
2. *Muscle proteins* form 20% of the muscle mass. These include the contractile proteins (actin, myosin, troponin and tropomyosin), myogen and myoglobin. Myoglobin is a conjugated protein. Like haemoglobin, its main function is to carry oxygen.
3. *Organic substances other than proteins* present in the muscle fibre include:
 - *Carbohydrates*: glycogen and hexaphosphate.
 - *Lipids*: neutral fat, cholesterol, lecithin and steroids.
 - *Nitrogenous substances*: ATP, adenylic acid, creatine, phosphocreatine, urea, uric acid, xanthine and hypoxanthine.
4. *Inorganic substances* present in the muscle are:

- *Cations*: potassium, sodium, calcium, magnesium and
- *Anions*: chloride, phosphate and sulphate.

Energy source for muscle contraction

The muscle contraction requires lot of energy. In fact, the muscle has been labelled as a *machine for converting chemical energy into mechanical work*. The immediate source of energy is ATP and the ultimate source is the intermediary metabolism of carbohydrate and lipids.

Hydrolysis of ATP

The hydrolysis of ATP provides energy for muscle contraction (for details see molecular basis of muscle contraction page 89). ATP stored in the muscle initiates the contractile activity but is consumed after a few twitches. In about 3 s, all the ATP stored in the muscle cell is depleted. Thus, there is need for resynthesis of ATP.

Resynthesis of ATP

There are three ways in which a muscle fibre can resynthesize ATP from ADP during contractile activity:

1. Phosphorylation of ADP by creatine phosphate.

Immediately after the depletion of ATP stores of the muscle, ATP is regenerated using the energy released by the dephosphorylation of creatine phosphate (CP) reserves of the muscle fibre.

The above reaction, known as *Lohman's reaction*, is rapid and requires only single enzyme. It is reversible and obeys law of mass action. Since the amount of creatine phosphate is limited, the amount of ATP formed by this mechanism is only sufficient for contraction of the muscle for next about 5 s. Therefore, the next mechanism comes into play immediately.

[At rest, the muscle contains large quantities of ATP, therefore, the reaction proceeds from right to left forming creatine phosphate, and thus the store is built up.]

2. Glycolysis.

After depletion of creatine phosphate reserves, the next important source of energy which is used to reconstitute both ATP and phosphocreatine, is glycogen (previously stored in the muscle cell) by the process of glycolysis which can sustain muscle contraction for about 1 min. As shown in Fig. 2.3-35, each molecule of glycogen after glycolysis produces two molecules of pyruvic acid and two molecules of ATP. Further changes in pyruvic acid depend upon the availability of oxygen.

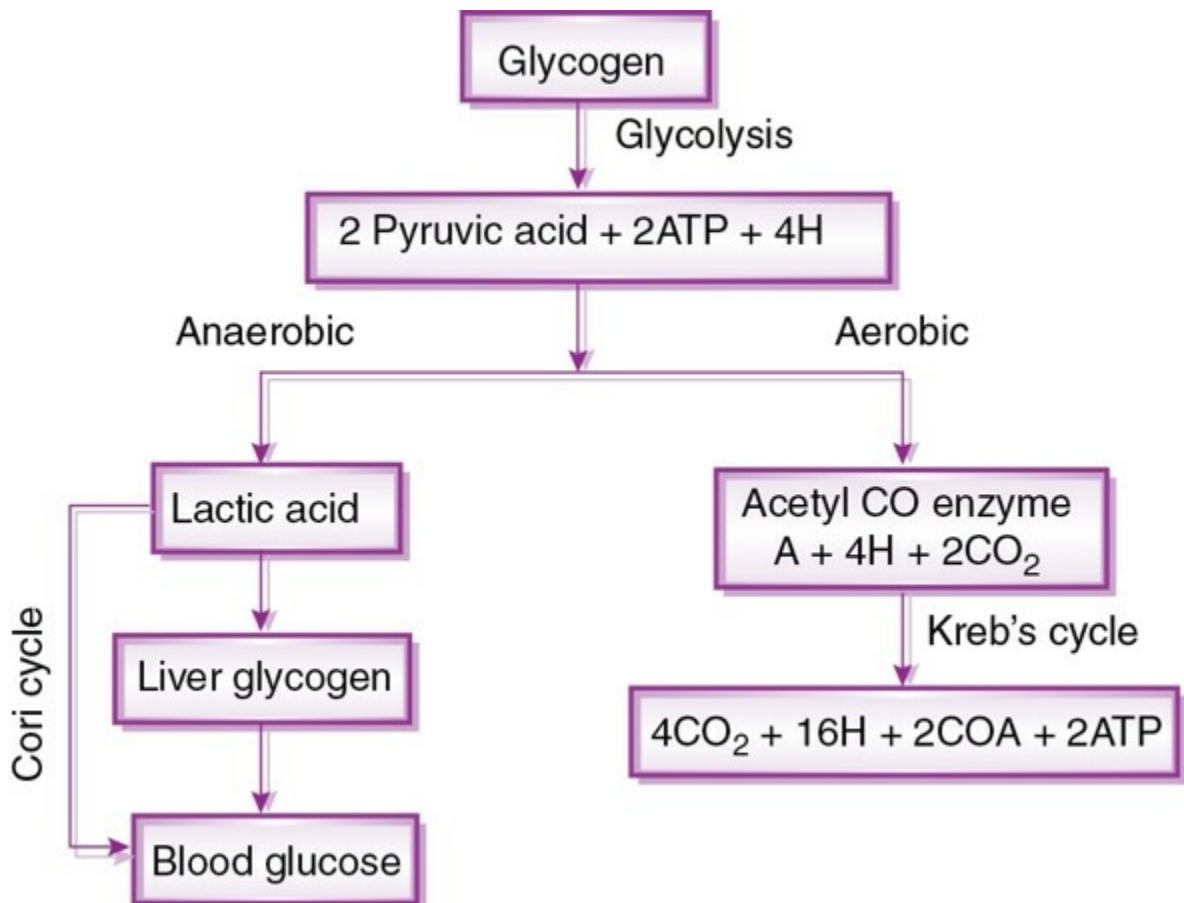

FIGURE 2.3-35 Schematic diagram showing breakdown of glycogen stored in a muscle cell.

- **In the absence of oxygen,**

the pyruvic acid is converted into lactic acid which is released into the blood. From the blood, lactic acid is taken up by the kidney and liver where it is reconverted into glucose and released back into circulation (Cori cycle).

- **If oxygen is available,**

the pyruvic acid enters into *Krebs' cycle*.

A total of 38 ATP molecules are formed during breakdown of each glycogen molecule as below:

- 2 molecules of ATP are formed during glycolysis,
- 2 molecules of ATP are formed during Krebs' cycle and
- 34 molecules of ATP are formed utilizing the hydrogen ions produced during breakdown of a glycogen molecule.

Importance of glycolysis is two fold:

- First, the glycolytic reactions occur even in the absence of oxygen, so that muscle contraction can be sustained for a short time even when oxygen is not available.
- Second, the rate of formation of ATP by glycolysis process is about 2½ times as rapid as ATP formation when the cellular foodstuffs react with oxygen.

3. Oxidative metabolism.

Oxidative metabolism, i.e. combining of oxygen with various cellular foodstuffs to liberate ATP is the final source of energy during muscle contraction. This source contributes more than 95% of all energy used by the muscles for sustained long-term contraction. Foodstuffs used in oxidative metabolism include fats, carbohydrates and proteins as:

- *Fatty acids* are used for resynthesis of most of the ATP during prolonged muscle contraction lasting over a period of many hours.
- *Glycogen* contributes about half of the energy required for muscle contraction lasting for 2–4 h.

Important Note

- During intense but short lasting exercise, e.g. in a 100m race that takes 10 s, 85% of the energy consumed is derived anaerobically.
- During moderate intensity exercise, e.g. in a 3 km race that takes 16 min, 20% of the energy consumed is derived anaerobically.
- During mild intensity prolonged exercise, e.g. in a long distance race

that takes about an hour, only 5% of the energy comes from anaerobic metabolism.

Oxygen demand, consumption and debt

Oxygen demand increases with the intensity of exercise (i.e. intensity of muscle contraction). It has been reported that in a sprint lasting for $\frac{1}{2}$ min, the oxygen demand is around 20 L/min.

Oxygen consumption

or oxygen utilization is the volume of oxygen which has been actually consumed during the exercise. The maximum amount of oxygen that can be consumed by a person while performing severe exercise (irrespective of the demand) is VO_2 max. A world-class sprinter is expected to have a VO_2 max around 75 ml/kg/min (about 4 L/min).

Oxygen debt.

During intense exercise, the maximum oxygen consumed is much less than the oxygen demand. So the energy requirement is met with by the *anaerobic pathway*. After the period of exercise, extra O_2 is consumed to remove the excess lactate collected due to anaerobic glucose breakdown, replenish the ATP and phosphoryl creatine store, and replace the small amounts of oxygen that have come from myoglobin. This amount of extra oxygen consumed is called O_2 debt and is proportionate to the extent to which energy demands during exercise exceeded the capacity of aerobic synthesis of energy store, i.e. extent to which *oxygen deficit occurred* during exercise. Oxygen debt can be measured experimentally by determining oxygen consumption after exercise until constant basal consumption is reached and then subtracting the basal oxygen consumption from total oxygen consumed during this period (Fig. 2.3-36).

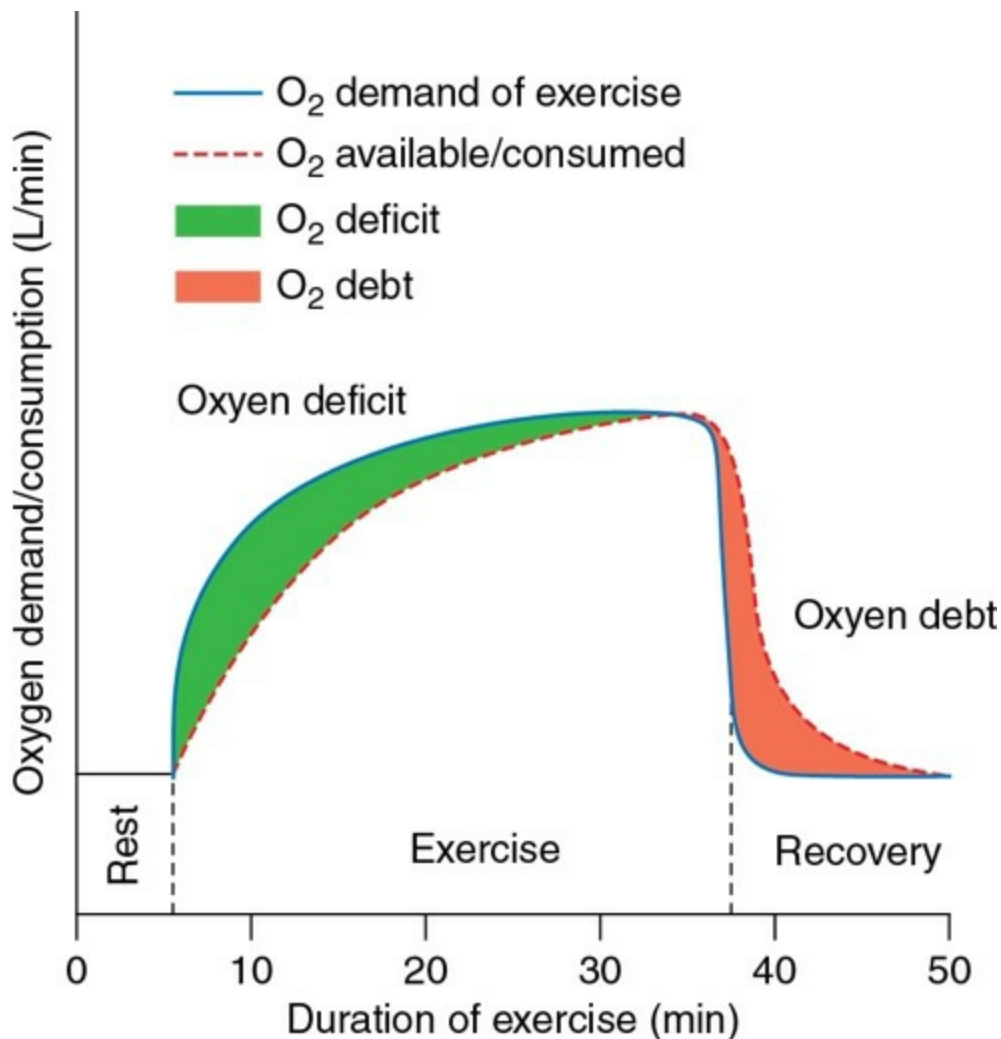

FIGURE 2.3-36 Oxygen debt.

Applied Aspect

To avoid excessive O₂ debt early in the race, the experienced long-distance runners begin the race very slowly to allow the cardiorespiratory system to gear up to the energy demands of muscular activity; once a steady state is attained due to cardiorespiratory readjustment, the oxygen supply balances the oxygen requirements of the muscles. This state of oxidative metabolism to provide energy for the muscles can continue for several hours without producing excessive oxygen debt. This prevents too much anaerobic metabolism and accumulation of lactic acid which hamper the efficiency.

Mechanical efficiency of muscle

During contraction, the efficiency of muscle is about 25%. Mechanical efficiency is equal to output/input. Therefore, mechanical efficiency is equal to

$$\frac{\text{Work done by the muscle (W)}}{\text{Oxygen consumption (VO}_2\text{)}}$$

OR

$$\frac{W \text{ (kilopond metre/min/426.7)}}{\text{VO}_2\text{(L/min)} \times 5}$$

(Since 426.7 kilopond metre/min = 1 kcal, and 1 L/min VO₂ at STPD produces 5 kcal of energy; STPD means standard temperature (0°C) pressure (760 mmHg) and dry)

- Therefore, mechanical efficiency in isotonic contraction is approximately 25% of the energy expenditure and rest 75% is degraded as heat and
- During isometric contraction as no external work is done, therefore, mechanical efficiency is nil and 100% energy expenditure disappears as heat

Changes in pH during muscle contraction

Changes occurring in the pH and reaction of the muscle during contraction are as follows:

- *During resting condition*, the reaction of muscle is alkaline with a pH of 7.3.
- *During onset of muscle contraction*, due to dephosphorylation of ATP to ADP, the pH of muscles becomes acidic.
- *During later part of muscle contraction*, due to resynthesis of ATP from creatine phosphate, the muscle reaction again becomes alkaline.
- *At the end of muscle contraction*, due to formation of pyruvic acid and/or lactic acid, the muscle reaction once again becomes acidic.

Thermal changes during muscle contraction

Thermal changes in the muscle during contraction can be accurately measured using suitable thermocouple. The different phases of heat production during muscle contraction are:

1. Resting heat.

Resting heat is in the heat generated when the muscle is at rest, i.e. not contracting. It is the external manifestation of the basal metabolic process of the muscle.

2. Initial heat.

Initial heat refers to the heat generated in excess of resting heat during muscular contraction. It is made up of the following components:

- *Activation heat* refers to initial rapid liberation of energy before the actual contraction of the muscle. It is mostly due to the heat liberated while calcium ions are released from the L-tubules of sarcoplasmic reticulum and the myosin ATPase is activated.
- *Shortening heat* is produced when the muscle contracts isotonicly. It is produced due to various structural changes in the muscle fibre like movement of cross-bridges and myosin heads and breakdown of glycogen. It is absent during isometric contraction.
- *Maintenance heat* is generated during isometric contraction when no actual shortening of the muscle fibre takes place. Its cause is complicated and mostly obscure.

3. Recovery heat.

Recovery heat refers to the heat produced in excess of resting heat, following muscle contraction. It continues for about 30 min after the cessation of muscle contraction. This heat is generated by the metabolic processes that restore the muscle to its precontraction state. These include calcium ATPase activity which pumps back calcium into the sarcoplasmic reticulum and also regeneration of ATP and other energy substrates. The recovery heat is approximately equal to initial heat (heat produced during contraction).

4. Relaxation heat.

This is the extra heat, in addition to the recovery heat, which is produced during relaxation of the isotonicly contracted muscle. It is the external manifestation of the extra work done on the muscle to stretch it back to

its original length.

Important Note

Fenn effect

Fenn effect states that the heat produced is directly proportional to the work done. When the work done is more, the expenditure of ATP will also be more; therefore, Fenn effect can be considered to state that more work done causes more expenditure of energy.

COMPARISON OF SKELETAL, SMOOTH AND CARDIAC MUSCLES

Smooth muscle

Functional anatomy and organization

Smooth muscles (nonstriated muscles), as the name indicates, are characterized by the absence of the typical cross-striated patterns seen in skeletal muscles. Because of their spontaneous activity or activity through the autonomic nervous system, they are also called *involuntary muscles*.

The smooth muscle cells are long fusiform in shape and are aggregated to form bundles or *fasciculi*. The fasciculi are aggregated to form layers of variable thickness. Thus, smooth muscles exist either in sheet or bundles of fibres. In each layer, the cells are so arranged that the thick central part of one cell is opposite the thin tapering ends of adjoining cells (Fig. 2.4-1.)

FIGURE 2.4-1 Arrangement of smooth muscle fibres.

Types of smooth muscles

Smooth muscles are of two types: single-unit or unitary and multiunit smooth muscles.

1. Single-unit smooth muscles

Single-unit smooth muscles are also called *visceral smooth muscles* since they are present in the walls of hollow viscera such as gastrointestinal tract, uterus, ureters, urinary bladder and respiratory tract.

Salient features of single-unit smooth muscles are:

- These are arranged in the form of large sheets and have low-resistance bridges between individual muscle cells and function in a *syncytial fashion* and that is why they are called single-unit muscles (Fig. 2.4-2). The low-resistance intercellular bridges or the so-called *gap junctions* are in abundance and have high conductance for the ions. Therefore, the syncytium contracts as a single unit in many large areas.
- These muscles have their own rhythmic contractility *myogenic tone* that is independent of the nerve supply. The rate of contraction may be determined by the *pacemaker regions* present within the muscles. The nervous influence only modulates their activity, i.e. the role of the nerves is to increase or decrease the rate of rhythmic contraction.
- Contraction of this kind of smooth muscles is also stimulated by *stretching*. The muscles of smaller blood vessels are mainly of this kind and their contraction in response to stretch is involved in autoregulation of blood flow.
- In addition to the autonomic nervous system, their contractile activity is also influenced by some non-neural stimuli, e.g. hormones and local tissue factors (such as temperature and pH).

FIGURE 2.4-2 Single-unit smooth muscle fibre showing gap junctions between two adjacent cells.

2. Multiunit smooth muscles

Multiunit smooth muscles, as the name indicates, are made up of multiple individual units without interconnecting bridges, i.e. *nonsyncytial* in character (Fig. 2.4-1). These are *located* in most blood vessels, epididymis, vas deferens, iris, ciliary body and piloerector muscles.

Salient features.

of Multiunit Smooth Muscles are:

- These muscles are made up of multiple individual units of muscle fibres, each innervated by a single nerve ending.
- Each muscle fibre has got an outer membrane made up of glycoproteins which help to insulate and separate the muscle fibres from each other. These muscles contract when an appropriate nerve stimulus reaches, i.e. contraction is *neurogenic*. Here, a single stimulus to the nerve causes repeated firing of action potential which produces *irregular tetanic contraction* (rather than a single muscle twitch produced by a single action potential as seen in skeletal muscle).
- These fibres do not exhibit spontaneous contraction, i.e. *no pacemaker activity*.
- Since the *gap junctions* are not present, the excitation remains localized within the motor unit.
- These muscles do not respond to stretch.

Innervation and neuromuscular junction of smooth muscles

Nerve supply

Smooth muscles are innervated by autonomic nerves, both sympathetic as well as parasympathetic. The two have opposite effects. In some organs, sympathetic stimulation causes contraction and parasympathetic stimulation causes relaxation of smooth muscles. While in some other organs, a reverse action is seen. The autonomic nerves supplying the smooth muscles emerge out as *preganglionic fibres* which relay in a ganglion. Postganglionic fibres run along the length of muscle fibres and groove them.

Neuromuscular junction

The postganglionic nerve fibres, approach the smooth muscles, branch extensively and come in close contact with large number of smooth muscle fibres (Fig. 2.4-3). The neuronal network so formed has a beaded appearance due to the large enlargements called *varicosities* (Fig. 2.4-4). These varicosities contain the chemical neurotransmitter (acetylcholine or norepinephrine).

FIGURE 2.4-3 The nerve supplying to smooth muscle showing varicosities (beaded appearance).

FIGURE 2.4-4 Detailed structure of postganglionic nerve ending innervating smooth muscle cells.

In the smooth muscle, the nerve fibres are not ending in *motor end plates* (as seen in skeletal muscles), i.e. the nerve fibres do not make any direct contact with the muscle fibres. Instead, the nerve fibres release its neurotransmitter from each varicosity into the interstitial fluid close to the muscle fibres. The neurotransmitter so released diffuses into a large number of cells and causes activation of all muscle fibres up to where it is forming a syncytium. Therefore, here a single stimulus does not cause stimulation of all muscle fibres in the whole organ. Thus, repeated stimuli are needed to cause release of more chemical transmitter to stimulate the remaining cells. Further, in a sheet of smooth muscle cells, often only the cells on the surface are innervated. The deeper cells are stimulated by spread of action potentials through the gap junctions.

Excitatory Junctional Potential (EJP) or Inhibitory Junctional Potential (IJP), i.e. either a depolarizing or a hyperpolarizing response may be recorded from a smooth muscle, in response to an appropriate nerve stimulus. These potentials summate with repeated stimuli. The EJP and IJP are *local responses* like those seen in a synapse (excitatory and inhibitory postsynaptic potential, EPSP and IPSP).

Structure of smooth muscle fibre

Each smooth muscle fibre is a long spindle-shaped cell (myocyte) having a broad central part and tapering ends (Fig. 2.4-5A). The length of smooth muscle fibre is highly variable (15–500 μm) depending upon the

organ in which they are present. For example,

- *Digestive tract* fibres are 30–40 μm long and 5 μm in diameter,
- Fibres in *blood vessels* are 15–20 μm long and 2–3 μm in diameter and
- Fibres in *uterus* are 300 μm long and 10 μm in diameter.

FIGURE 2.4-5 Structure of smooth muscle: **A**, arrangement of thin (actin filaments attached to dense bodies) and thick (myosin) filaments; **B**, position of dense bodies in relaxed state; and **C**, the dense bodies are drawn closer to each other in contracted state.

Salient features of structure of a smooth muscle fibre

Plasma membrane.

which binds the smooth muscle is surrounded by an external lamina. Adjacent smooth muscle cells communicate through gap junctions.

Nucleus.

is oval or elongated and lies in the central part of the cell.

Sarcoplasm,

in addition to a single nucleus, contains other cell organelles like mitochondria (source of energy), a Golgi complex, some granular endoplasmic reticulum and free ribosomes. Apart from these, it also contains myofibrils and intermediate filaments.

Sarcoplasmic reticulum

similar to that in skeletal muscle is present, but is not as developed.

Myofibrils

are made up of contractile proteins, myosin and actin filaments. The *longitudinal striations* seen on light microscopy are due to these myofibrils. Since the thick and thin filaments do not have the highly ordered arrangement as seen in striated muscles, no cross striations are seen. Other salient differences from the skeletal muscle are:

- The *sarcotubular system* and *triads* encountered in striated muscles are not well developed in smooth muscles.
- Smooth muscles contain relatively less *thick filaments* and more *thin filaments*.
- Z-line is not well defined in smooth muscles.
- *Myosin-II* present in smooth muscle is chemically different from that seen in skeletal muscles. It binds to actin only if its light chain is phosphorylated. Thus, phosphorylation of myosin is necessary for the contraction of smooth muscles.
- *Thin actin filaments* are also different from those in skeletal muscle due to absence of the troponin protein molecules.
- *Dense bodies* are bounded by α -actinin, (Fig. 2.4-5B) and attached to the cell membrane through α -actinin. The actin filaments are attached to these dense bodies. In between actin filaments, the thick myosin filaments are situated. There are cross-bridges between actin and myosin, which help in the sliding mechanism of muscle contraction. When the muscle contracts, the points on the cell membrane where dense bodies are attached, are drawn closer to each other. This

converts an oblongated smooth muscle into one that is oval (Fig. 2.4-5C).

Process of excitability and contractility

- Process of muscle excitation
- Process of excitation–contraction coupling
- Process of muscle contraction

Process of muscle excitation

Process of muscle excitation basically includes the electrical activity in smooth muscle which differs in a multiunit smooth muscle from that of in a single-unit muscle, and so is discussed separately.

Electrical activity in single-unit (visceral) smooth muscles

Resting membrane potential.

The resting membrane potential in a visceral smooth muscle ranges between -50 and -75 mV. Sometimes it may reach as low as -25 mV. Thus, the peculiarity of the resting membrane potential is its *unstability*, i.e. there is no true resting value, rather it keeps on oscillating between -55 and -35 mV (Fig. 2.4-6). These oscillations in the RMP occur due to superimposition by the *pacemaker potentials* which in turn occur due to rhythmic changes in either Ca^{2+} channel permeability and/or the activity of $\text{Na}^+ - \text{K}^+$ pump.

FIGURE 2.4-6 Resting membrane potential (fluctuating type) in visceral smooth muscle.

Action potential.

When depolarization reaches threshold potential, an action potential is generated, which is transmitted to the adjacent muscle cells through the gap junction. Three types of action potentials are known to occur in the visceral smooth muscle fibres, viz. spike potential, spike potential superimposed over pacemaker potential and action potential with plateau.

1. Spike potential.

A typical spike potential, similar to that seen in skeletal muscles, is also observed in most, if not all, single-unit smooth muscles. However, it differs from the spike potential of skeletal muscle in many ways: (i) its average duration varies between 10 and 50 ms; (ii) its amplitude is very low and (iii) it does not reach the isoelectric base (Fig. 2.4-7A). The spike action potential, in a smooth muscle, can occur due to following modes of stimulations:

- Electrical stimulation,
- Effect of hormones on the smooth muscle,
- Action of neurotransmitters from the nerve fibre and
- By stretch of a smooth muscle as seen in gut wall.

FIGURE 2.4-7 Three types of action potentials recorded from smooth muscles: **A**, spike potential; **B**, spike potential superimposed over slow wave potentials; and **C**, action potential with plateau.

For example, when the gut is overfilled by intestinal contents, due to stretch there occurs local automatic contraction which sets up a peristaltic wave that moves the contents away from the overfilled intestine.

2. Spike potential superimposed over slow wave potentials.

The slow wave rhythms, also called as pacemaker waves, are seen in many visceral smooth muscles such as muscles of gut. These waves themselves cannot cause muscle contraction. However, in self-excitatory smooth muscles, the slow waves can initiate action potential. When the potential of slow waves rises above the level of about -35 mV (the approximate threshold for eliciting action potential in most visceral smooth muscles), an action potential develops and spreads over the muscle mass. Such a spike potential appears rhythmically at a rate of about one or two spikes superimposed at the peak of each slow wave (Fig. 2.4-7B) and causes rhythmic contractions of the self-excitatory smooth muscles.

3. Action potential with plateau

is seen in some tissues such as in the ureter, the uterus under some conditions and some types of vascular smooth muscles. As shown in Fig. 2.4-7C, this type of action potential starts with rapid depolarization as is seen in the skeletal muscles. However, like skeletal muscles, the repolarization does not occur immediately, but is delayed by 100–1000 ms. This prolonged depolarization accounts for the sustained contraction of certain smooth muscle fibres.

Ionic basis of action potential.

In smooth muscles, the depolarization occurs due to entry of Ca^{2+} ions from ECF to the inside of the cell rather than Na^{+} ions (as seen in skeletal muscles). The smooth cell membrane has far more *voltage-gated calcium channels* than does skeletal muscle but few voltage-gated sodium channels. Unlike sodium channels, the calcium channels open and close slowly. This accounts for the prolonged action potential observed in smooth muscles. The calcium ions, in addition to causing depolarization, also produce contraction of smooth muscles by directly acting on the contractile mechanism.

Electrical activity in multiunit smooth muscles

The multiunit smooth muscles (such as the muscles of iris and piloerector muscles) usually respond to nerve stimuli. The nerve endings secrete the neurotransmitter (acetylcholine or norepinephrine), which causes depolarization of the smooth muscle membrane. Since fibres are too small, they do not generate an action potential. The local depolarization is called the *excitatory junctional potential (EJP)*. However, the EJP spreads electrotonically over the entire fibre and is sufficient to cause the muscle contraction.

Process of excitation–contraction coupling

Excitation–contraction coupling refers to the sequence of events by which an excited plasma membrane of a muscle fibre leads to cross-bridge activity by increasing cytosolic (sarcoplasmic) calcium concentration. Since a smooth muscle can be excited by so many possible ways, there are different ways of excitation–contraction coupling as well. Three different mechanisms of excitation–contraction coupling known in smooth muscles are described below:

1. Electromechanical coupling

occurs when the smooth muscle is excited through sarcolemmal depolarization. Due to depolarization of the membrane, the *voltage-gated* Ca^{2+} channels present on it are opened and the Ca^{2+} ions from the ECF move into the sarcoplasm. These Ca^{2+} ions in turn stimulate the release of more Ca^{2+} from the sarcoplasmic reticulum. This process is called *Ca²⁺-induced Ca²⁺ release (CICR)*. The raised sarcoplasmic Ca^{2+} level brings about the excitation–contraction coupling.

2. Pharmaco-mechanical coupling

occurs when the smooth muscle is excited by some chemical agent and not by membrane depolarization. Two mechanisms of pharmaco-mechanical coupling known are:

- The chemical agents (neurotransmitters and hormones) bind to the *ligand-gated* Ca^{2+} channels present on the sarcolemma and open them up resulting in influx of Ca^{2+} from the ECF.
- The chemical agents bind to the *membrane receptors* and activate the second messenger system of G-protein → generation of inositol triphosphate (IP_3) from the membrane phospholipids → release of calcium ions from the *intracellular* Ca^{2+} stores, i.e. from the sarcoplasmic reticulum.

3. Mechano-mechanical coupling

occurs when the muscle is excited by stretch. Due to stretching, the *stretch-sensitive* Ca^{2+} channels present on the sarcolemma open up resulting in influx of Ca^{2+} from the ECF.

The excitation–contraction coupling in smooth muscle is a slow process. Calcium initiates this process by binding with calmodulin. The *calcium–calmodulin complex* so formed triggers muscle contraction by a sequence of events discussed below.

Process of smooth muscle contraction

The molecular mechanism of smooth muscle contraction by cross-bridge cycling and sliding of filaments is similar to the skeletal muscle. However, since the smooth muscle does not contain the regulatory proteins tropomyosin and troponin, its regulation is different. In a smooth muscle, one of the light chains of the myosin filament located in the neck region serves the function of tropomyosin and thus is called the *regulatory chain of myosin*. Similarly, the Ca^{2+} -binding protein *calmodulin*

plays the role of troponin.

Steps of cross-bridge cycling

Steps of cross-bridge cycling in a smooth muscle are summarized (Fig. 2.4-8):

FIGURE 2.4-8 Steps of cross-bridge cycling in smooth muscle: **A**, relaxed muscle; **B**, activation of myosin light chain kinase (MLCK) catalyses phosphorylation of myosin regulatory chain and initiates cross-bridging between myosin head and actin filament; **C**, power stroke, triggered by conformational change in myosin head due to formation of actin–myosin ADP-Pi complex; and **D**, dephosphorylation of myosin regulatory protein resulting in cessation of cross-bridging.

1. Activation of the enzyme myosin light chain kinase (MLCK).

The enzyme MLCK is activated by the Ca²⁺–calmodulin complex.

2. Phosphorylation of the myosin regulatory chain.

The activated enzyme MLCK uses ATP to phosphorylate the myosin regulatory chain.

3. Cross-bridging.

When the myosin regulatory chain is phosphorylated, the head of myosin filament acquires the capability to bind with actin filament to form the cross-bridge (Fig. 2.4-8B).

4. Power stroke.

Formation of the actin–myosin ADP-Pi complex triggers a conformational change in the myosin head causing it to flex towards the arm of the cross-bridge. The flexion of the myosin head generates mechanical force (*the power stroke*) (Fig. 2.4-8C).

Due to power stroke, the actin filament slides over the myosin filament producing contraction. As shown in Fig. 2.4-5C, the *dense bodies* play a role in the contraction of a smooth muscle fibre. In fact, the dense bodies of smooth muscles serve the same role as the Z-disc (Z-line) in skeletal muscle.

5. Relaxation of smooth muscle.

To cause relaxation of the smooth muscle contraction, it is necessary to remove the calcium ions from the sarcoplasm. This is accomplished by the calcium pump which pumps the calcium from ICF to ECF and also from ICF into the sarcoplasmic reticulum. When the cytoplasmic Ca^{2+} falls to the resting level, the processes involved in the contraction of smooth muscle automatically reverse except for the phosphorylation of the myosin head. Reversal of this occurs when the enzyme *myosin phosphatase* causes dephosphorylation of the myosin regulatory chain. After this, the cross-bridge cycling stops and the contraction ceases (Fig. 2.4-8D). The time required for relaxation of contracted muscle, therefore, is determined to a great extent by the amount of active myosin phosphatase in the cell.

The calcium pumps operating in the smooth muscles are slow acting in comparison with the fast-acting sarcoplasmic reticulum pump in skeletal muscles. Therefore, the duration of smooth muscle contraction is prolonged (in seconds) as compared to skeletal muscles (from 1/100th to 1/10th of a second).

Characteristics of smooth muscle excitation and contraction

Certain characteristic features of smooth muscle excitation and contraction are as follows:

1. Slow excitation–contraction coupling

As shown in Fig. 2.4-9, a smooth muscle starts contracting approximately 200 ms after the start of the spike potential (i.e. 150 ms after the spike is over). The peak of contraction is reached after 500 ms of the spike. Thus, the excitation–contraction coupling is very slow in smooth muscles compared with the skeletal muscles.

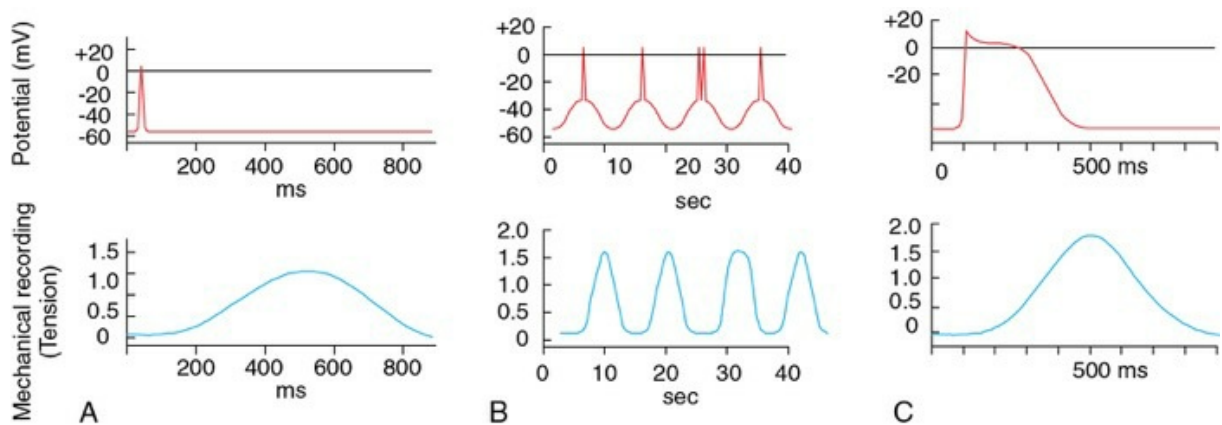

FIGURE 2.4-9 Record of mechanical activity of smooth muscle following various types of potential: **A**, spike potential; **B**, spike potential superimposed over slow wave potential; and **C**, action potential with plateau.

2. Plasticity

A smooth muscle exhibits the property of plasticity, i.e. it can readjust its resting length (the length at which a muscle generates maximum active tension). Thus, the smooth muscle defies the usual *length–tension relationship* that is valid for striated muscles (skeletal as well cardiac muscles); when a smooth muscle is passively stretched, it first exerts increased tension, which gradually reduces to prestretch level (even when the stretch is maintained). Therefore, the *length–tension relationship curve* in a smooth muscle is not a smooth curve but a jagged line (Fig. 2.4-10).

FIGURE 2.4-10 Plasticity in smooth muscle fibre.

It has been explained by the observation that at longer fibre lengths, the thick filaments are disposed in series (Fig. 2.4-11A) while at shorter length, the thick filaments are disposed in *parallel* (Fig. 2.4-11B).

FIGURE 2.4-11 **A**, At longer fibre length, myosin filaments are disposed in series; and **B**, at shorter fibre length, thick filaments are disposed in parallel.

3. Latch phenomenon

Latch phenomenon is another characteristic exhibited by smooth muscles. It refers to the mechanism by which a smooth muscle can maintain a high tension without actively contracting. This phenomenon allows long-term maintenance of tone in many smooth muscle organs. In

such a state, the muscle cannot generate active tension but can effectively resist passive stretching. This phenomenon appropriately suits the function of smooth muscles, since in most instances, it has to resist stretch rather than actively move a load. These smooth muscles are mostly found in the walls of hollow viscera that must resist excessive stretching. The latch phenomenon can be explained by the fact that when the myosin kinase and myosin phosphatase enzyme are both strongly activated, the cycling frequency of the myosin heads and the velocity of contraction are great. Then, as the activation of the enzymes decreases, the cycling frequency decreases, but at the same time, the lower activation of the enzymes causes the myosin heads to remain attached to the actin filaments for a larger and longer proportion of the cycling period. Therefore, the number of heads attached to the thin filament at any given time remains large. Because the number of heads attached to the actin determines the static force of contraction, tension is maintained, yet little energy is used by the muscle, because ATP is not degraded to ADP, except on the rare occasion when head detaches.

4. Marked shortening of smooth muscle during contraction

Marked shortening of smooth muscle during contraction is another characteristic of smooth muscle that makes it different from the skeletal muscle. A smooth muscle can contract more than two thirds its stretched length, while a skeletal muscle can contract up to one third its stretched length. This property allows the smooth muscle to perform, especially important, functions in the hollow viscera, allowing the gut, bladder, blood vessels and other internal bodily structures to change their lumen diameters from very large down to almost zero.

5. Energy required to sustain smooth muscle contraction

Energy required to sustain smooth muscle contraction is much less that required by a skeletal muscle. It is because of the fact that the attachment cycling of the cross-bridges is slow in smooth muscles and that only one molecule of ATP is required for each cycle, regardless of its duration.

Excitation and inhibition of smooth muscles

Excitation of smooth muscles

Multiunit smooth muscles

are stimulated only through nerves.

Single-unit smooth muscles

can be excited by several ways:

- Through nerves (i.e. by neurotransmitter such as ACh),
- By hormones (Fig. 2.4-12A and B),
- Through pacemaker (spontaneous excitation),
- Stretching (due to stretch receptor) and
- Cold temperature.

FIGURE 2.4-12 Effect of various agents on the membrane potential of smooth muscles: **A**, intestinal wall; and **B**, uterus.

Functions.

After excitations, smooth muscles perform following functions:

- Control the movement of material through most of the hollow organs.
- Propel material in the gastrointestinal tract.
- Control flow of blood in the arterioles.
- Expel material from the bladder and vas deferens.
- Control piloerection.
- Muscles of iris control the amount of light reaching the retina.

Inhibition of smooth muscles

- **Through nerves**

(i.e. by neurotransmitter epinephrine) by sympathetic stimulation, e.g. in

case of intestinal smooth muscle.

- **Through hormones,**

e.g. progesterone decreases the activity of the uterus by acting on pacemaker potential (Fig. 2.4-12A and B).

Applied Aspects

- In *Bronchial asthma*, over excitation of airway's smooth muscles leads to bronchial constriction, therefore, for quick relief, inhalers are commonly used because they deliver β -adrenergic agonist (e.g. ventoline, albuterol and sambutirol).
- *To increase blood flow*, nitric oxide (NO) is a natural molecule that relaxes smooth muscles of the blood vessels. Its mechanism of action through enzyme phosphodiesterase (PDE), which transforms cyclic guanosine monophosphate (c GMP) into GMP. The specific inhibitors of PDE V (an isoform found in corpora cavernosa of penis) like sildenafil, tadalafil and vardenafil are used for increasing blood flow to offset erectile dysfunction. For details see page 351.

Cardiac muscle

Blood and Immune System

OUTLINE

Introduction

3.1. Plasma and plasma proteins

3.2. Red blood cells and anaemias

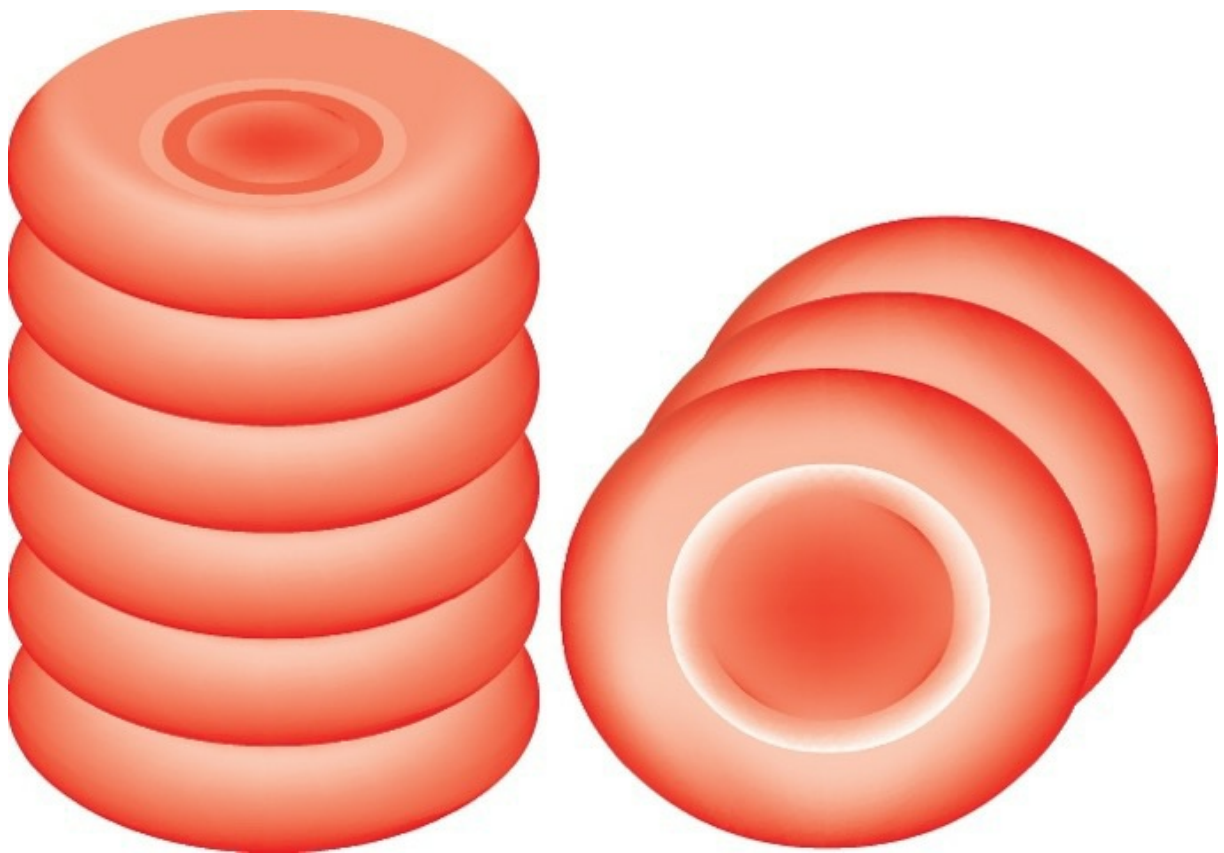

3.3. White blood cells

3.4. Immune mechanisms

3.5. Platelets, haemostasis and blood coagulation

3.6. Blood groups and blood transfusion

Introduction

Blood is a fluid connective tissue which transports substances from one part of the body to another. It provides nutrients and hormones to the tissues and removes their waste products. Blood, confined in the cardiovascular system, constitutes a major part of the extracellular fluid of the body.

Some of the important physical characteristics of blood are:

- **Colour** of blood is opaque red due to the pigment haemoglobin in the RBCs. The arterial blood is bright red and venous blood is dark red in colour.

- **Volume** of blood in an average adult is about 5–6 L (8% of the body weight or 80 ml/kg body weight).
- **Viscosity** of blood is five times more than that of water.
- **Specific gravity** of blood is 1.050–1.060. Specific gravity of RBC is greater (1.090) than that of plasma (1.030).
- **pH of blood** is about 7.4 (ranges from 7.38 to 7.42), i.e. it is alkaline in nature. In acidosis, pH of blood falls below 7.38 and in alkalosis pH is more than 7.42.

Blood is composed of two main components, plasma and cellular elements.

Plasma constitutes about 55% of the blood volume. It is a clear straw-coloured fluid portion of blood. **Plasma proteins**, an important constituent of plasma, form about 7% of its volume.

Cellular elements of blood are about 45% of the total blood volume and constitute the so-called packed cell volume (PCV).

Blood cells are:

- Erythrocytes or red blood cells (5 million/mm³),
- Leucocytes or white blood cells (4000–11,000/mm³) and
- Platelets or thrombocytes (1.5–4 lakh/mm³).

Functions of blood

1. **Nutritive function.** Blood carries the nutritive substances like glucose, amino acids, fatty acids, vitamins, electrolytes and others, from the gut to the tissues where they are utilized.

2. **Respiratory functions.** Blood picks up oxygen from the lungs and delivers it to the various tissues. The most important function of blood is the uninterrupted delivery of O₂ to the heart and brain. It also carries away CO₂ from the tissues to the lungs, from where it is expelled out in the expired air.

3. **Excretory function.** Blood transports various metabolic waste products, such as urea, uric acid and creatinine, to the excretory organs

(kidney, skin, intestine and lungs) for their disposal.

4. **Transport function.** The various hormones produced by the endocrine glands, the biological enzymes and antibodies are transported by the blood to the target tissue, to modulate metabolic process.

5. **Protective function.** Blood plays an important role in the defence mechanism of the body:

- Neutrophils and monocytes engulf the microorganisms entering the body by phagocytosis.
- Lymphocytes and gamma globulins initiate an immune response.
- Eosinophils accomplish detoxification, disintegration and removal of foreign proteins.

6. **Homeostatic function.** Blood plays an important role in maintaining the internal environment of the body (homeostatic function):

- The water content of blood is freely interchangeable with the interstitial fluid and helps in maintaining the water and electrolyte balance of the body.
- Plasma proteins and haemoglobin act as buffers, and help in maintaining the acid–base balance and pH of the body fluids.

7. **Maintenance of body temperature.** Blood plays an important role in regulation of the body temperature, as described:

- *Specific heat* of blood is high, which is useful in buffering the sudden changes in the body temperature.
- *High heat conductivity of blood* renders it possible for the

distribution of heat from deep organs to the skin and lungs for dissipation.

- Due to *high latent heat of evaporation* of blood, a large amount of heat is lost from the body by evaporation of water from the lungs and skin.

8. **Storage function.** Blood serves as a ready-made source of substances stored in it (such as glucose, water, proteins and electrolytes for use in emergency conditions like starvation, fluid loss and electrolyte loss).

Immune system

The immune system that constitutes the body's defence system consists of immunological cells distributed in two main components: mononuclear phagocytic system and lymphoid component. The immune system of the body responds to an antigen by two ways:

- **Humoral or antibody-mediated immunity (AMI)** which is mediated by antibodies produced by plasma cells.
- **Cell-mediated immunity (CMI)** which is mediated directly by the sensitized lymphocytes.

- Changes in plasma proteins in health and disease

Plasma

Plasma is the clear straw-coloured fluid (with dissolved solid substances) portion of the blood minus its cellular elements. It constitutes about 55% of the blood volume.

Composition

Plasma contains the following constituents:

Water.

Water is the main constituent of plasma, forming 91% of it.

Solids.

The solids dissolved in the plasma constitute a total of 9% of the plasma. The solid constituents of the plasma are given below.

- *Plasma proteins* form 7% of the solids in plasma. Their normal value ranges from 6.4 to 8.3 g/dL. They include albumin, globulins, fibrinogen and others.
- *Other organic molecules* which form 1% of the solids include the following:
 - *Carbohydrates*, mainly glucose (100–120 mg/dL).
 - *Fats* are neutral fats (30–150 mg/dL), phospholipids (150–300 mg/dL) and cholesterol (150–240 mg/dL).
 - *Nonprotein nitrogenous (NPN) substances* (28–40 mg/dL) are ammonia (traces), amino acids, creatine (1–2 mg/dL), creatinine (0.6–1.2 mg/dL), xanthine (traces), hypoxanthine (traces), urea (20–40 mg/dL) and uric acid (2–4 mg/dL).
 - *Hormones, enzymes and antibodies.*
 - *Inorganic substances* which constitute 1% of the solids in plasma include sodium, potassium, calcium, magnesium, chloride, iodide, iron, phosphates and copper.

Gases.

Gases present in the plasma are oxygen, carbon dioxide and nitrogen.

Serum

Plasma from which fibrinogen and clotting factors (II, V and VIII) have

been removed is called serum. Serum is formed when the blood is allowed to clot in a test tube and clot is retracted. Serum has a higher serotonin (5HT) content because of the breakdown of platelets during clotting.

Plasma proteins

Classification of plasma proteins

Plasma proteins form the major solid constituent of the plasma. The total plasma protein concentration is 7.4 g/dL (ranges from 6.4 to 8.3 g/dL). The major forms of plasma proteins are albumin, globulins and fibrinogen. Since serum is plasma minus clotting protein (fibrinogen), therefore, the albumin and globulins are usually referred to as serum albumin and serum globulins. Presently, more than 100 types of plasma proteins have been identified. The original classification is based on the classical method of precipitation of salts as described by Howe (1922). By electrophoretic techniques, the globulins have been further subclassified. Based on these, the important fractions of plasma proteins are given below:

- Albumin (4.8 g/dL),
- Globulins (2.3 g/dL) include:
 - Alpha 1 (α_1) globulin,
 - Alpha 2 (α_2) globulin,
 - Beta (β) globulin and
 - Gamma (γ) globulin.
- Fibrinogen (0.3 g/dL).

Methods of separation of plasma proteins

1. Precipitation by salting out

Different fractions of the plasma proteins are precipitated out by using different concentrations of the salts as described below.

Sodium sulphate solution was used by Howe in 1922. He fractionized the plasma proteins in three major fractions:

- *Fibrinogen* is removed with clot converting plasma into serum,
- *Globulins* are precipitated out by 22% sodium sulphate solution from the serum and
- *Albumin* remains in the serum.

Ammonium sulphate solution is utilized to precipitate the plasma protein fractions in different strengths:

- *Albumin* is precipitated by full saturation.
- *Globulins* are precipitated by half saturation. Among the globulins, there is a fraction which can be precipitated by one-third saturation with ammonium sulphate and is termed *euglobulin*. The rest is called *pseudoglobulin*.
- *Fibrinogen* is separated by one-fifth saturation with ammonium sulphate.

2. Cohn's fractional precipitation method

Varying concentrations of *ethanol* solution are used at low temperature to fractionalize the plasma proteins. Each fraction, so obtained, though being a mixture of proteins, it contains one of the proteins predominantly as given below.

- *Fraction I* is rich in fibrinogen,
- *Fraction II* mainly contains gamma globulins,
- *Fraction III* contains alpha and beta globulins, including isoagglutinins and prothrombin,
- *Fraction IV* mainly consists of alpha and beta globulins and
- *Fraction V* is rich in albumin.

3. Electrophoresis separation of protein fractions

The electrophoresis method separates the plasma proteins into different fractions, depending upon the electric charge of each fraction due to a difference in their migration rates. Serum should be used for electrophoresis, as the fibrinogen of plasma gives a discrete band which can easily be mistaken for a paraprotein.

Technique. Various techniques of electrophoresis have been developed. Depending upon the support medium used, common methods are:

- Tiselius or free boundary electrophoresis,
- Paper electrophoresis,
- Cellulose acetate strip electrophoresis and
- Agar gel electrophoresis.

Electrophoretic protein patterns. Mostly in clinical laboratories, cellulose acetate is used as a supporting medium. After resolution and staining, five bands of plasma proteins are identified. The amount of these bands can be quantified using densitometric staining techniques. On the basis of paper electrophoresis, the following classes of serum proteins (Fig. 3.1-1) are identified:

- Albumin (55%),
- Alpha-1 globulins (5%),
- Alpha-2 globulins (9%),
- Beta globulins (13%) and
- Gamma globulins (11%).

FIGURE 3.1-1 Paper electrophoresis showing: **A**, relative amount of plasma proteins and **B**, bands of different plasma proteins.

Clinical use. Electrophoretic separation is very useful in clinical diagnosis. It helps in knowing:

- The change in relative concentration of different proteins,
- The presence of abnormal proteins and
- The absence of normal proteins.

4. Immunelectrophoresis technique

This technique makes use of the antigenicity and electric charge of protein to separate them. The proteins are separated on the basis of electrophoretic patterns formed by precipitation at the site of antigen-antibody reaction. This technique is more specific and the number of

fractions obtained is much more than the ordinary electrophoresis.

5. Ultracentrifugation technique

In this technique, a suitable preparation of plasma in buffered solution is centrifuged at a speed up to 60,000 rpm and a force up to 160,000 g. The proteins are separated into fractions depending upon their *sedimentation constant*, which is the property of weight, shape and density of the protein molecules.

Three different sediments, albumin, globulin and fibrinogen, are formed. This method is also useful in determining the molecular weight of these proteins.

Properties of plasma proteins

1. Molecular weight

Plasma proteins are large molecules with the following molecular weight:

- Albumin: 69,000,
- Globulins: From 90,000 to 156,000 and
- Fibrinogen: 500,000.

Thus, fibrinogen has the highest molecular weight. Relative size and shape of different plasma proteins are shown in [Fig. 3.1-2](#).

FIGURE 3.1-2 Relative dimensions, molecular weights and shapes of different plasma proteins.

2. Osmotic pressure

The plasma proteins exert an oncotic pressure of about 25 mmHg.

3. Specific gravity

The specific gravity of the plasma proteins is 1.026.

4. Isoelectric point

Proteins can ionize either as acids or as bases owing to the fact that the side chains of their constituent amino acids contain a selection of amino group (NH_2) and carboxyl groups ($-\text{COOH}$). At an intermediate pH (specific for each protein), the protein molecules carry an equal number of positive and negative charges and hence, have a zero net charge. This pH value for electrical neutrality of the molecule is known as the *isoelectric point*.

5. Electrophoretic mobility

Proteins act as *anions* in alkaline solutions and as *cations* in acidic solutions. Because of this property, they possess electrophoretic mobility.

6. Precipitation by salts

Proteins can be precipitated by different concentrations of salts. This property of proteins is utilized for their separation by the precipitation method.

7. Water solubility

Protein molecules are soluble in water because of the presence of polar residues like NH_2 and COOH .

8. Amphoteric nature

Protein molecules are amphoteric in nature because of the presence of NH_2 and COOH groups. By virtue of their amphoteric nature, the plasma proteins act as efficient buffers.

Features of individual fractions of plasma proteins

1. Albumin.

- *Plasma levels* are 4.8 g/dL (range 3–5 g/dL).
- *Molecular weight* of prealbumin is 60,000 and that of albumin is 69,000.
- *Synthesized* in liver.
- *Half-life* is about 10 days.

2. Globulins.

- *Plasma levels* are 2.3 g/dL (range 2–3 g/dL).
- *Molecular weight* varies from 90,000 to 15,600.
- *Types* include alpha-1, alpha-2, beta-1, beta-2 and gamma globulins.
- *Forms of globulins* are described below:

i. *Glycoproteins* consist of carbohydrates and protein.

ii. *Lipoproteins* consist of alpha-2 globulin and lipids. It has got the following subtypes:

- *High-density lipoproteins (HDL)*. These are alpha lipoproteins which contain 50% protein with large amount of cholesterol and phospholipids.
- *Low-density lipoproteins (LDL)*. These are beta lipoproteins and contain large amount of glycerides.
- *Very low-density lipoproteins (VLDL)*. These are also beta lipoproteins and have higher proportion of fat in the form of triglycerides or cholesterol.
- *Chylomicron (CM)* contains 98% triglycerides. It is synthesized in the intestine following a meal.

Important Notes

The HDL level is decreased by smoking, sedentary habits and obesity, whereas exercise and moderate intake of alcohol increase the level of HDL.

iii. *Transferrin* is an alpha 2-beta globulin having a molecular weight of 90,000. It has the specific property of iron binding, and thus helps in its transport and storage. Each molecule of transferrin binds two atoms of ferric iron.

iv. *Haptoglobin (Hb–Hp)* is an alpha-2 globulin having a molecular weight of 90,000. It forms stable complexes with free haemoglobin. However, the Hb–Hp complex is too large to pass through glomerulus; thus

the function of Hb–Hp is to prevent the loss of free Hb into the urine, thereby conserving valuable iron present in the haemoglobin.

- Haptoglobin is an acute phase protein and its level is elevated in many inflammatory states.

v. *Ceruloplasmin* is an alpha 2-beta globulin having a molecular weight of 16,000. It binds with copper and helps in its transport and storage. Its deficiency causes Wilson's disease (hepatolenticular degeneration), a disease caused due to abnormal copper metabolism in which the liver and brain are damaged due to high levels of free copper.

Menkes disease is another disorder of copper metabolism that occurs due to mutation in the gene for copper binding P-Type of ATPase. It is a sex-linked disease, which affects only the male infants mainly involve the nervous system, connective tissue and vasculature, and is usually fatal in infancy. This disease is also called '*Kinky or Steely hair disease*'.

vi. *Fetuin* is a growth-promoting protein seen in infants and newborns.

vii. *Immunoglobulins* are gamma globulins which play a role in immunity.

viii. *Angiotensinogen* is an alpha-2 globulin.

ix. *Haemagglutinins* are antibodies against the red blood cells antigens.

3. Fibrinogen

- *Plasma levels* are 0.3 g/dL.
- *Molecular weight* varies from 400,000 to 500,000.
- *Synthesized* in the liver.
- *Chemical structure*. Protein part of the molecule is made up of six polypeptide chains (α_2 , β_2 and γ_2) joined by disulphide bonds.
- *Functions* as a clotting protein.

4. Prothrombin

- *Plasma levels* are 40 mg/dL.
- *Molecular weight* is 68,000.
- *Synthesized* in the liver. Synthesis is promoted by vitamin K.

Functions of plasma proteins

1. Exert osmotic pressure

Protein molecules are unable to pass across the capillary membrane and consequently exert colloid osmotic pressure of about 25 mmHg on the capillary membrane. About 70–80% of the osmotic pressure is contributed by the albumin fraction. The colloid osmotic pressure plays an important role in the exchange of water between the blood and tissue fluid as explained below:

- At the *arterial end of capillaries*, due to higher hydrostatic pressure than the colloid osmotic pressure, filtration of fluid out from vessels to tissue spaces occurs.
- At the *venous end of capillaries*, due to lower hydrostatic pressure than the colloid osmotic pressure, absorption of fluid from the tissue spaces into the vessels occurs (see page 318).

2. Contribution to blood viscosity

Plasma proteins, owing to their size and particularly their shape, greatly

contribute to the blood viscosity. Fibrinogen and globulins are significant contributors to blood viscosity because of their asymmetrical shape. The blood viscosity plays an important role in the maintenance of blood pressure by providing resistance to the flow of blood in blood vessels.

3. Role in coagulation of blood

Fibrinogen, prothrombin and other coagulation proteins present in the plasma play an important role in the coagulation of blood. Whenever there is injury to the blood vessels, fibrinogen is converted into fibrin which forms a blood clot. For details see page 210

4. Role in defence mechanism of the body

The gamma globulins are antibodies which play an important role in the immune system meant for defence of the body against microorganisms. For details see page 185

5. Role in maintaining acid–base balance of the body

Plasma proteins act as buffers and contribute for about 15% of the buffering capacity of blood. Because of their amphoteric nature, plasma proteins can combine with acids and bases as explained below:

- *In acidic pH*, the NH_2 group of the proteins acts as a base and accepts proton and is converted to NH_4^+ .
- *In alkaline pH*, the COOH group of the proteins acts as an acid and can donate a proton and thus becomes COO^- and
- *At normal pH* of blood, proteins act as acids and combine with cations (mainly sodium).

6. Transport function

Plasma proteins combine easily with many substances and play an essential role in their transport as explained below:

- *Carbon dioxide* is transported by plasma proteins in the form of carbamino compound.
- *Thyroxine* is transported by an alpha globulin called thyroxine-binding protein (TBP).
- *Cortisol* is transported by transcortin which is a mucoprotein.

- *Vitamin A, D and E* are transported by the high- and low-density lipoproteins (HDL and LDL).
- *Vitamin B12* is bound to transcobalamin for transport.
- *Bilirubin* is associated with albumin and also with fractions of the alpha globulin.
- *Drugs* of various types are transported after combining with albumin.
- *Calcium* present in the plasma is partly (50%) bound to the proteins for transport.
- *Copper* is bound to ceruloplasmin (alpha-2 globulin) for transport.
- *Free haemoglobin* in the vessels is bound by haptoglobin and carried to the reticuloendothelial system.

7. Role as reserve proteins

Plasma proteins serve as reserve proteins and are utilized by the body tissues during conditions like:

- Fasting,
- Inadequate protein intake and
- Excessive catabolism of body proteins.

8. Role in the suspension stability of the red blood cells

Suspension stability refers to the property of red blood cells by the virtue of which they remain uniformly suspended in the blood. Globulins and fibrinogen accelerate this property.

9. Fibrinolytic function

The enzymes of the fibrinolytic system digest the intravascular clot (thrombus) and thus save from the disastrous effects of thrombosis.

10. Role of nourishment of tissue cells

Plasma proteins are utilized by the leucocytes to produce substances known as *trephones* or *carrel*, which are essential for the nourishment of tissue cells.

11. Role in genetic information

Many plasma proteins exhibit *polymorphism*. Polymorphism is a Mendelian trait that exists in the population with differing prevalence. They serve as a valuable tool for the studies of population genetics. Plasma proteins that show polymorphism are haptoglobin, transferrin, ceruloplasmin and immunoglobulins.

Synthesis of plasma proteins

Site of synthesis

In an embryo, plasma proteins are synthesized by the mesenchymal cells through a process of secretion or dissolution of their substances. First, albumin is produced and then other proteins are synthesized.

In adults, plasma proteins are synthesized as described below:

- Albumin and fibrinogen are synthesized mostly by reticuloendothelial cells of the liver.
- Alpha and beta globulins are synthesized by the liver, spleen and bone marrow.
- Gamma globulins are synthesized by B lymphocytes.

Plasma proteins are generally synthesized on the membrane-bound polyribosomes. They traverse the major secretory route in the cell (rough ER membrane → smooth ER membrane → Golgi apparatus → secretory vesicle) before entering into the plasma. Thus, most plasma proteins are synthesized as preprotein form.

Factors affecting synthesis of plasma proteins

1. Dietary proteins.

Dietary proteins play the most essential role in the synthesis of plasma proteins. The relation of plasma proteins to diet was studied in plasma protein-depleted dogs first by Whipple George H in 1956 by an experiment procedure called *plasmapheresis*.

Plasmapheresis.

In this experiment, the dog is rendered hypoproteinaemic by repeatedly withdrawing whole blood and injecting back the cellular elements of the

blood (suspended in Ringer–Locke solution). This process is repeated daily till the level of plasma proteins falls to 4 g/100 ml. Thereafter, different standard diets are given and their effects on protein synthesis are studied. Following conclusions have been drawn from these experiments:

- *Dietary proteins* are essential for the synthesis of plasma proteins.
- *Chemical resemblance* of food protein amino acid with those of the plasma proteins to be synthesized determines their efficacy to synthesize a particular protein.
- *Essential amino acids* must be present in the diet for the satisfactory synthesis of plasma proteins.
- *Dietary proteins of animal origin* favour albumin synthesis.
- *Dietary proteins of plant origin* favour globulin synthesis.
- *Regeneration period.* Regeneration of plasma proteins occurs within 14 days.
- *Rate of regeneration* of plasma proteins is very fast, within first 24 h.

2. Other factors.

Other factors which effect plasma protein synthesis in the body are as follows:

- *Presence of infection* in the body reduces plasma protein synthesis.
- *Exposure to some antigen* stimulates formation of antibodies.
- *Inflammatory conditions* promote the synthesis of a number of other proteins.
- *Variation in colloid oncotic pressure* influences the albumin synthesis.
- *Interleukin-1*, a material released by the activated macrophages in the body, stimulates the synthesis of many acute phase proteins in the liver.
- *Prostaglandins* are also reported to increase the synthesis of acute phase

proteins, possibly through stimulation of macrophage release of interleukin-1.

Changes in plasma proteins in health and disease

Normal levels

- **Total proteins:** 7.4 g/dL (range 6.4–8.3 g/dL),
- **Albumin:** 4.8 g/dL (range 3.5–5.5 g/dL),
- **Globulin:** 2.3 g/dL (range 2–3.5 g/dL) and
- **Albumin: globulin ratio** (*A/G ratio*) is 1.7:1.

Physiological variations

- **In infants,** the total protein level is low (about 5.5 g/dL) due to low gamma globulins.
- **In old age,** there is a tendency for the albumin level to fall and the total globulin level to rise.
- **In pregnancy,** during first 6 months, the albumin and globulin levels decrease while the fibrinogen level increases.

Abnormalities of plasma protein levels

Hypoproteinaemia.

Hypoproteinaemia refers to generalized decrease in the levels of plasma proteins.

Causes of hypoproteinaemia

include the following:

- **Dietary deficiency** and starvation are associated with hypoproteinaemia after the body's reserve proteins are depleted.
- **Malabsorption syndrome** due to intestinal diseases, such as sprue, is associated with hypoproteinaemia.

- *Liver diseases* like hepatitis and cirrhosis cause hypoproteinaemia due to reduced synthesis of proteins in the liver.
- *Renal diseases* like nephrotic syndrome cause hypoproteinaemia due to more loss of proteins in the urine.
- *Haemorrhage and extensive burns* are associated with acute hypoproteinaemia.
- *Hereditary analbuminaemia* is an inborn defect in the genetic level, where there is no synthesis of albumin.
- *Congenital afibrinogenaemia* is a rare condition characterized by defective blood clotting.

Effects of hypoproteinaemia

Low levels of plasma proteins are associated with a decrease in the plasma osmotic pressure, which causes water retention and oedema of the body tissue.

Hyperproteinaemia.

Hyperproteinaemia, i.e. increase in the plasma protein levels, is seen in the following conditions:

- *Acute inflammatory conditions* are associated with increased synthesis of the so-called *acute phase proteins*, which include C-reactive proteins, alpha antitrypsin, haptoglobin, fibrinogen and ceruloplasmin.
- *Acute tissue destruction* as in myocardial infarction is also associated with raised levels of acute phase proteins.
- *Chronic inflammation and malignancies* are also associated with raised levels of C-reactive proteins.
- *Multiple myeloma* is associated with the increased levels of the so-called *Bence–Jones* proteins and myeloma globulin due to their abnormal formation in the bone marrow.

Reversal of normal A/G ratio

The normal albumin: globulin (A/G) ratio (1.7:1) is reversed in the following conditions:

- When albumin synthesis is decreased as it occurs in liver diseases (globulin levels being normal because many globulins are synthesized by B lymphocytes).
- When globulin levels are increased (as occurs in most of the conditions) associated with hyperproteinaemia.

 - Hepatic jaundice
 - Posthepatic jaundice

ANAEMIAS

- Definition and classification
- General clinical features
- Description of different types of anaemia
 - Iron deficiency anaemia
 - Megaloblastic anaemia

Characteristic features of red blood cells

Functional morphology

The red blood cells (mature erythrocytes) form one of the important constituents of the cellular elements of the blood. Each red blood cell (RBC), like any other cell in the body is bounded by a *cell membrane* but is *non-nucleated* and lacks the usual cell organelles. The cytoplasm of the RBC contains a special pigmented protein called the *haemoglobin* which forms 90% of the weight of the erythrocyte. The red colour of the RBCs, and thus of the blood, is due to the presence of haemoglobin.

Normal size, shape and counts of RBCs

Normal size

- *Diameter* of each RBC is 7.2 μm (range 6.9–7.4 μm),
- *Thickness* in the periphery is 2 μm and in the centre 1 μm ,
- *Surface area* of each RBC is about 120–140 μm^2 and
- *Volume* is about 80 μm^3 (range 78–86 μm^3).

Normal shape

The red blood cells are circular, biconcave discs ([Fig. 3.2-1](#)).

FIGURE 3.2-1 Size and shape of a normal red blood cell: **A**, biconcave disc (diameter $7.2\ \mu\text{m}$); and **B**, thickness ($2\ \mu\text{m}$ at the periphery and $1\ \mu\text{m}$ in the centre).

Advantages of biconcave shape are:

- It renders the red cells quite flexible so that they can pass through capillaries whose minimum diameter is $3.5\ \mu\text{m}$ (Fig. 3.2-2).
- The biconcavity provides greater surface area as compared to volume which allows considerable alterations in the cell volume. Thus, the RBC can withstand considerable changes of osmotic pressure or minimum tension is offered on the membrane when changes in volume of cells occur. In this way, the RBCs can resist haemolysis to a

certain extent when placed in hypotonic solutions.

- Greater surface area allows easy exchange of O_2 and CO_2 and rapid diffusion of other substances.

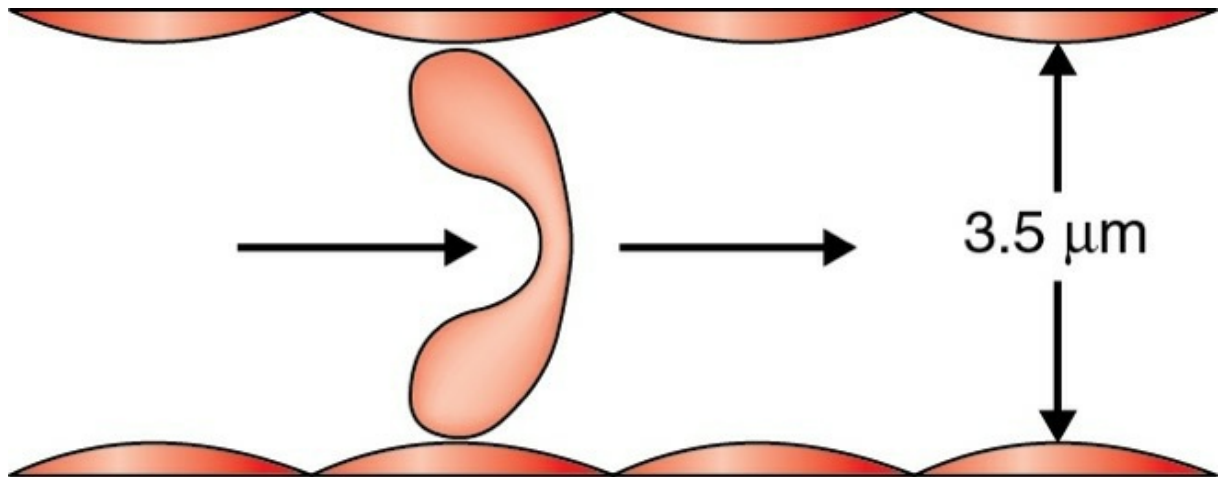

FIGURE 3.2-2 Showing how flexibility of red blood cell allows it to pass through smaller capillaries (diameter $3.5 \mu\text{m}$).

Normal counts

- *At birth*, normal RBC count is 6–7 million/ mm^3 .
- *In adult males*, the normal count varies from 5 to 6.5 million/ mm^3 (average 5.5 million/ mm^3).
- *In females*, it varies from 4.5 to 5.5 million/ mm^3 (average 4.8 million/ mm^3).
- *Clinically*, a count of 5 million/ mm^3 is considered as 100%.

Variations in size, shape and counts of RBCs

Variations in size.

Variation in size is called *anisocytosis*:

- *Microcytosis*, i.e. decrease in the size of red blood cells occurs:
- In iron deficiency anaemia,

- During prolonged forced breathing and
- When osmotic pressure of blood is increased.
- *Macrocytosis*, i.e. increase in the size of red blood cells occurs:
- In megaloblastic anaemia,
- During muscular exercise and
- When osmotic pressure of blood is decreased.

Variations in shape.

Variation in shape is called *poikilocytosis*. Abnormal shapes of the RBCs are (Fig. 3.2-3) given below:

- *Crenation or shrinkage* of RBCs is seen when they are suspended in hypertonic solution. This occurs because of the outward diffusion of water from the red blood cells.
- *Spherocyte* is a globular-shaped RBC. It is seen in a hereditary disease called spherocytosis. These cells are more fragile. Similar changes in the shape of RBCs are observed when they are suspended in hypotonic solutions.
- *Elliptocytes*, i.e. elliptical shape of the RBCs is seen in certain anaemias.
- *Sickle cell*, i.e. crescent shape of the RBCs occurs in sickle cell anaemia because of the presence of abnormal haemoglobin (haemoglobin S).
- *Poikilocytes*, i.e. unusual shapes of RBCs such as flask-shaped, hammer-shaped or other abnormal shapes occur due to deformed cell membrane.

FIGURE 3.2-3 Variations in the shapes of red blood cells: **A**, normal; **B**, crenation; **C**, spherocyte; **D**, elliptocyte; **E**, sickle cell; **F**, discocyte; **G**, stomatocyte; and **H**, echinocyte.

Variations in counts

Physiological increase in the RBC count (physiological polycythaemia) is seen in the following circumstances:

- *Age.* At birth, the RBC count is 6–7 million/mm³ of blood. After about 10 days of birth, the count decreases due to destruction of cells. This is the cause of *physiological jaundice* in the newborn. In infants, the RBC count is slightly more than that in the adults.
- *Sex.* RBC count in adult females (average 4.8 million/mm³) is lower than adult males (average 5.5 million/mm³).
- *High altitude.* RBC count of the individuals residing in high-altitude areas (above 10,000 feet from the sea level) have high RBC count (7 million/mm³) because of hypoxic stimulation of erythropoiesis.
- *Excessive exercise.* Mild hypoxia and spleen contraction cause temporary increase in the RBC count.
- *Emotional conditions* like anxiety are associated with temporary increase in the RBC count due to sympathetic stimulation.
- *Increase in atmospheric temperature* causes a temporary elevation of RBC count.

- *After meals*, the RBC count is raised slightly.

Polycythaemia

or pathological increases in RBC count (above 7 million/mm³) is of two types:

- **Primary polycythaemia** or polycythaemia vera is also called erythema, and occurs in myeloproliferative disorders, like malignancies of the bone marrow. The RBC count is persistently above 14 million/mm³ and is always associated with high WBC count.
- **Secondary polycythaemia** occurs due to certain conditions producing a state of chronic hypoxia in the body, such as:
 - Congenital heart disease,
 - Chronic respiratory disorders like emphysema,
 - Repeated mild haemorrhages and
 - Phosphorus and arsenic poisoning.

In polycythaemia, haematocrit may be raised up to 60–70% and total blood volume also increases. As a result, there is engorgement of the entire vascular system. Blood viscosity also increases (three times as that of normal).

Effects of polycythaemia

Greater increase in blood viscosity is responsible for:

- Thrombosis:* The incidence of thrombosis increases because the blood flow through peripheral vessels becomes sluggish.
- Increase in arterial pressure* due to rise in total peripheral resistance.
- Ruddy complexion:* A person with polycythaemia vera has a ruddy complexion due to increased RBC count with a blueish tint (cyanotic) to the skin due to increased deoxygenated Hb, as a result of the sluggish blood flow through the skin capillaries.

Physiological decrease in RBC count

is seen in the following conditions.

- *At high barometric pressure*, the RBC count is decreased slightly due to high O₂ tension of the blood.
- *After sleep*, the RBC count is decreased slightly.
- *In pregnancy*, there occurs relative reduction in RBC count due to haemodilution caused by increase in the plasma volume.

Anaemia.

In anaemia, there may occur marked reduction in the RBC count, or the haemoglobin level, or both (see page 156).

Packed cell volume and red cell indices

The red cell indices or absolute values (blood standards) include the entities mean corpuscular volume (MCV), mean corpuscular haemoglobin (MCH) and the mean corpuscular haemoglobin concentration (MCHC). These indices are quite helpful in diagnosing the type of anaemia. These indices are calculated from the values of packed cell volume, the haemoglobin concentration and the red cell count.

Packed cell volume

Packed cell volume (PCV) refers to the percentage of the cellular elements (RBCs, WBCs and platelets) in the whole blood. Since the volume of WBCs and platelets is very less, so for all practical purposes the PCV is considered equivalent to the volume of packed red cells (VPRC), or the so-called *haematocrit value*. However, in conditions where the number of WBCs is markedly increased, the values of PCV differ from that of the VPRC (haematocrit values). The normal values of PCV in males are about 45% and in females about 42%. The VPRC is increased in polycythaemia and decreased in anaemia.

Determination of PCV.

The blood is mixed with anticoagulant oxalate and is centrifuged in a graduated tube called the *haematocrit tube* or the Wintrobe tube (Fig. 3.2-4) at a speed of 3000 rpm for about 30 min. The heavier red blood cells settle at the bottom leaving clear plasma above. The white blood cells and platelets which constitute only about 1% of the volume of blood are seen as a thin white layer called *buffy coat* on the top of the red cell mass.

- *Observed haematocrit* is the value of haematocrit obtained by the above

described method.

- *True haematocrit* is calculated by multiplying observed haematocrit by 0.98. It is calculated because even if the red cells are fully packed, about 2% of plasma is trapped in between the cells.
- *Body haematocrit* is present in large and small blood vessels. It is calculated by multiplying the observed haematocrit with 0.87. It is calculated because the haematocrit is estimated from the venous blood whose haematocrit is greater than the whole body. In general, haematocrit in larger vessels is more than in the smaller vessels.

FIGURE 3.2-4 Wintrobe's tube showing packed cell volume.

Red cell indices

The red cell indices defined below are calculated taking normal values of RBC count 5 million/mm³, PCV 45% and haemoglobin (Hb) level of 15 g/dL.

1. Mean corpuscular volume.

The mean corpuscular volume (MCV) refers to the average volume of a single red blood cell. It is calculated by dividing the packed cell volume (PCV) by the red cell count.

$$\begin{aligned} \text{MCV} &= \frac{\text{PCV in 1000 ml of blood, i.e. (PCV} \times 10)}{\text{RBC count/mm}^3} \\ &= \frac{45 \times 10}{5} = 90 \mu\text{m}^3 \end{aligned}$$

- One cubic micrometer (mm³) is equal to one femtolitre (fL).
- Normal value of MCV is 90 μm³ (range 78–94 μm³) when the MCV value is normal is referred as *normocytosis*.
- Decreased value of MCV occurs in *microcytosis*.
- Increased value of MCV occurs in *macrocytosis*.

2. Mean cell (corpuscular) haemoglobin.

Mean cell haemoglobin (MCH) refers to the average weight of haemoglobin (Hb) contained in each red blood cell. It is calculated by dividing the amount of Hb in 1 L of blood by the red cell count in 1 L of blood.

$$\begin{aligned} \text{MCH} &= \frac{\text{Hb gm/L}}{\text{RBC count/L}} = \frac{\text{Hb g/dL} \times 10}{\text{RBC count/mm}^3 \times 10^{12}} \\ &= \frac{15 \times 10}{5 \times 10^{12}} = 30 \times 10^{-12} \text{ gm.} \\ &= 30 \text{ pg [since } 10^{-12} \text{ gm = one picogram (pg)]} \end{aligned}$$

- *Normal value of MCH* is 30 pg (range 27–33).
- *Increased values of MCH* occur in spherocytosis and megaloblastic anaemia.
- MCH is not used to find out the type of anaemia.

3. Mean cell (corpuscular) haemoglobin concentration.

The mean cell haemoglobin concentration (MCHC) refers to the amount of Hb expressed as percentage of the volume of a RBC. It is calculated by dividing the amount of Hb in g/dL by the volume of packed cells in 100 ml of blood and then multiplying by 100.

$$\text{MCHC} = \frac{\text{Hb g/dL}}{\text{PCV/100 ml}} \times 100 = \frac{15}{45} \times 100 = 33.3\%$$

- *Normal values of MCHC* are 33.3% (range 30–38%). RBCs with normal value of MCHC are called *normochromic*.
- *In hypochromic RBCs*, the values of MCHC are less than the normal, as is seen in iron deficiency anaemia.
- *Hyperchromia* is very rare, high levels of MCHC (>38%) cannot occur, since the RBCs cannot hold Hb beyond the saturation point.
- Since MCHC is independent of RBC count and size of RBCs, it is considered to be of greater clinical significance compared with other absolute values.

4. Colour index.

The colour index (CI) refers to the ratio of haemoglobin to RBC. For calculating CI, Hb of 14.8 g/dL is taken as 100% and RBC count of 5 million/mm³ is taken as 100%.

$$\text{CI} = \frac{\text{Percentage of normal Hb}}{\text{Percentage of normal RBC count}} = \frac{100}{100} = 1$$

For example, if the Hb level is 14.8 g/dL, i.e. 100% of normal values and RBC count is 4.5 million, i.e. $4.5 \times 100 = 90\%$ of the normal values, then $CI = 100/90 = 1.11$.

- Normal values of colour index vary from 0.85 to 1.15.
- Colour index is insignificant because normal range of RBC is very wide. Therefore, it has been long abandoned and is not used for any diagnostic purposes.

Rouleaux formation and erythrocyte sedimentation rate

Rouleaux formation

- Rouleaux formation refers to the tendency of RBCs to pile-up one over the other like a pile of coins (Fig. 3.2-5). The discoid shape and protein coating of red cells play a major role in Rouleaux formation. Rouleaux formation does not occur in normal circulation under physiological conditions, as the moving cells show little or no tendency to adhere. However, within a blood vessel, in the absence of significant flow and when the blood is taken out, the red cells tend to form Rouleaux.
- This is a reversible phenomenon, but it promotes sedimentation of RBCs. It should not be confused with agglutination where the cells are irreversibly clumped.
- Albumin decreases the Rouleaux formation, while fibrinogen, globulin and other products of tissue destruction increase Rouleaux formation.

FIGURE 3.2-5 Rouleaux formation.

Erythrocyte sedimentation rate

Erythrocyte sedimentation rate (ESR) is the rate at which the red blood cells sediment (settle down) when the blood containing an anticoagulant is allowed to stand in a vertically placed tube. It is expressed in millimetre at the end of the first hour.

Methods of determination of ESR

1. Westergren's method.

A total of 1.6 ml of blood diluted with 0.4 ml of 3.8% sodium citrate (making a total of 2 ml) is loaded in the Westergren pipette which is then fitted to stand vertically. The reading is taken after 1 h. The Westergren tube is 30 cm long and is open at both the ends ([Fig. 3.2-6A](#)).

FIGURE 3.2-6 Westergren's pipette (A) and Wintrobe's tube (B) used for determining erythrocyte sedimentation rate (ESR).

2. Wintrobe's method.

About 1 ml of blood mixed with anticoagulant EDTA is loaded in a Wintrobe tube up to '0' mark and the reading is taken after 1 h. The Wintrobe tube is 11 cm long and is open only at one end (Fig. 3.2-6B).

Note. *Since the Westergren pipette is longer, chances of an error in measurement of ESR is reduced. Therefore, Westergren's method is preferred over Wintrobe's method for estimation of ESR.*

Clinical significance of ESR

- *Normal values* of ESR by Westergren's method in males vary from 3 to 7 mm and in females from 5 to 9 mm in the first hour.

- Values of ESR are raised in a large number of pathological conditions, so it has got no specific diagnostic value. However, raised levels of ESR do suggest presence of some chronic inflammatory condition in the body.
- Estimation of ESR is more useful as a *prognostic test*, i.e. to judge the progress of the disease in patients under treatment.

Factors affecting ESR

- *Rouleaux formation*. Increased tendency of Rouleaux formation raises the erythrocyte sedimentation rate. Fibrinogen and the proteins, which enter the plasma in inflammatory (globulins) and neoplastic diseases, favour Rouleaux formation and thus increase ESR. Increase in MCV, decrease in MCH and spherocytosis retard Rouleaux formation and thus decrease ESR.
- *Size of the red blood cells*. Increase in the size of the RBCs (macrocytosis) raises the ESR.
- *Number of red blood cells*. When the number of RBCs increased, the ESR is decreased and when the number of RBCs is decreased (as in anaemia), the ESR is increased.
- *Viscosity of blood*. ESR is increased when the viscosity of blood is decreased and vice versa.

Physiological variations in ESR

- *Age*. ESR is less in infants and old people compared with young adults.
- *Sex*. ESR is greater in females (5–9 mm) than males (3–7 mm).
- *Menstruation*. ESR is slightly raised during menstruation in females.
- *Pregnancy*. ESR is raised in pregnancy from third month to parturition and returns to normal after 3–4 weeks of delivery.

Pathological variations in ESR

Increase in ESR is seen in the following pathological conditions:

- Tuberculosis,

- Malignant diseases,
- Collagen diseases,
- All anaemias except sickle cell anaemia and
- Chronic infections.

Decrease in ESR occurs in the following pathological conditions:

- Polycythaemia
- Decreased fibrinogen levels,
- Sickle cell anaemia,
- Allergic conditions and
- Peptone shock.

Red cell membrane, composition and metabolism of red blood cells

Red cell membrane

Structure

- Red cell membrane is a *trilaminar structure* having a bimolecular lipid layer interposed between the two layers of proteins (Figs 3.2-7 and 1.2-2).
- *Important lipids* of the cell membrane are glycolipids, phospholipids and cholesterol.
- *Proteins* in the cell membrane are present as peripheral proteins and integral proteins spanning the whole membrane.
- The outer peripheral protein surface is rich in *lecithin and sphingomyelin*.
- The important membrane spanning integral proteins

include an anion exchange protein (*band 3*) and *glycophorins* which contain a number of polysaccharide *blood group antigens*.

- *Band-3* is a transmembrane glycoprotein with its carboxyl terminal end (towards external surface) and its amino terminal end (towards cytoplasmic surface), extending across the bilayer at least 10 times, therefore, also called multipass membrane protein. It forms a tunnel permitting exchange of Cl^- for HCO_3^- . The cytoplasmic amino acid terminal binds many proteins (4.1, 4.2, ankyrin, several glycolytic enzymes and also haemoglobin).
- *Glycophorins A, B and C* are single pass type of transmembrane proteins. The amino acid terminal extrude out from the surface of RBCs which contain polysaccharides (blood group antigens). The carboxyl terminal end extends into the cytosol and binds to protein 4.1, which in turn binds to spectrin.
- The inner surface of the cell membrane contains more phosphatidylserine and phosphatidyl ethanolamine. The peripheral proteins like spectrin, ankyrin and actin present on the inner surface of the membrane help in maintaining the shape and flexibility of the RBC. *Spectrin* is the major protein of the cytoskeleton; protein 4.1 binds both to spectrin and actin and also interacts with certain phospholipids (thereby connecting the cytoskeleton to the lipid layer).

FIGURE 3.2-7 Schematic diagram showing ultra-structure of red cell membrane.

Applied Aspects

Abnormalities in the amount or structure of spectrin cause hereditary spherocytosis or elliptocytosis. *Hereditary spherocytosis* is a genetic disease transmitted as an autosomal dominant trait, which affects about 1: 5000 North Americans. It is characterized by spherocytes (spherical RBCs with low surface area to volume ratio) in the peripheral blood. The spherocytes are nondeformable structures susceptible to osmotic lysis. Their lifespan is shorter than normal RBCs.

Hereditary elliptocytosis is also a genetic disorder similar to hereditary spherocytosis. In this condition, red cells assume an elliptical or disc-like shape. It also occurs due to abnormality of spectrin or 4.1 or glycophorin C.

Permeability.

The red cell membrane is a *semi-permeable membrane*, allowing some substances to pass through and preventing some.

- *Impermeable* to sodium, calcium and barium ions, to fats and sugars;
- *Slightly impermeable* to amino acids; and
- *Freely permeable* to all anions like Cl^- , SO_4^- and HCO_3^- , and to urea, ammonia, aldehyde, alcohol and bile salts.

Composition of red blood cells

The body of RBCs bounded by the cell membrane contains a sponge-like stroma which is composed of the following structures:

- *Water* constitutes 60% of the wet weight of RBC.
- *Haemoglobin*, held in the meshes of stroma, constitutes 35% of the wet weight and 90% of the dry weight of RBC.
- *Lipids* form the major constituents of the rest of 5% of stroma. These include cephalin, lecithin and cholesterol.
- *Proteins* include glutathiones and an albumin-like insoluble protein. These act as reducing agents preventing damage to the haemoglobin.
- *Lipoproteins*. Almost half of the lipids are bounded to the protein forming a lipoprotein complex known as *elenin (Calvin)*.
- *Enzymes* of the glycolytic system, catalase, carbonic anhydrase and other enzymes and inorganic salts are also present in the RBC.
- *Glucose and amino acids* are present in small amounts.
- *Ions*. Anions of the plasma (Cl^- , PO_4^- , HCO_3^-) are present often in large amounts. The cations Na^+ and Ca^{2+} are either present in very small amount or are absent. Cation K^+ is present in sufficient amount inside the RBC.
- *Nonprotein nitrogenous (NPN) substances*. Urea, NH_4 , creatine and uric acid have a higher concentration inside the RBC than the plasma.

Metabolism of red blood cells

Glucose, taken up by facilitated diffusion, is the only fuel utilized by the RBC. The mature RBC has a low respiratory quotient and consumes very little oxygen. The glucose metabolism and its special significance in RBC are described below:

Embden–meyerhof pathway

is responsible for 90% of the glycolysis. Two molecules of ATP are generated from each molecule of glucose. Special significance of this pathway is given below.

2,3-Biphosphoglycerate (2,3-BPG) synthesized in a side reaction in this pathway influences the oxygen affinity of haemoglobin and thus plays an important role in the red cell physiology. Factors affecting 2,3-BPG concentration in RBC include the following:

- Acidaemia hinders glycolysis and thereby decreases 2,3-BPG synthesis.
- Hypoxia prevents Krebs' cycle and thereby increases 2,3-BPG synthesis.
- Thyroid hormone, androgens and growth hormone increase 2,3-BPG concentration.

Hexose monophosphate (HMP) shunt

oxidizes about 10% of glucose. Special significance of this pathway in RBC metabolism is given below:

- NADPH generated by this pathway keeps the glutathione in reduced form. Reduced glutathione, in turn protects sulphhydryl groups in haemoglobin and RBC membrane from oxidation by peroxides, superoxide, drugs and toxins.
- *Glucose-6 phosphate dehydrogenase (G6PD)* is the key enzyme in the HMP shunt. Inherited deficiency of this enzyme leads to compromise of RBC function and viability in the face of such oxidant stress; thus causing a number of disorders characterized by susceptibility to haemolysis (see page152).

Utilization of ATP

- A major portion of ATP obtained through glycolysis is utilized in maintaining the Na^+/K^+ ATPase pump.
- Some of the energy is utilized in maintaining the integrity of the red cell membrane.
- Some of the energy is spent in maintaining the haemoglobin iron in reduced form (Fe^{2+}).

Formation of red blood cells

Formation of red blood cells is a part of the process of development of blood cells (RBCs, WBCs and platelets) called *haemopoiesis* which includes:

- Erythropoiesis, i.e. development of RBCs,
- Leucopoiesis, i.e. development of WBCs and
- Thrombopoiesis or megakaryocytopoiesis, i.e. development of platelets.

Sites of haemopoiesis

- *In the first 2 months of gestation*, the *yolk sac* is the main site of haemopoiesis (*mesoblastic stage*) (Fig. 3.2-8).
- *From the third month of gestation*, the liver and spleen become the main sites of blood formation and continue to do so till birth. The spleen makes a small contribution as compared to the liver (*hepatic stage*).
- *From the 20th week of gestation*, haemopoiesis begins in the bone marrow and by the seventh or eighth month, it becomes the main site (*myeloid stage*).
- *At birth* (in normal full-term), almost whole of the haemopoiesis occurs in the bone marrow.
- *In young children*, active haemopoietic bone marrow is found in both axial skeleton and bones of extremities. The active haemopoietic bone marrow is red in colour due to marked cellularity and hence is called *red bone marrow*. However, during this period, there occurs a progressive fatty replacement throughout the long bones converting red bone marrow into the so-called *yellow bone marrow*.
- *In adults*, therefore, haemopoietic (red) bone marrow is confined to *axial skeleton* (skull, vertebrae, sternum, ribs, sacrum and pelvis) and *proximal ends of long bones* (humerus, femur and tibia). Even in these haemopoietic areas, about 50% of the bone marrow consists of fat. The differences between red and yellow bone marrow are summarized in Table 3.2-1.

- In adults, during pathological conditions, when there is an increased demand of blood cells, the *nonhaemopoietic (yellow) marrow* is capable of reverting back to active haemopoiesis.
- During pathological conditions, when the increased demand of blood cells cannot be met by the hyperactivity of bone marrow alone, even the liver and spleen resume their fetal role of haemopoiesis, as the stem cell retains its potential haemopoietic activity. Such a situation is referred to as *extra medullary haemopoiesis*.

FIGURE 3.2-8 Sites of haemopoiesis during different periods in human life: **A**, yolk sac; **B**, liver; **C**, spleen; and **D**, bone marrow.

TABLE 3.2-1

Differentiating Features of Red and Yellow Bone Marrow

Red bone marrow	Yellow bone marrow
1. Red bone marrow is red in colour and active haemopoietic tissue.	1. Yellow bone marrow is yellowish in colour and inactive.
2. Cellularity is marked. It contains different stages of all types of developing blood cells.	2. Cellularity is very less and replaced by fatty tissue.
3. Red bone marrow is present in axial skeleton (skull, vertebrae, sacrum, sternum and pelvis) and long bones in children.	3. In adults, except ends of long bones and axial skeleton, all other bones contain yellow bone marrow.

Blood cell precursors

The stem cells.

The *monophyletic theory* of haemopoiesis is now widely accepted, according to which all blood cells originate from a single ancestral cell called *pluripotent* or *multipotent stem cell*. The stem cells have the appearance of small or intermediate-sized lymphocytes. Stem cells possess two *fundamental properties*:

- *Self-replication*, i.e. stem cells are capable of cell division to give rise to more stem cells, and
- *Differentiation and commitment*, i.e. the stem cells have the ability to differentiate into specialized cells called *progenitor cells* (committed stem cell).

Progenitor cells.

The stem cells, after a series of divisions differentiate into progenitor cells:

- *Pluripotent progenitor cells* which can give rise to any type of blood cells,
- *Lymphoid (immune system)* stem cells which ultimately develop into lymphocytes, and
- *Myeloid (trilineage) stem cells* which later differentiate into three types of cell lines:
 - *Granulocyte–monocyte progenitors* which produce all leucocytes except the lymphocytes,
 - *Erythroid progenitors* which produce red blood cells, and

- Megakaryocyte progenitors which produce platelets.

Features of progenitor cells.

Morphologically, the progenitor cells present in the bone marrow cannot be differentiated from the stem cells, as they both look alike. However, they can be differentiated by immunological techniques, taking advantage of the different types of molecules present on their cell membrane.

Progenitor cells possess ability to give rise to clones (group of cells), so they are also called colony-forming cells (CFC) or colony-forming units (CFU). The three types of progenitor cells are given:

- **CFU-GEMM** (colony-forming unit–granulocyte, erythroid, megakaryocyte, macrophage) refers to a multipotent progenitor cell, i.e. *myeloid progenitor cells*.
- **BFU-E** (burst-forming unit–erythroid) form large colonies of erythroid series.
- **CFU-E** (colony-forming unit–erythroid) develops into erythrocytes.
- **Ba-CFU** refers to basophil colony-forming units.
- **Eo-CFU** are eosinophil colony-forming units.
- **M-CFU** refers to monocyte colony-forming units.
- **G-CFU** are neutrophil-forming units.

The broad outlines of haemopoiesis discussed above are summarized in [Fig. 3.2-9](#). Further details of erythropoiesis are discussed in this chapter and details of development of other blood cells are discussed in the relevant chapters.

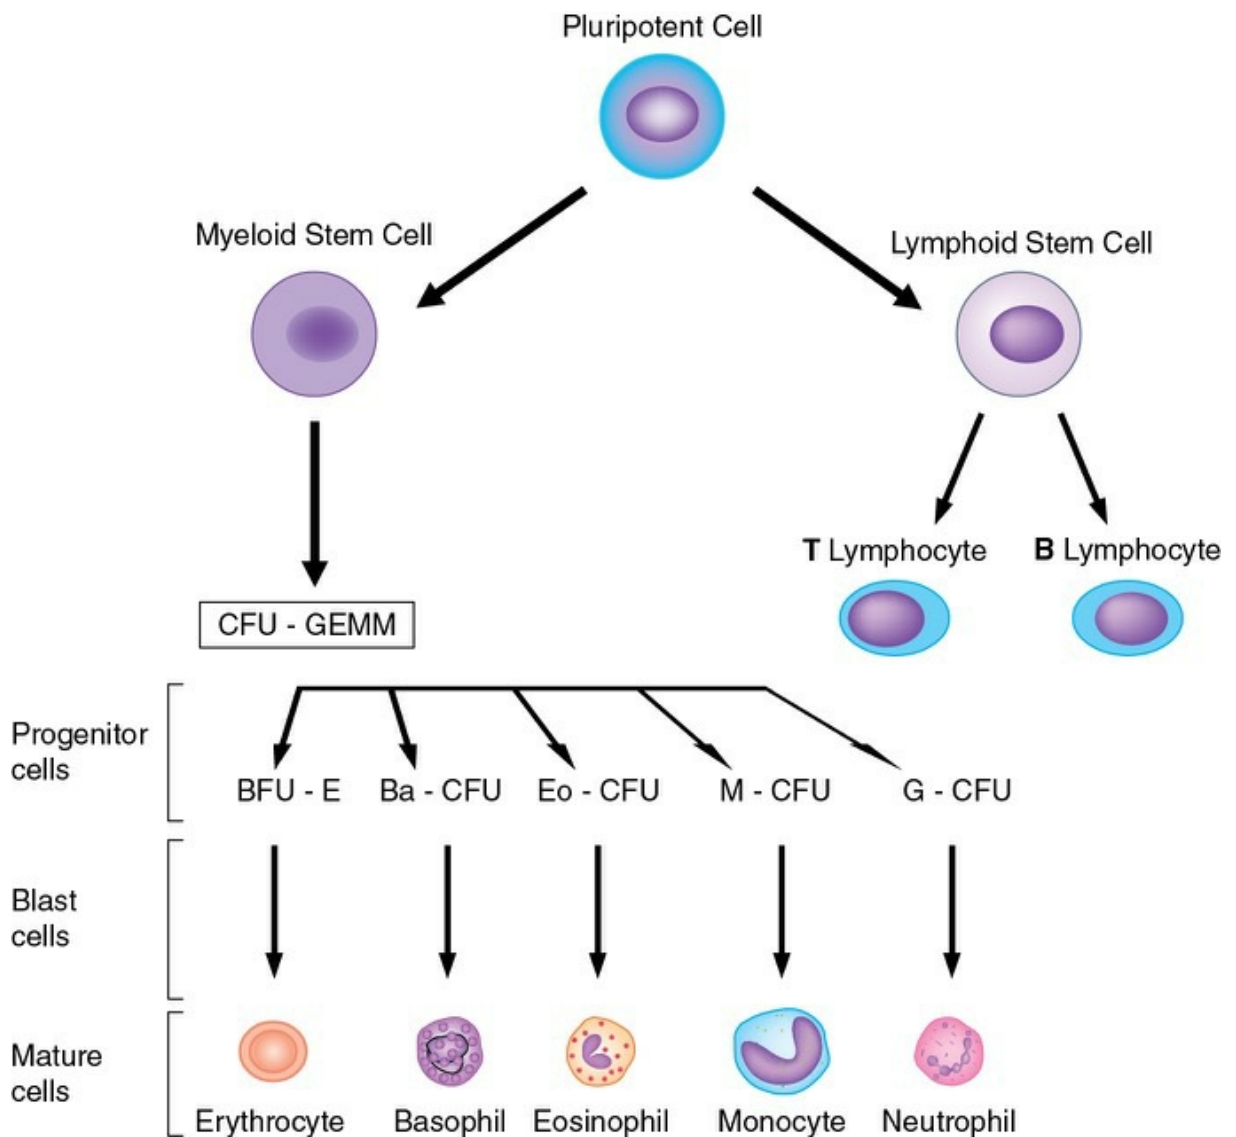

FIGURE 3.2-9 Schematic broad outline of haemopoiesis.

Bone marrow examination.

The red bone marrow contains the stem cells, progenitor cells, colony-forming cells and various types of blood cells in different stages of development, which can be observed in a stained smear of red marrow obtained from the iliac bone or sternum (Fig. 3.2-10). Normally, in the red marrow the haemopoietic stem cells comprise only 0.01–0.5% of the total marrow population. About 75% of the cells are immature white cells and about 25% of the cells are immature red cells, thus forming a ratio of 3:1; while in peripheral blood the ratio of white and red cells is 1:600. This vast difference is because the lifespan of red cells is far greater than that of the white cells.

FIGURE 3.2-10 Smear from red bone marrow showing various types of cells at different stages of development.

Control of haemopoiesis

The growth of different blood cells from the stem cells is controlled and regulated by the haemopoietic growth factors, which in general are called *cytokines*. Cytokine is a general term used to denote the proteins released by cells that act as intercellular mediators. The cytokines which control the formation of different types of blood cells are called *colony stimulating factors (CSF)*, which are given below:

- *G-CSF* stimulates granulocytic precursors,
- *M-CSF* stimulates monocytic precursors,
- *GM-CSF* stimulates both the granulocytic and monocytic precursors.
- *Interleukins (1L)* refer to the cytokine stimulating lymphocytic precursor, for example, IL-1, IL-3, etc.
- *Erythropoietin* refers to the cytokine stimulating the erythroid series of cells.

Stages of erythropoiesis

The red blood cells develop from the burst-forming unit-erythrocyte (BFU-E) and colony-forming unit-erythrocyte (CFU-E) which are derived from the committed progenitor cells.

The well-defined and readily recognizable lineages of nucleated red cells (erythroid series) which form different stages of erythropoiesis (Fig.

3.2-11, Table 3.2-2) are as under:

TABLE 3.2-2
Characteristic Features of Cells at Different Stages of Erythropoiesis

Stage	Size (µm)	Nucleus	Cytoplasm		Mitosis
			Hb	Staining	
1. <i>Homocytoblast (stem cell)</i>	19–23	<ul style="list-style-type: none"> • Very large (almost occupying whole of the cell) • Deep basophilic • Containing 4–5 nucleoli 	Absent	Deep basophilic	Present++
2. <i>Pronormoblast (proerythroblast)</i>	15–20	<ul style="list-style-type: none"> • Large (central) • Deep basophilic • Fine reticular chromatin • 2–3 nucleoli 	Absent	Scanty and deep basophilic	++
3. <i>Early normoblast</i>	12–16	<ul style="list-style-type: none"> • Large • Chromatin strand becomes thicker and coarser • Nucleoli disappears 	Absent	Still basophilic	++
4. <i>Intermediate normoblast (polychromatic normoblast)</i>	10–14	<ul style="list-style-type: none"> • Nucleus becomes condensed, coarse and basophilic • Nucleoli absent 	Appears	Acidophilic with basophilic hue (polychromatic)	+
5. <i>Late normoblast (orthochromatic normoblast)</i>	8–10	<ul style="list-style-type: none"> • Nucleus small, pyknotic with dark chromatin (cart-wheel appearance) • Nucleoli absent 	Increased in amount	Acidophilic	Absent
6. <i>Reticulocyte</i>	7–7.5	<ul style="list-style-type: none"> • Nucleus absent • With supravital stain (brilliant cresyl blue) remnants of RNA appear in the form of reticulum in the cytoplasm 	Increased in amount	Acidophilic	Absent

1. Pronormoblast or proerythroblast

is the earliest recognizable cell of the erythroid series seen in the red bone marrow. Its features are the following:

- *Size* is large with a diameter of 15–20 µm.
- *Cytoplasm* is scanty and deeply basophilic. The deep blue colour of cytoplasm is due to high content of RNA which is associated with active protein synthesis.
- *Nucleus* is large, central with a fine reticular chromatin and contains many nucleoli.
- *Haemoglobin* is absent at this stage.

- *Mitosis* is seen in these cells.

2. Early (basophilic) normoblast

(basophilic early erythroblast). The pronormoblast progresses into the early normoblast, which is a round cell having the following features:

- *Size* is large with a diameter of 12–16 μm .
- *Cytoplasm* is scanty and still basophilic.
- *Nucleus* is large, chromatin strands are thicker and coarse and nucleoli have disappeared.
- *Haemoglobin* is not present.
- *Mitosis* is seen. The basophilic normoblasts undergo rapid proliferation.

3. Intermediate (polychromatic) normoblast

(polychromatic erythroblast) is the next maturation stage in the erythroid series. Its features are the following:

- *Size* is about 10–14 μm .
- *Cytoplasm* becomes polychromatic, i.e. contains admixture of basophilic RNA and acidophilic haemoglobin.
- *Nucleus* becomes condensed, coarse and deeply basophilic with no nucleoli.
- *Haemoglobin* appears.
- *Mitosis* is still present.

4. Late (orthochromatic) normoblast

(orthochromatic erythroblast) is the last nucleated cell of the erythroid series. Its features are the following:

- *Size* is reduced to 8–10 μm .
- *Cytoplasm* is characteristically acidophilic with diffuse basophilic hue.
- *Nucleus* at this stage is small, pyknotic with dark chromatin.

- *Haemoglobin* increases in amount.
- *Mitosis* is absent at this stage.

5. Reticulocyte

is the last stage in the formation of erythrocytes, which is why it is also called young red cell. Its features are the following:

- *Size and shape.* The reticulocyte is a flat, disc-shaped, slightly larger (7–7.5 μm) than the mature erythrocytes.
- *Cytoplasm* still contains small amounts of RNA. With supervital stain such as brilliant cresyl blue, the RNA appears in the form of a reticulum (net-like structure) and because of this character the cell is called a reticulocyte. With Romanowsky stain, the cytoplasm gives a faint polychromatic tint.
- *Nucleus* is absent, the reticulocyte results when the nucleus is extruded from the late normoblast within the marrow.
- *Haemoglobin* increases in amount equal to that present in a mature erythrocyte.
- *Mitosis* is absent.

Maturation of reticulocyte into erythrocyte.

The reticulocytes are juvenile red cells devoid of nucleus but contain ribosomal RNA so that they are still able to synthesize haemoglobin. A reticulocyte spends 1–2 days in marrow and circulates for 1–2 days in the peripheral blood before maturing in the spleen, to become a biconcave red cell. The mature red cell has lost its nucleus, as well as the ribosomes and mitochondria. It thus cannot synthesize haemoglobin and any other protein. The immature cells in various stages of development are found outside (around) the blood sinusoids of the bone marrow. Normally, only mature blood cells are able to enter the circulation. The reticulocytes are also found normally in the peripheral blood. Normal range of reticulocytes in healthy adults is 0.5–2% and in infants is 2–6%.

Abnormal increase in circulating reticulocytes is called *reticulocytosis*. This is seen when the rate of erythropoiesis is very high, as occurs in haemolytic anaemia and following the treatment of deficiency anaemias.

The reticulocytes in the peripheral blood are distinguished from

mature red cells by a slightly basophilic hue in the cytoplasm, similar to that of an orthochromatic normoblast. Reticulocytes can be counted in the laboratory by vital staining with dyes, such as new methylene blue or brilliant cresyl blue.

Summary of changes occurring in cells of erythroid series during maturation.

It takes 7 days for the formation and maturation of red blood cells. Till the reticulocyte stage,, it takes 5 days and to become a matured red cell from the reticulocyte, it takes 2 days. Various changes which occur during maturation from the pronormoblast to the erythrocyte stage are summarized below:

- **Size** of the cell (from 15–20 μm of pronormoblast) goes on decreasing with subsequent stages till it reaches about 7 μm .
- **Nucleus** first condenses, then becomes pyknotic and finally disappears at the stage of reticulocyte formation.
- **Haemoglobin synthesis** starts at the stage of intermediate normoblast and then its content increases progressively.
- **Cytoplasm staining.** Initially, before the appearance of haemoglobin, the cytoplasm is basophilic. When haemoglobin starts appearing cytoplasm becomes polychromatic, i.e. stained both by acidic and basic dyes. In the stage of late normoblast when haemoglobin synthesis is almost completed, cytoplasm is stained by acidic dye.
- **Mitosis** is seen up to the stage of intermediate normoblast. During these stages, 3–5 cell divisions occur. In this way, each pronormoblast gives rise to 8–320 late normoblasts. From the stage of late normoblast onwards, the mitosis ceases and the cell only matures.

Regulation of erythropoiesis

Erythropoietin.

Erythropoietin is a hormone which regulates the process of erythropoiesis. It is a glycoprotein having a molecular weight of 34,000.

Site of formation.

Erythropoietin is mainly (85%) produced by the juxtaglomerular

apparatus of the kidney. Extrarenal sources like the liver and cells of the tissue macrophage system produce about 15% of erythropoietin, especially when hypoxia is marked.

Stimulus for secretion.

A certain basal level of the hormone is necessary for the normal rate of erythropoiesis. The main function of the red blood cells is to supply oxygen to the tissues. Therefore, whenever, there is hypoxia or a decrease in the number of red blood cells (e.g. after haemorrhage or in haemolytic anaemia), there occurs a release of renal erythropoietic factor from juxtaglomerular cells of the kidney. The renal erythropoietic factor acts on the plasma alpha globulin called erythropoietinogen to form the erythropoietin (Fig. 3.2-12). Thus, the levels of erythropoietin vary with degree of hypoxia or the number of circulating red blood cells. This explains how polycythaemia (increased red blood cell count) is observed in hypoxic states such as in normal individuals residing at high altitude or in patients suffering from cardiopulmonary disorder. On the other hand, if the number of red blood cells in circulation is more, e.g. after transfusion of blood in a normal person, the erythropoietin formation is decreased. For details see page 796.

FIGURE 3.2-12 Mechanism of erythropoietin secretion.

Actions of erythropoietin.

Erythropoietin increases erythropoiesis by acting at the site of erythropoiesis (It may be yolk sac, liver, spleen and bone marrow depending upon the age). Erythropoietin, along with co-operation of other factors (e.g. interleukin-3 and insulin-like growth factor) promotes erythropoiesis because of its following actions:

- Erythropoietin exerts its chief effect on the stem cells causing them to differentiate into burst-forming units (BFU-E).

- It promotes haemoglobin synthesis by increasing globin synthesis and potentiating δ -aminolevulinic acid synthetase.
- It also promotes every stage of maturation from pronormoblast to the mature red cells.
- Erythropoietin also promotes release of RBCs from bone marrow into the peripheral circulation.

Mechanism of action.

Erythropoietin (EPO) acts by binding to specific receptors present on the surface of erythroid precursor cells. For further details see page 796.

Factors increasing erythropoietin secretion.

The degree of oxygenation and number of RBCs in circulation act as feedback mechanisms to control the secretion of erythropoietin, i.e. depending upon the condition, they either increase or decrease erythropoietin secretion to normalize the erythropoiesis. Other factors which increase secretion of erythropoietin are:

1. Hormones

which increase erythropoietin secretion are:

- *Androgens* (male sex hormones) enhance erythropoietin secretion. This explains the greater RBC counts in males compared with females.
- *Thyroxine* also promotes erythropoiesis. This explains the occurrence of polycythaemia in hyperthyroidism.
- *Other hormones* which increase erythropoietin secretion are growth hormone, prolactin, ACTH and adrenocortical steroids.

2. Haemolysates,

i.e. the products released following RBC destruction, also increase erythropoietin secretion.

3. Nucleotides

which enhance erythropoietin secretion include cAMP, NAD and NADP.

4. Vasoconstrictor drugs

produce renal hypoxia, which in turn increases erythropoietin secretion.

Factors decreasing erythropoietin secretion

are the following:

- **Adenosine antagonists,**

e.g. theophylline and

- **Oestrogen**

decreases erythropoietin secretion by:

- Decreasing synthesis of globin in liver, and
- Depressing the erythropoietic response to hypoxia.

Important Notes

For therapeutic purpose (in anaemic state due to renal failure) recombinant erythropoietin (rEPO) is available as epoetin α .

Factors necessary for erythropoiesis

Factors necessary for erythropoiesis can be divided in three groups:

- General factors,
- Special maturation factors and
- Factors necessary for haemoglobinization.

I. General factors.

The main general factors necessary for the process of erythropoiesis are optimum level of the hormone *erythropoietin* and the efficient *feedback mechanism* controlling the secretion of *erythropoietin*.

All the factors (including hypoxia) affecting erythropoietin and feedback mechanism have been discussed in the regulation of erythropoiesis.

II. Special maturation factors.

Special factors which are essential for maturation of a red blood cell include vitamin B₁₂, intrinsic factor of Castle and folic acid.

Vitamin B₁₂.

Vitamin B₁₂ (cyanocobalamin), also known as extrinsic factor is essential for maturation of red cells.

- **Daily requirement** of vitamin B₁₂ in adults is 1–2 µg. Since its deficiency causes pernicious anaemia, it is also called antipernicious factor.
- **Sources of vitamin B₁₂**. There is no plant source for vitamin B₁₂. Dietary sources of vitamin B₁₂ are milk, meat and liver of animals. It is present in the normal diet and is also synthesized by the bacterial flora of the colon. The colonic cobalamins are unabsorbable in humans.
- **Absorption of vitamin B₁₂**. is not possible in the absence of the intrinsic factor. The *intrinsic factor of Castle* is a glycoprotein secreted by the parietal cells of gastric mucosa. It combines with dietary vitamin B₁₂ present in the stomach to form the intrinsic factor – cyanocobalamin complex which then becomes bound to specific receptors in the ileum and is absorbed by endocytosis (Fig. 3.2-13).
- **Transport of vitamin B₁₂**. Inside the mucosal cells, the cobalamin is transferred from the intrinsic factor to transcobalamin II, another binding protein which transports vitamin B₁₂ in the blood (Fig. 3.2-13).
- **Storage of vitamin B₁₂**. It is stored in large amounts in liver (there may be up to 3 years supply) and also to some extent in the muscles. Whenever required, it is transported from the liver into the bone marrow.
- **Role of vitamin B₁₂**. It is required for the synthesis of DNA and maturation of nucleus and cell. Its interaction with folic acid is shown in Fig. 3.2-14. Deficiency of vitamin B₁₂ leads to:
 - Failure of maturation of nucleus.
 - Cells remain large (megaloblasts) and become more fragile. Normally, during maturation, cell size decreases progressively.
 - There occurs a reduction in the cell division.

FIGURE 3.2-13 Schematic diagram showing absorption and transport of vitamin B₁₂.

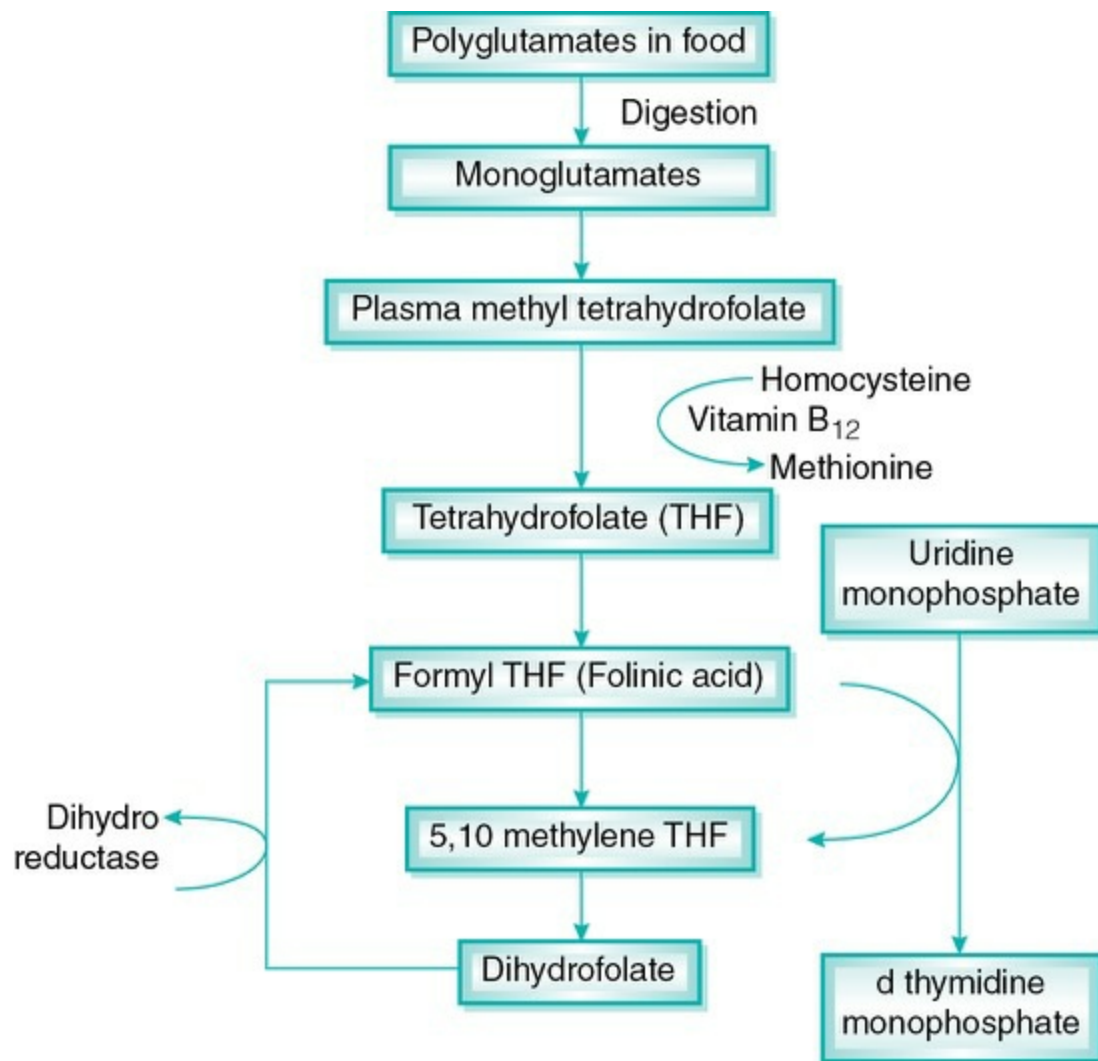

FIGURE 3.2.14 Metabolic pathway showing interaction of vitamin B₁₂ and folate in the synthesis of DNA.

Folic acid.

Folic acid (pteroylglutamic acid) and related compounds are known as folates—play an important role in the synthesis of DNA.

- **Daily requirement**

of folates for a normal healthy adult is 100 µg.

- **Sources of folates**

are leafy vegetables, yeasts, pulses and liver. The body obtains folates by the breakdown of food polyglutamates to monoglutamates in the small intestine or mucosal cells. Folic acid, as such, is available only as a medicinal compound.

- **Role of folic acid in DNA synthesis.**

In the plasma, folate appears as methyl tetrahydrofolate, which is changed to tetrahydrofolate (THF) by a pathway for which vitamin B₁₂ is essential (Fig. 3.2-14). Without this, active folate co-enzymes are poorly formed. For synthesis of DNA, 5,10 methylene THF is the essential form. Dihydrofolate from this step is reconverted to the THF by dihydrofolate reductase, an enzyme inhibited by the folate antagonist (methotrexate). Formyl THF (folinic acid) will bypass both the metabolic blocks created by vitamin B₁₂ deficiency or methotrexate and acts as an antidote to this drug.

- **Folate deficiency**

causes megaloblastic anaemia (see page 162).

III. Factors necessary for haemoglobinization.

Various factors necessary for haemoglobin formation in the red blood cells are described on page 150.

Haemoglobin

The cytoplasm of erythrocytes (red blood cells) contains an *oxygen-binding protein* called haemoglobin. Erythrocyte precursors synthesize haemoglobin, while the mature erythrocytes lose the property of synthesizing haemoglobin. The inclusion of haemoglobin within the erythrocytes is most effective for functional purposes, since it avoids the following *disadvantages* which would have occurred if the haemoglobin was present in the plasma as free haemoglobin:

- Increase in blood viscosity causing a rise in blood pressure,
- Increase in the osmotic pressure,
- Rapid destruction of haemoglobin by the reticulo–endothelial system and
- Excretion of haemoglobin by kidney (haemoglobin urea).

In pathologic states, e.g. acute haemolytic disorder, Hb appears in the plasma and may lead to above-mentioned consequences.

Normal blood haemoglobin

The normal blood haemoglobin concentration at different ages is given below (Fig. 3.2-15).

FIGURE 3.2-15 Normal blood haemoglobin concentration at different ages.

- **In fetus,**

just before birth, the haemoglobin concentration of blood from the umbilical cord ranges from 16.5 to 18.5 g/dL.

- **After birth,**

the haemoglobin concentration increases rapidly and may reach up to 23 g/dL. This occurs due to:

- the transfusion of cells from the placenta to infant, and
- haemoconcentration by reduction of plasma volume.

- **At the end of 3 months.**

After 2 days of birth, the haemoglobin levels start falling and stabilize at the end of 3 months to 10.5 g/dL.

- **At 1 year of age.**

The concentration then rises gradually to reach 12 g/dL.

- **In adult males,**

the mean blood haemoglobin (Hb) concentration is 15.5 g/dL (range 14–18 g/dL) and

- **In adult females,**

the mean Hb concentration is 14 g/dL (range 12–15.5 g/dL).

Important Notes

- The normal haemoglobin becomes 100% saturated when blood is equilibrated with 100% oxygen (PO_2 , 760 mmHg).
- One gram of haemoglobin when fully saturated combines with 1.34 ml oxygen. Thus, Hb concentration is an index of oxygen carrying capacity of blood. Thus, normal values of oxygen carrying capacity in males is $1.34 \times 15.5 =$ about 21 ml/dL, and in females is $1.34 \times 14 =$ about 18.5 ml/dL.
- *Clinically*, irrespective of the age, a level of 14.8 g/dL is considered as 100% haemoglobin.

Structure of haemoglobin

Haemoglobin is a globular molecule having a molecular weight of 68,000. It consists of the protein *globin* combined with iron containing pigment called *haem*.

Structure of globin.

The protein globin, present in the haemoglobin, is made up of four polypeptide chains. The polypeptide chains are of different types (described in types of haemoglobin). The globin of the common type of adult haemoglobin called HbA consists of the following four polypeptide chains:

- *Two α chains*, each containing 141 amino acid residues and
- *Two β chains*, each containing 146 amino acid residues.

Therefore, the normal adult haemoglobin A is written as HbA ($\alpha^2\beta_2$).

Structure of haem.

The haem is an iron–porphyrin complex called *iron–protoporphyrin IX*, i.e. it consists of a porphyrin nucleus and iron. The structural characteristics of the haem (iron–protoporphyrin IX) are given below (Fig. 3.2-16A, B and C).

FIGURE 3.2-16 Chemistry of haemoglobin: **A**, structure of a pyrrole ring; **B**, conventional outline of a pyrrole ring; **C**, arrangement of pyrrole rings in one unit of haem (iron protoporphyrin IX); and **D**, arrangement of four units of haem

in one molecule of haemoglobin.

Porphyrin nucleus

- The porphyrin nucleus consists of four *pyrrole rings* numbered I, II, III and IV, i.e. porphyrins are tetrapyrroles.
- The pyrrole rings are joined together by four *methine bridges* (=CH—). The carbon atoms of methine bridges are labelled α , β , γ and δ .
- Eight *side chains* are attached to the pyrrole ring at positions labelled 1 to 8. These are:
 - Four *methyl* (H_3C) side chains at positions 1, 3, 5 and 8,
 - Two *vinyl* ($\text{CH}\cdot\text{CH}_2$) side chains at positions 2 and 4 and
 - Two *propionic acid* ($\text{CH}_2\cdot\text{CH}_2\cdot\text{COOH}$) side chains at positions 6 and 7.

The iron

- The iron in the haem is in *ferrous* (Fe^{2+}) form.
- The iron is attached to the nitrogen atom of each pyrrole ring.
- On the iron (Fe^{2+}) a bond is available for loose union, where:
 - In oxyhaemoglobin, O_2 is attached,
 - In carboxyhaemoglobin, CO is attached, and so on (see [derivatives of haemoglobin](#)).

Attachment of haem to globin.

One molecule of haemoglobin contains four units of haem, each attached to one of the four polypeptide chains constituting globin ([Fig. 3.2-16D](#)). As there are four units of haem in one molecule of haemoglobin, so there are four iron atoms in one molecule of Hb which can carry four

molecules (eight atoms) of oxygen.

Functions of haemoglobin

1. Transport of O₂ from lungs to tissues

- *In the lungs*, one molecule of O₂ is attached loosely and reversibly at the sixth covalent bond of each iron atom of the haemoglobin to form *oxyhaemoglobin* represented as HbO₂:

- Oxygenation of the 1st haem molecule in the haemoglobin increases the affinity of the 2nd haem for oxygen, which in turn increases the affinity of the 3rd haem and so on. In this way, affinity of haemoglobin for the 4th oxygen molecule is many times that for the 1st molecule. Because of this:
- Haemoglobin reacts with oxygen very rapidly taking less than 0.01 s. Similarly, deoxygenation of haemoglobin is also very rapid, and
- The oxygen–haemoglobin dissociation curve becomes sigmoid shaped (see page 430).
- The affinity of haemoglobin for oxygen is influenced by pH, temperature and concentration of 2,3-diphospho-glycerate or biphosphoglycerate, i.e. 2,3-BPG (a product of metabolism of glucose) in the RBCs.
- As the concentration of 2,3-BPG rises, the affinity of Hb for oxygen falls and the oxygen–haemoglobin dissociation curve is shifted to the right (see page 432) and as a result more oxygen is released by blood to the tissues. *It is important to note that:*

- *At high altitude* (e.g. 5000 m above the sea level) 2,3-BPG concentration in red cells increases by 50% and thus more oxygen is available to the tissues.
- *As 2,3-BPG accumulates*, it depresses hexokinase and 2,3-BPG mutase activity by negative feedback control. Glucose metabolism in this way is related to oxygen transport via intracorpuseular 2,3-BPG concentration.
- *Stored blood* loses its 2,3-BPG concentration and oxygen affinity increases resulting in less release of oxygen. The addition of inosine and adenosine to stored blood increases 2,3-BPG formation and restores the normal affinity of haemoglobin for oxygen.

2. Transport of CO₂ from the tissues to the lungs.

Haemoglobin also transports CO₂ from the tissues to the lungs.

- It is important to note that CO₂ from the tissues is transported by combining with amino acids of the globin part as shown below and not in combination with Fe²⁺ atom like O₂.

- Deoxygenated Hb forms carbamino-haemoglobin more readily than oxygenated Hb. That is why venous blood becomes more suitable for transport of CO₂ from the tissues to the lungs.

3. Control pH of the blood.

The haemoglobin constitutes the most important acid–base buffer system of blood. Although, the concentration of Hb is roughly twice the concentration of plasma proteins, Hb has six times the buffering capacity compared with plasma proteins.

Development of haemoglobin

- The human haemoglobin first appears at about six weeks after gestation. The red cells contain embryonic haemoglobin Portland ($\zeta_2\gamma_2$), Hb Gower I ($\zeta_2\varepsilon_2$) and Hb Gower II ($\alpha_2\varepsilon_2$) (Fig. 3.2-17)
- At about 10–11 weeks, fetal Hb [HbF($\alpha_2\gamma_2$)] becomes prominent.
- At about 38 weeks, there is synthesis of adult Hb [HbA ($\alpha_2\beta_2$)], a small amount of HbF is produced during postnatal life because few red cell clones called F cells (small pool of immature committed erythrocyte precursor) retain the ability to produce Hb F.

FIGURE 3.2-17 Development of human haemoglobin chains.

The human haemoglobin is encoded by gene clusters (α and β). The α -like gene clusters are located on chromosome 16 and β -like on chromosome 11. The locus control region (LCR) element is located in the upstream control expression of each cluster. Therefore, normal red blood cells differentiation requires co-

ordinated expression of the globin genes, genes responsible for haem and Fe metabolism.

Varieties of haemoglobin

Apart from species differences, several varieties of haemoglobin occur in human beings. In all varieties of haemoglobin, the haem moiety remains the same. It is the composition of polypeptide chains of the globin part of the haemoglobin which differs in various varieties of haemoglobin.

Various varieties of haemoglobin can be grouped as under:

- Physiological varieties of haemoglobin, and
- Haemoglobinopathies.

Physiological varieties of haemoglobin

Adult haemoglobin.

Adult haemoglobin is of two types.

i. *Haemoglobin A* [HbA ($\alpha_2\beta_2$)]. It is the main form of normal adult haemoglobin. As described on page 144, its globin part consists of two alpha and two beta polypeptide chains. It is a spheroidal molecule with a molecular weight of 68,000.

ii. *Haemoglobin A₂* [HbA₂ ($\alpha_2\delta_2$)]. It is a minor component (about 2.5% of the total Hb) in normal adults. Its globin part consists of two alpha and two delta polypeptide chains. Delta chains have slightly different amino acid composition (out of 146, 10 amino acids are different) compared with β chains.

Fetal haemoglobin.

Fetal haemoglobin, or haemoglobin F [HbF $\alpha_2\gamma_2$] as the name indicates, refers to the haemoglobin present in the fetal RBCs and gradually disappears 2–3 months after birth.

• Amount of HbF and HbA

present at various stages is as given in [Table 3.2-3](#).

TABLE 3.2-3

Amount of HbF and HbA at Various Stages in Human Beings

Stage	HbF	HbA
• At 20 weeks of intrauterine	94%	6%
• At birth	80%	20%
• At 2 months after birth	50%	50%
• At 4 months after birth	10%	90%
• At more than 1 year after birth	<1%	>99%

• Structure of HbF

is similar to that of HbA, except that its globin part consists of two alpha and two gamma polypeptide chains (in place of beta chains). Gamma chains also have 146 amino acids, but its 37 amino acids are different than that of beta chains.

• Special features

of HbF are given below.

- **Affinity for oxygen** in case of HbF is more than that of HbA, i.e. it can take more oxygen than HbA at low oxygen pressure. It is owing to poor binding of 2,3-BPG by the gamma polypeptide chain. Because of this, movement of oxygen from maternal to fetal circulation is facilitated. At PO_2 20 mmHg, HbF is 70% saturated while HbA is only 30–35% saturated. For details see page 433.
- **Resistance to action of alkalis** is more in HbF than HbA. This property is used in a photoelectric colorimetric method to estimate HbF in the presence of HbA.
- **Lifespan** of HbF is much less (1–2 weeks) compared with that of HbA (120 days).

Haemoglobinopathies.

Haemoglobinopathies, i.e. abnormal formation of haemoglobin occurs due to disorders of globin synthesis, haem synthesis being normal.

Classification:

There are five major classes of haemoglobinopathies. Structural haemoglobinopathies occur due to gene mutation resulting in alteration in amino acid sequence in the globin chain include:

- Sickle cell anaemia* occurs due to HbS and is an example of structural haemoglobinopathy.

- ii. *Thalassaemia syndromes* occur due to mutation that impairs the production of globin mRNA resulting in deficient or absent globin biosynthesis.
- iii. *Thalassaemic haemoglobin variants*: when there are combined features of thalassaemia and structural haemoglobinopathies, e.g. Hb E, Hb C, Hb L and Hb J.
- iv. *Hereditary persistence of fetal haemoglobin (HPFH)*: due to increased levels of fetal haemoglobin in adult life.
- v. *Acquired Haemoglobinopathies* occur due to modification of Hb molecule by toxins, e.g. methaemoglobin, sulphaemoglobin, carboxyhaemoglobin and haemoglobin H in leukaemia.

1. Sickle cell haemoglobin

or haemoglobin S (HbS)

- HbS is the most important haemoglobinopathy.
- It occurs in 10–20% of Negroes. Sickle cell gene originated in the black population in Africa.
- HbS is formed due to substitution of valine for glutamic acid at position 6 in the beta chain of HbA.
- When HbS is reduced (e.g. in low O₂ tension or when pH at tissue level is low), it becomes much less soluble and precipitates into crystals within the RBCs. The crystals elongate producing changes in shape of the cells from biconcave to sickle-shaped cells (sickling), (Fig. 3.2-18).
- The cells containing HbS are less flexible compared with RBCs containing HbA, hence leading to blockade of microcirculation.
- Sickle-shaped cells greatly increase blood viscosity thereby decreasing the blood flow to tissues.
- Sickle-shaped cells are more fragile and are very liable to undergo haemolysis producing the so-called sickle cell anaemia.
- Sickle trait is inherited as Mendelian dominant, but the full-blown disease is autosomally recessive. Heterozygous individual with sickle

cell trait rarely has severe symptoms, but homozygous develop full-blown disease.

- The individual with the sickle cell trait has resistance to one type of malaria.

FIGURE 3.2-18 Mechanism of sickling of red blood cell containing haemoglobin S (HbS).

Pathophysiology

of sickle cell crisis *has been depicted in* [Fig. 3.2-19](#).

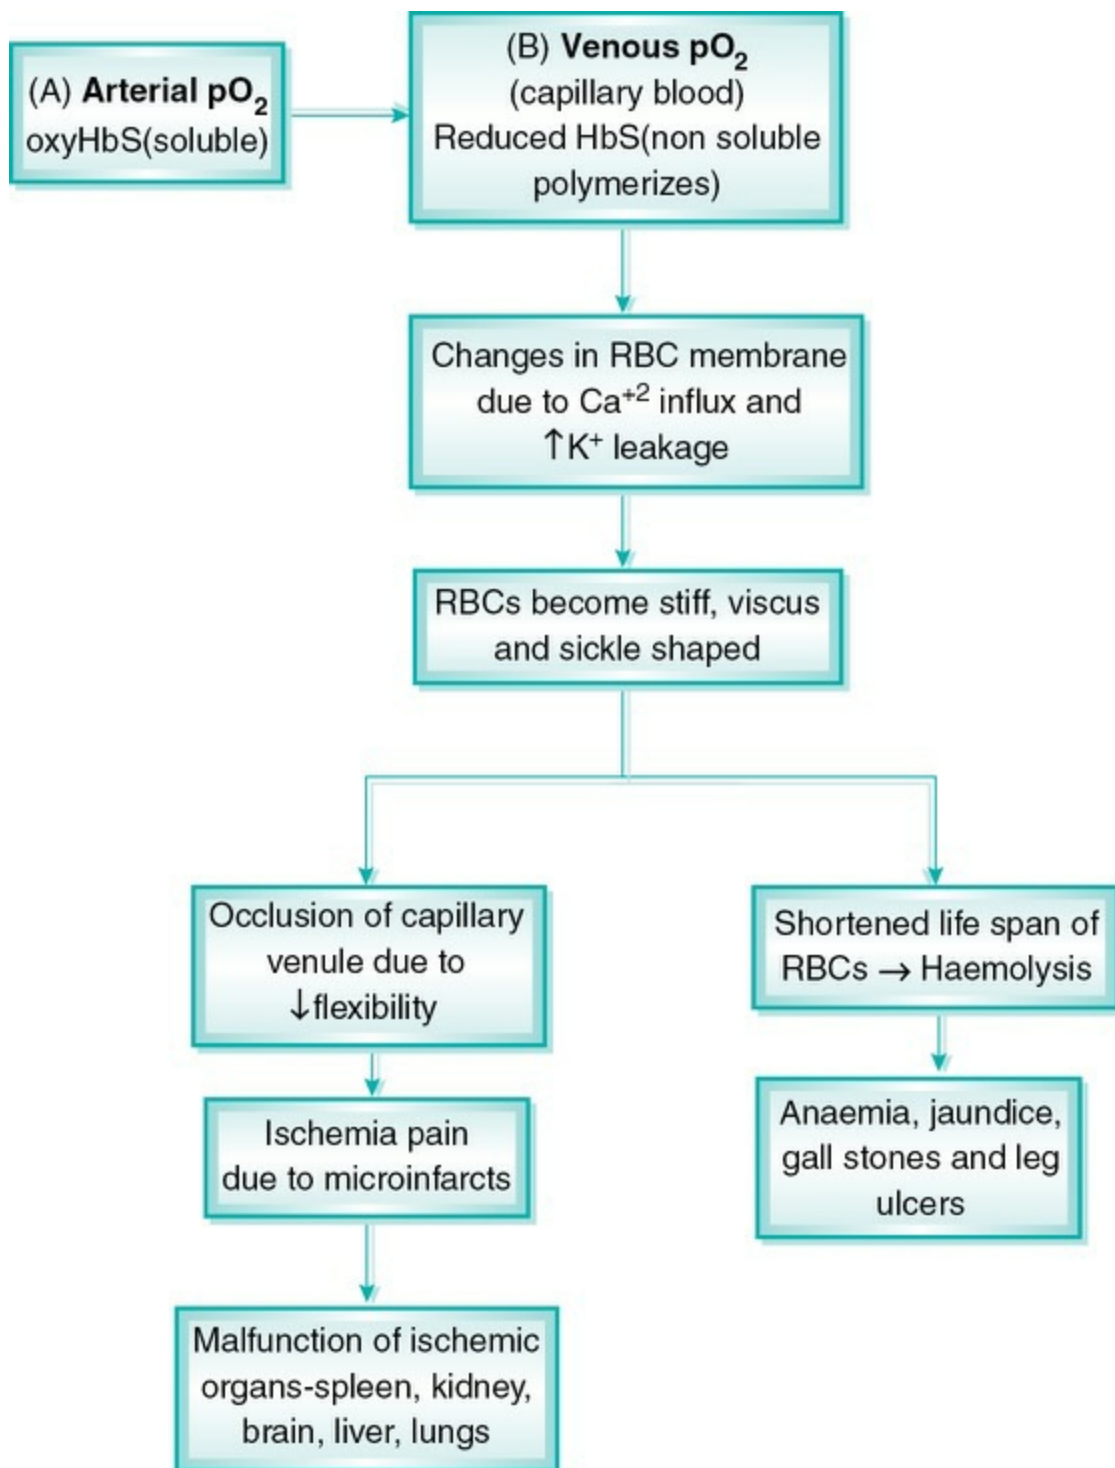

FIGURE 3.2-19 Pathophysiology of sickle cell crisis.

Treatment of sickle cell anaemia

- Presence of HbF in RBCs decreases the polymerization of deoxygenated HbS. There are two drugs: *5-azacytidine* and *hydroxyurea*, which lead to formation of HbF in children and adults. These drugs have been tried in patients with sickle cell anaemia and have shown good preliminary results.

- Bone marrow transplantation has cured the disease in some cases.

2. Thalassaemia

(Mediterranean anaemia) is a haemoglobinopathy characterized by the following features:

- **Cause.** Thalassaemia results due to defect in the synthesis of polypeptide chain α and β of HbA.
- **Types.** Depending upon whether α or β chains are not synthesized, α thalassaemia or β thalassaemia may occur, respectively. *α thalassaemia syndrome* may present in the following forms depending on deletion on α globin loci:
 - i. *The α thalassaemia trait:* May be asymptomatic or silent carrier state or may resemble β thalassaemia minor.
 - ii. *The homozygous state of α thalassaemia:* In this condition there is excess of γ globin form, i.e. Hb Barts (Υ_4) which has very high oxygen affinity. Hence, there is no delivery of the oxygen to fetal tissues leading to asphyxia, oedema (Hydrops foetalis), congestive heart failure and death in utero.
- **β Thalassaemia** is more common and is further of two types: thalassaemia major and thalassaemia minor.
- **Features** of thalassaemia major and minor are depicted in [Table 3.2-4](#).

TABLE 3.2-4

Main Differentiating Features of Thalassaemia β Major and Minor

Sr. No.	β Thalassaemia major	β Thalassaemia minor
1.	Thalassaemia major is also called as <i>Mediterranean anaemia</i> or <i>Cooley's anaemia</i> is less common.	Thalassaemia minor is more common.
2.	It is inherited as homozygous transmission (i.e. abnormal genes are inherited from both the parents), therefore,	It is inherited as heterozygous transmission (i.e. abnormal gene is inherited from one parent), Therefore, <ul style="list-style-type: none"> • The synthesis of β chain is not completely absent (partial). • Anaemia is of mild type.

	<ul style="list-style-type: none"> • There is complete absence of β chain synthesis. • Absence of β chain synthesis results in moderate to severe anaemia. • HbF level is markedly increased. 	<ul style="list-style-type: none"> • HbF level is either normal or slightly elevated.
3.	The individual suffering from thalassaemia major has short lifespan, i.e. dies young (17–18 years)	The individuals suffering from thalassaemia minor comparatively survive longer (up to adult) and transmit abnormal gene to their offspring.
4.	Diagnosis: the patient presents with: <ul style="list-style-type: none"> • Severe anaemia. • Haematocrit is very low. • Ineffective erythropoiesis. • Blood picture shows marked microcytosis. • Elevated levels of HbF and HbA₂. 	<ul style="list-style-type: none"> • β thalassaemia minor usually presents with microcytosis and hypochromia but with minimal or mild anaemia. • Hepatosplenomegaly. • Haematocrit 28–40%. • Blood picture as of iron deficiency anaemia. • HbA₂ levels are usually normal or may be elevated to 4–8%.
5.	Treatment: <ul style="list-style-type: none"> • Blood transfusion maintains haematocrit at least 27–30%. • Allogenic bone marrow transplantation. • Fe-chelating agents (deferoxamine to avoid hemosiderosis). • Folic acid supplements. • Splenectomy increases the volume of RBCs per/kg body weight to more than 50%. • Employ treatment of Fe deficiency anaemia. 	<ul style="list-style-type: none"> • Usually requires no treatment, but genetic counselling and parent education about the effect of the disease is important.

3. Hemoglobin variants include:

i. **Haemoglobin E (HbE)**, i.e. $\alpha_2\beta^{2(26\text{glu lys})}$ is the most common variant of Hb detected in the United States. Hb E homozygous are asymptomatic. Blood picture shows that microcytosis, hypochromia and Hb levels are rarely less than 10 g/dL.

ii. **Haemoglobin C (HbC)**. Hb C, like Hb S is formed by substitution of lysine for glutamic acid at β 6 position. In Hb C type of variant there is no sickling of RBCs, but HbC may precipitate in polymer formation in association with Hb S. Homozygous HbC disease presents with mild haemolytic anaemia, splenomegaly, mild jaundice and pigment gall stones (Ca-bilirubinate stones).

iii. **Haemoglobin lupore: (HbL i.e. $\alpha_2(\delta\beta_2)$)** In haemoglobin lupore, globin is synthesized poorly and a person with HbL present like β thalassaemia with added presence of 2–20% HbL.

iv. **Haemoglobin H disease:** In this disease, patients present with:

- Marked haemolytic anaemia, and
- Haematocrit is 22–32%
- MCV is markedly low (60–70 μm^3)

- Peripheral blood smear shows abnormal cells with hypochromia, microcytosis, target cells and poikilocytosis. Peripheral smear stained with supravital stain detects HbH.

v. *Other haemoglobin variants are: Hb J and HbM disease, cause haemolytic anaemia.*

Detection and characterization of haemoglobinopathies

Detection and characterization of haemoglobinopathies can be made by the following tests:

- *Routine investigations* include complete haemogram and examination of peripheral blood smear.
- *Screening and Quantification* can be done by haemoglobin electrophoresis and also by using specialized technique like isoelectric focusing and high-pressure liquid chromatography (HPLC).
- *Function assays* for HbS include sickling test, solubility test, precipitation test and oxygen affinity (P_{50}) to detect low/high affinity of oxygen.
- *Spectrophotometry* to detect % of abnormal Hb, e.g. methaemoglobin and carboxyhaemoglobin.
- *For complete characterization of haemoglobinopathy, the following tests should be done:*
 - Amino acid sequencing,
 - Polymerase chain reaction (PCR),
 - Allele specific oligomerotide hybridization, automated DNA hybridization and
 - Automated DNA sequencing.

Derivatives of haemoglobin (reactions of haemoglobin)

Haemoglobin has the property to readily react with any gas or other substance to form the so-called derivatives of haemoglobin. These include:

1. Oxyhaemoglobin.

As described on page 145, haemoglobin reacts readily with oxygen to form oxyhaemoglobin which is an unstable and reversible compound, i.e. oxygen can be released from this compound. In this compound iron remains in ferrous state.

2. Reduced haemoglobin

or deoxygenated haemoglobin is formed when oxygen is released from the oxyhaemoglobin.

3. *Carbamino-haemoglobin* is a compound of Hb with carbon dioxide

4. *Carboxyhaemoglobin* or carbon monoxy haemoglobin is a compound of Hb with carbon monoxide (CO):

The affinity of haemoglobin for CO is much more (200–250 times) than its affinity for oxygen. Because of this, the CO displaces oxygen from haemoglobin, thereby reducing the oxygen carrying capacity of blood. For details see page 433.

5. Methaemoglobin.

When reduced or oxygenated haemoglobin is treated with an oxidizing

agent, e.g. potassium ferricyanide, the ferrous (Fe^{2+}) is oxidized to ferric (Fe^{3+}); the sixth bond is attached to OH to form the compound methaemoglobin. Methaemoglobin is represented as HbOH.

Disadvantages of methaemoglobin are:

- It cannot unite reversibly with gaseous oxygen; the O_2 of the attached OH is not given off in a vacuum.
- When present in large amount, it produces blue colour of skin (cyanosis) because of its dark colour.

Normally, some oxidation of haemoglobin to methaemoglobin (HbOH) does occur; but the methaemoglobin formed is soon converted back to haemoglobin by the enzyme NADH – methaemoglobin reductase present in the RBCs. Hereditary methaemoglobinaemia may result due to congenital absence of this enzyme.

6. Sulphaemoglobin

is formed by a combination of haemoglobin with hydrogen sulphide (H_2S).

7. Nitrous oxide haemoglobin

is formed when haemoglobin combines with nitrous oxide.

8. Glycosylated haemoglobin

is a derivative of haemoglobin A present in very small amounts, e.g. *haemoglobin A_{1C}* (*HbA_{1C}*), in which glucose is attached to terminal valine in the β chains. The level of glycosylated haemoglobin in the blood increases in poorly controlled patients of diabetes mellitus.

Important Note

Normally the fraction of Hb glycosylated is approximately 5% and is proportionately blood glucose level. Since half-life of an erythrocyte is 60 days (lifespan 120 days), therefore level of HbA_{1C} reflects the mean blood glucose concentration over preceding 6–8 weeks. Therefore, estimation of HbA_{1C} provides valuable information of management of diabetes mellitus.

Derived products of haemoglobin.

Derived products of haemoglobin are of two types: iron containing and

iron free.

1. Iron-containing derived products of haemoglobin

are:

- *Acid haematin* or *alkali haematin* is formed by the action of acid or alkali with haemoglobin.
- *Haemochromogen* is obtained by reduction of alkali haematin.
- *Cathaemoglobin* is a compound of haemoglobin containing ferric ion with denatured globin.
- *Haem*

Iron-Free Derived Products of Haemoglobin are:

- Haematoporphyrin,
- Haempyrrole,
- Haematoidin and
- Bilirubin.

Synthesis of haemoglobin

Haemoglobin is synthesized in the cytoplasm of intermediate normoblasts. Four haem units join with one molecule of globin to form one unit of haemoglobin.

Synthesis of haem.

Haem is synthesized in the mitochondria. Steps of synthesis are (Fig. 3.2-20):

- Succinyl-CoA (derived from the citric acid cycle in mitochondria) and glycine are the starting substances in the synthesis of haem. These condense to form α -amino- β -ketoacidic acid. The condensation requires pyridoxal phosphate for activation of glycine.
- The α -amino- β -ketoacidic acid gets rapidly decarboxylated to δ -aminolaevulinic acid (ALA) in the presence of enzyme ALA synthetase in the mitochondria.

- The *protoporphyrin IX* is then formed after a series of reactions promoted by other enzymes.
- Finally, ferrous ion is introduced into the protoporphyrin-IX molecule to form *haem* in a reaction catalysed by the enzyme haem synthetase.

FIGURE 3.2-20 Steps of synthesis of haemoglobin.

Synthesis of globin.

Globin, the protein part of the haemoglobin is synthesized in ribosomes.

Factors controlling haemoglobin formation.

Whipple's standard anaemic dog studies show that iron as well as dietary proteins, both play a very important role in the synthesis of haemoglobin. In addition, certain other minerals and vitamins also control the haemoglobin formation.

1. Role of proteins.

First class proteins provide amino acids required for synthesis of globin part of the haemoglobin. A low protein intake retards haemoglobin regeneration even in the presence of excess iron; the limiting factor being lack of globin. The relative values of various foods in providing the required amino acids are:

- *Most valuable* food is of animal origin and consists of liver, spleen, kidney and heart.
- *Foodstuffs of intermediate value* are again of animal origin and include the muscles.
- *Foodstuffs of least value* include bread and other cereals, dairy products, most vegetables and fruits and salmon.

2. Role of iron.

Iron is necessary for formation of haem part of haemoglobin. In addition to dietary iron, the iron released by degradation of RBCs is also reused for synthesis of haemoglobin. Various aspects of iron metabolism are discussed on page 158.

3. Role of other metals.

- *Copper*. Copper is essential for haemoglobin synthesis, as it promotes the absorption, mobilization and utilization of iron. Usually, copper deficiency seldom occurs, since requirement of copper is very little and that it occurs in adequate amounts in the diet and most iron preparations contain traces of copper.
- *Cobalt*. Cobalt is required for synthesis of vitamin B₁₂ by bacterial action in the lumen of gut of sheep and other cattle. However, its role in humans is not evidenced. Further, in some species, cobalt increases the production of erythropoietin which in turn stimulates RBC formation.
- *Calcium*. Calcium is reported to help indirectly by conserving iron and its subsequent utilization.

4. Role of vitamins.

Vitamin B₁₂, folic acid and vitamin C help in synthesis of nucleic acid which in turn, is required for the development of RBCs. Vitamin C also

helps in absorption of iron from the gut.

5. Role of bile salts.

Presence of bile salts in the intestine is necessary for proper absorption of metals like copper and nickel, which in turn are essential factors for synthesis of haemoglobin.

Degradation of haemoglobin

Tissue macrophages (reticuloendothelial system), especially those lining the hepatic and splenic sinusoids phagocytize the old RBCs.

Haemoglobin is broken down and bilirubin is formed within the macrophages. The iron released from degraded haemoglobin enters the plasma and the bilirubin enters into the bile canaliculi. For details see page 151.

Red cell fragility

Red cell fragility refers to the susceptibility of red cell membrane to break or burst. The process of breaking of RBCs and release of haemoglobin into the plasma is called haemolysis. Red cell fragility, depending upon the underlying mechanism, is of two types:

- Osmotic red cell fragility, and
- Mechanical red cell fragility.

Osmotic red cell fragility

Osmotic red cell fragility refers to the susceptibility of the red cell membrane to get lysed due to changes in the osmotic pressure of the solution in which they are suspended.

Effect of osmotic pressure of solution on the RBCs

- **Isotonic solutions** have tonicity as that of plasma. These include 0.9% NaCl, 5% glucose, 10% mannitol and 20% urea. When RBCs are placed in these solutions, they remain suspended in them, i.e. neither swell nor shrink. This is because the osmotic pressure of the isotonic solutions is equal to the osmotic pressure within the RBCs.
- **Hypertonic solutions** (e.g. >0.9% NaCl, 20% mannitol) have osmotic

pressure more than the osmotic pressure within the RBCs. Therefore, when the RBCs are placed in such solutions, fluid goes out of the cells and they shrink.

- **Hypotonic solutions** (e.g. <0.9% NaCl) have osmotic pressure less than the osmotic pressure within the RBCs. Therefore, when the RBCs are placed in such solutions, they swell up by absorbing water from outside and finally burst, i.e. get haemolyzed.

Osmotic red cell fragility test.

To perform the osmotic red cell fragility test, the NaCl solutions of different concentrations (from 0.2 to 0.9%) are taken in series of Cohn's tubes. One or two drops of blood are added in each tube, mixed gently and left undisturbed for 1 h. Following observations may be made:

- **No haemolysis.** The RBCs settle down as red dots at the bottom of the tube with clear saline solution above.
- **Onset of haemolysis.** A few RBCs rupture and the saline is tinged red with the released haemoglobin. The RBCs which have not ruptured are seen as red dots at the bottom of tube with red-tinged saline solution above.
- **Completion of haemolysis.** All the RBCs rupture and make the whole saline solution uniformly red with no red dots at the bottom of the tube.

Normal values (index of fragility)

- **Onset of haemolysis** (fragility) in normal RBCs occurs in 0.48% NaCl, and
- **Completion of haemolysis** (ending of fragility) occurs in 0.35% NaCl.
- **Explanation.** Normally, only the older red cells with comparative fragile membrane are haemolyzed in around 0.48% of NaCl solution, since these cells cannot withstand this hypotonicity. But, younger cells are not affected. In 0.35% NaCl, even the youngest cells are haemolyzed and so haemolysis is completed.

Abnormal osmotic fragility.

Increase in osmotic fragility index occurs in following conditions:

- *Congenital spherocytosis*, i.e. when the RBCs are spherical. In this condition onset of haemolysis occurs at 0.7% NaCl and it is completed at 0.45% NaCl solution.
- *Autoimmune haemolytic anaemia* in which the autoantibodies damage the structure proteins and render the red cells more fragile.
- *Deficiency of glucose 6-phosphate dehydrogenase (G6PD)* increases the tendency of red cells to get haemolyzed by antimalarial drugs and other agents.
- *Venom of cobra and other insects* contains lecithinase, which dissolves lecithin from red cell membranes making them more fragile.

Decrease in osmotic fragility index occurs when the RBCs become slender, e.g. in iron deficiency anaemia. In this condition, the onset of haemolysis occurs at 0.36% NaCl and is completed at 0.24% NaCl solution.

Mechanical red cell fragility

The red cells are subjected to mechanical stress and trauma as they pass through the capillaries and trabeculae of the spleen some 300,000 times during their lifespan of 120 days. They are made more brittle due to unusual mechanical stress. The red cells can become more rigid as a result of pathological changes in the membrane or in the cell contents caused by a number of red cell disorders. The cells thus become mechanically more fragile, i.e. less liable to tolerate deforming stresses, than the normal healthy red cell.

A normal or less osmotic fragility does not rule out the possibility of high mechanical fragility. For example, in sickle cell anaemia, the RBCs are sickle-shaped and have a high mechanical fragility, but the osmotic fragility of the sickled cells is normal or even low.

Mechanical fragility test.

Mechanical fragility test can be performed by placing blood in a flask containing glass beads, and vigorously rotating the flask. The haemoglobin concentration of the supernatant is then measured, which provides an idea about the degree of haemolysis.

Lifespan and fate of red blood cells

Lifespan of red blood cells

Normally, the average lifespan of red blood cells is 120 days.

Determination of lifespan of red blood cells

1. Differential Agglutination Method.

In this method, an individual is transfused with red blood cells of a different but compatible group. For example, 'O' group blood is transfused to an 'A' group individual. About one litre of blood should be transfused so that substantial number of donor cells can be obtained to count. Then, a small quantity of blood is withdrawn from the recipient. The red cells are separated and treated with anti-A serum. The 'A' cells agglutinate and 'O' cells remain dispersed, which are counted. The procedure is repeated every day till the group 'O' cells are seen. The experiments show that some of the transfused cells can be seen surviving for about 120 days.

2. Radioactive isotope method.

In this method, about 15–20 ml of blood is withdrawn from an individual and then put RBCs are tagged with radioactive substances like radioactive iron or radioactive chromium. These RBCs are injected back into the same individual. Blood samples are then collected from the individual every day and radioactivity is determined. The isotope survival curve is plotted by plotting the radioactivity of blood as a function of time and the mean lifespan of red blood cells is calculated. If the curve for loss of radioactivity is suitably corrected, it is found to be almost linear, falling to zero at about 120 days. The half-life of the cells (50% destruction) being about 60 days, the curve gives the maximum survival time of the youngest cells, the mean survival time, and the average destruction of the cells in a heterogeneous sample.

Causes of reduction in the lifespan of red blood cells

I. Defects in red blood cells (corpuscular defects)

1. Hereditary spherocytosis.

It is an autosomal dominant disorder characterized by small and spherical red blood cells. These cells cannot be compressed; therefore, they get easily ruptured while passing through pulp of spleen. They show increased osmotic fragility so that haemolysis may commence at

0.7% NaCl and be completed at 0.4% NaCl solution, lifespan of such RBCs is reduced to 15–20 days. In this condition, the spleen is enlarged and serum bilirubin level may be raised to 20–50 mmol/L.

2. Sickle cell anaemia.

In this condition, RBCs contain abnormal haemoglobin, called haemoglobin-S. The cell membrane of sickle-shaped red blood cells is more fragile and gets easily haemolyzed and their lifespan is reduced. For details see page 147.

3. Thalassaemias.

In this condition, the red blood cells are abnormal in having reduced amount of HbA, to compensate for which there are increased amounts of HbA₂ ($\alpha_2\delta_2$) and HbF ($\alpha_2\gamma_2$). The red cells are rapidly haemolyzed and thus their lifespan is reduced. Children with thalassaemia get hypochromic anaemia, fail to thrive and die young. For details see page 148.

4. Deficiency of red cell enzymes.

The red blood cells deficient in certain enzymes become more susceptible to haemolysis and their lifespan is decreased. Some of such conditions are:

- *Glucose 6-phosphate-dehydrogenase deficiency.* It is inherited as sex-linked character. Glucose-6 phosphate dehydrogenase catalyses the reaction in pentose phosphate pathway and produces NADPH. NADPH plays a key role as a reducing agent in RBCs and other cells.

NADPH in RBCs serves as a cofactor for glutathione reductase in generating reduced glutathione, which detoxifies hydrogen peroxide (H₂O₂). In absence of reduced glutathione, Hb is oxidized and gets denatured and forms precipitates called *Hienz's bodies*, which causes membrane damage. Therefore, deficiency of G6PD results in oxidative damage to RBCs due to impaired production of NADPH (Fig. 3.2-21).

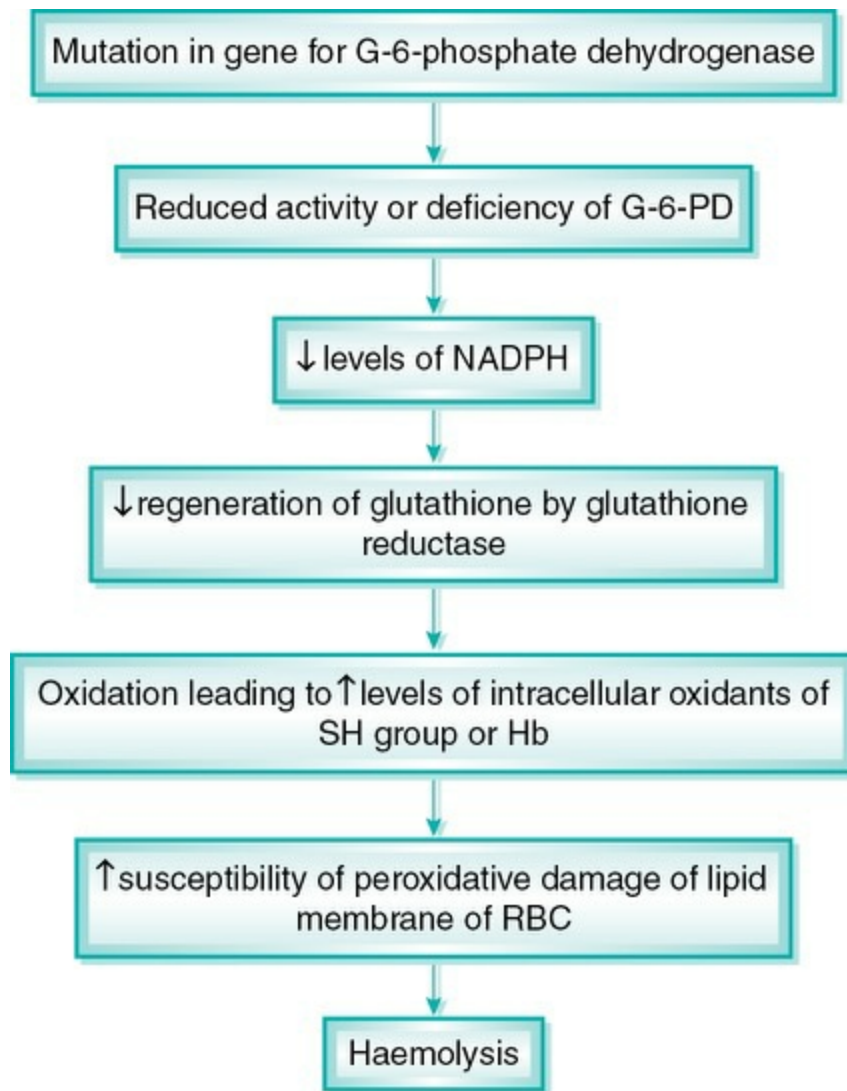

FIGURE 3.2-21 Flow diagram depicting effects of deficiency of G-6 phosphate dehydrogenase.

In this condition, as reducing power of the red cells is decreased and they become more vulnerable to damage by oxidizing agents such as primaquine and other antimalarial drugs.

- *Pyruvate kinase deficiency* may also produce haemolytic anaemia with reduction in lifespan of RBCs.
- *Paroxysmal nocturnal haemoglobinuria* is a rare condition in which red cells are hypersensitive to lysis by complement.

II. Extracorporeal defects

1. Transfusion of mismatched blood

produces haemolysis, drastically reducing lifespan of RBCs.

2. Autoimmune haemolytic disorders.

In such conditions, antibodies are formed against the patient's own red blood cells. These autoantibodies may be of IgG or IgM class and they may be bound to red cell membrane or occur in serum. Some react maximally at 37°C (warm type) and others at 20°C (cold type).

3. Hypersplenism,

due to any cause, may enhance destruction of red blood cells, leucocytes and platelets.

Fate of red blood cells

The cell membrane of old RBCs (after about 120 days) becomes more fragile due to decreased NADPH activity. The younger RBCs can easily pass through the capillaries which have a diameter smaller than the red cells. The older cells with fragile membranes are destroyed while trying to squeeze through the capillaries. The destruction of red cells occurs mostly in the capillaries of spleen because they have very thin lumen. Because of this, the spleen is also called the graveyard of red blood cells. The haemoglobin released after haemolysis of red cells is taken up by the tissue macrophages.

The tissue macrophage system (reticuloendothelial system) includes the following phagocytic cells:

- *In the bone marrow*, these cells form part of the lining of the blood sinuses (littoral cells);
- *In the liver*, they lie at intervals along the vascular capillaries (Kupffer cells),
- *In the spleen*, they are found in the pulp, and
- *In the lymph nodes*, they line the lymphatic paths.

Fate of haemoglobin (fig. 3.2-22)

- In the macrophages, the haem part of the haemoglobin molecule is altered by oxidation of one of its methine (=CH) bridges. The tetrapyrrole ring structure is thus broken and four pyrrole groups become arranged as a straight chain. As a result of this chemical change, the green iron-containing compound *choleglobin* is formed. As the name implies, the choleglobin molecule still contains the original

globin.

- Next, the *choleglobin* splits off into globin, iron and biliverdin (tetrapyrrole straight chain free from globin and iron).
- *Globin* is degraded into amino acids and joins the amino acid pool of plasma and is released.
- *Iron* released into the circulation is:
 - carried into the bone marrow for reutilization, and
 - in the other tissues it combines with apoferritin to form the ferritin (storage form of iron).
- *Biliverdin* (tetrapyrrole straight chain free from globin and iron) is converted into bilirubin (by the enzyme biliverdin reductase) and is released into the blood.

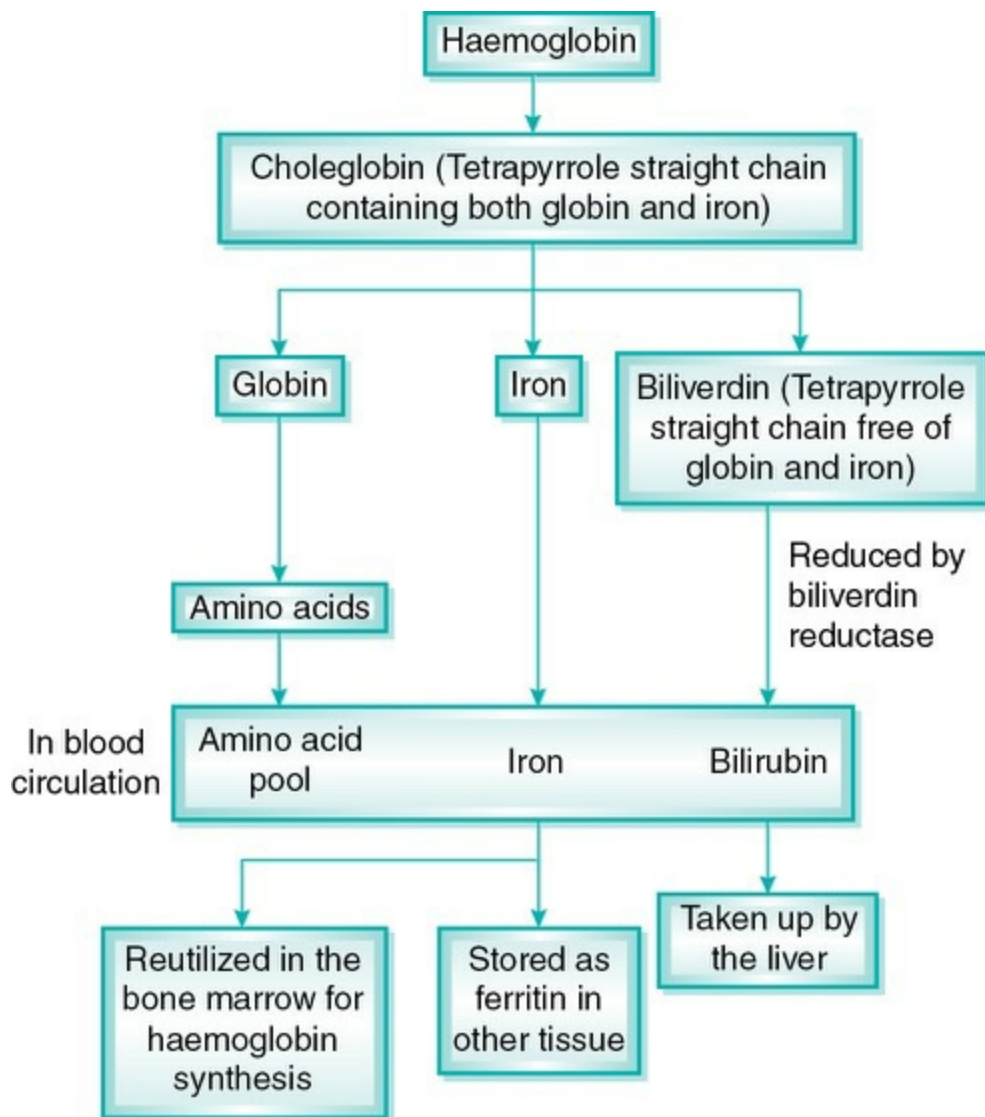

FIGURE 3.2-22 Fate of haemoglobin.

Bilirubin and jaundice

Bilirubin formation and its fate

As discussed above, the bilirubin is formed in the macrophages after degradation of haemoglobin. It undergoes the following changes (Fig. 3.2-23):

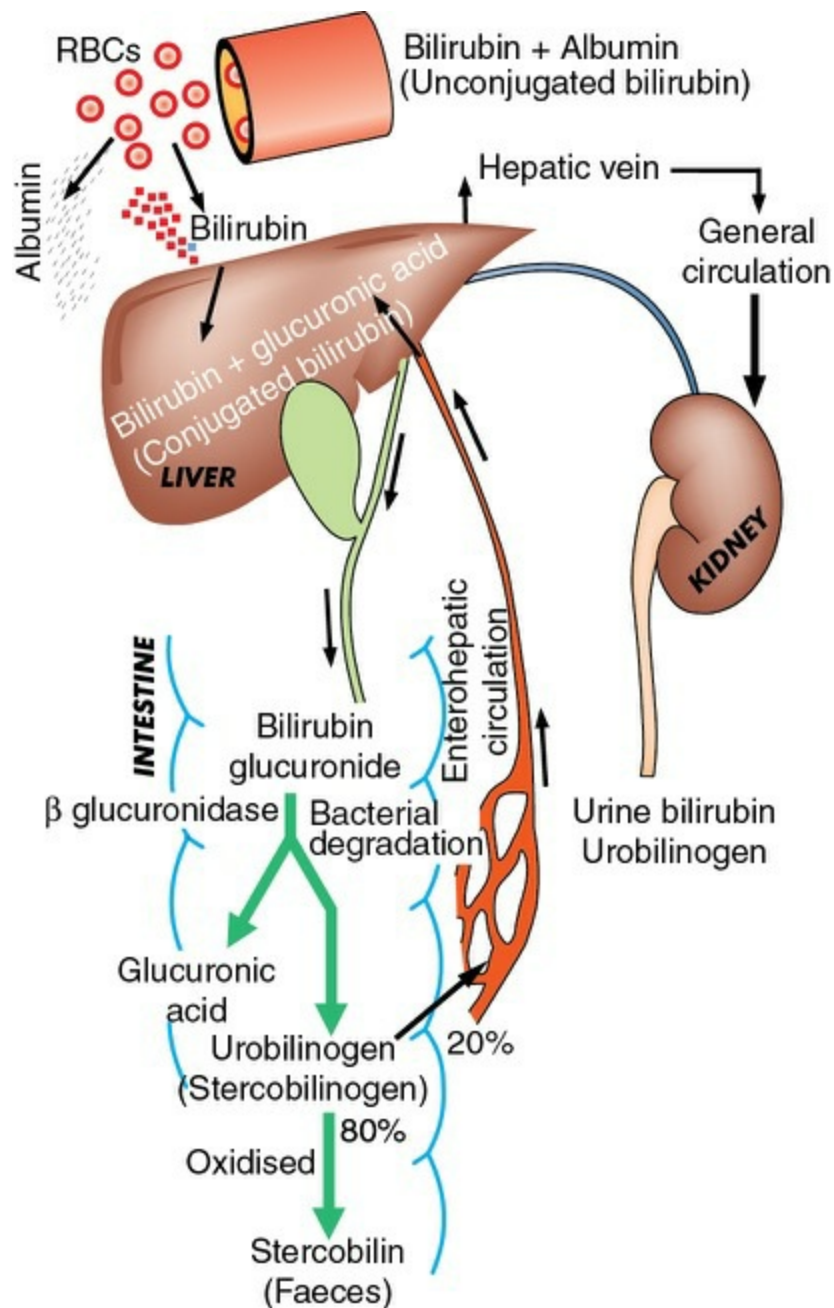

FIGURE 3.2-23 State of bilirubin in the body (details in the text).

1. Uptake of bilirubin.

Macrophages release the bilirubin into circulation. This bilirubin is called free or *unconjugated bilirubin*. It is a lipid soluble and in the plasma it is bound to the albumin (protein-conjugated). It is this protein conjugation of bilirubin which is responsible for solubility of the bilirubin complex in the plasma and which prevents its excretion by the kidneys.

2. Conjugation of bilirubin.

The unconjugated bilirubin (bound to albumin) from the circulation is

taken up by the liver.

- In the liver, the bilirubin is removed from the albumin and taken up at sinusoidal surface of hepatocytes by carrier-mediated transport system (facilitated diffusion).
- Once bilirubin enters the hepatocytes, it binds to certain cytosolic proteins (ligandin and protein Y). These proteins help to keep the bilirubin in solubilized form before conjugation, and also prevent efflux of bilirubin back into blood stream.
- In the hepatic cells it is conjugated with uridine diphosphate glucuronic acid (UDP-glucuronic acid) making it a water soluble conjugated *bilirubin*. The reaction is catalyzed by the enzyme *glucuronyl transferase* present in the hepatic microsomes (smooth endoplasmic reticulum of liver cells). The reaction occurs in two stages:

3. Excretion of bilirubin.

The conjugated bilirubin from the hepatic cells is excreted into the bile canaliculi through active transport, i.e. it is excreted against a concentration gradient into the bile canaliculi. This active transport is the rate-limiting step in the entire process of bilirubin excretion and needs energy. The protein involved is MRP-2 (multidrug resistance like protein-2) also called multispecific organic anion transporter (MOAT). It is located on the plasma membrane of bile canaliculi. Most of the conjugated bilirubin is excreted into the bile and enters the intestine. Some of it escapes into general circulation and is excreted by the kidneys in urine as *urine bilirubin*.

4. Formation and excretion of urobilinogen.

The conjugated bilirubin which enters the intestine with the bile is degraded by the intestinal bacteria in the terminal ileum and the large intestine. The bacterial enzyme β -glucuronidase splits off the glucuronide and converts bilirubin into the *urobilinogen* (stercobilinogen), which is a colourless compound.

- Some urobilinogen (20%) from the intestine is reabsorbed and goes via the portal system to the liver. From the liver some urobilinogen escapes into general circulation and some gets re-excreted into the bile (enterohepatic circulation).
- From general circulation, the urobilinogen is filtered off by the kidney and is excreted in the urine.

Bilirubin

The normal serum bilirubin level ranges from 0.3 mg–1.0 mg/dL. The total serum bilirubin includes conjugated, as well as, unconjugated bilirubin. The Van den Bergh test described below is helpful in determining the type of bilirubin present in the serum.

Van den Bergh test.

For quantitative estimation of bilirubin contents in the serum

Van den Bergh test is performed using the diazo reagent (mixture of sulphanic acid, hydrochloric acid and sodium nitrite). It is of two types:

Direct Van den Bergh reaction.

When diazo reagent is added to the serum containing conjugated bilirubin (water soluble), a reddish-brown colouration is obtained within 30 s. This is called direct positive Van den Bergh reaction.

Indirect Van den Bergh reaction.

When diazo reagent is added to the serum mainly containing unconjugated bilirubin (water insoluble), no colour is obtained. However, if some solvent like methanol (which dissolves the unconjugated bilirubin) is added, the reddish-brown colouration is obtained. This is called indirect positive Van den Bergh reaction.

Hyperbilirubinaemia (jaundice)

Jaundice (icterus) refers to the yellow appearance of the skin, sclera and mucous membranes resulting from an increased bilirubin concentration

(*hyperbilirubinaemia*) in the body fluids. Clinically, jaundice is detectable when the plasma bilirubin exceeds 2–3 mg/dL. Internal tissues and body fluids are coloured yellow, but not the brain, as bilirubin does not cross the blood–brain barrier other than in the immediate neonatal period.

Mechanisms producing jaundice.

Hyperbilirubinaemia producing jaundice can result from the following mechanisms:

1. Excessive breakdown (haemolysis) of red blood cells

produces the so-called haemolytic jaundice or prehepatic jaundice or retention hyperbilirubinaemia due to over production.

2. Damage to the liver cells

(infective or toxic) produces the so-called hepatic or hepatocellular jaundice.

3. Obstruction to bile ducts

produces the obstructive or posthepatic or cholestatic jaundice or regurgitation hyperbilirubinaemia (due to reflux into bloodstream).

Characteristic features of jaundice.

As mentioned above, depending upon the mechanism of production, jaundice is of three types:

- Prehepatic jaundice (haemolytic jaundice),
- Hepatic jaundice (heptocellular jaundice and
- Posthepatic jaundice (obstructive or cholestatic jaundice).

Characteristic features of these three varieties of jaundice are described in Table 3.2-5:

TABLE 3.2-5
Characteristic Features of Three Types of Jaundice

Haemolytic jaundice (prehepatic jaundice)	Hepatocellular jaundice (hepatic jaundice)	Cholestatic or obstructive jaundice (posthepatic jaundice)
---	--	--

1. Mechanism of production		
<i>Excessive breakdown of RBCs producing unconjugated bilirubin in amounts more than the healthy liver can conjugate and excrete.</i>	<i>Inability of the liver to efficiently conjugate as well as transport bilirubin into the bile due to liver cell damage caused by some infective or toxic agent.</i>	<i>Obstruction to the bile flow due to any cause from hepatocytes to duodenum.</i>
2. Types of serum bilirubin accumulated		
<i>Unconjugated hyperbilirubinaemia occurs since it is being produced in excess of what can be conjugated by the liver.</i>	<i>Both unconjugated as well as conjugated bilirubin is increased in serum.</i>	<i>Conjugated hyperbilirubinaemia results due to impaired flow of bile.</i>
3. Van den Bergh test		
<i>Indirect positive reaction (because unconjugated bilirubin is present in blood).</i>	<i>Biphasic reaction (because conjugated and unconjugated bilirubin are present).</i>	<i>Direct positive reaction (because only conjugated bilirubin is present).</i>
4. Urine bilirubin		
<i>Absent</i>	<i>Present</i>	<i>Present</i>
<i>(Unconjugated bilirubin is insoluble in water. It is transported in plasma in bound form with albumin. Since albumin is not filtered into urine, unconjugated bilirubin too is not filtered in urine. Because of this haemolytic jaundice is also called <i>acholuric jaundice</i> (no bile pigment in urine).</i>	<i>Conjugated bilirubin is water soluble and is present in plasma in dissolved form. It gets easily filtered in urine. This type of jaundice is also called <i>choluric jaundice</i>, i.e. (bile pigment present in urine).</i>	<i>(Since conjugated bilirubin is filtered in urine).</i>
5. Urine urobilinogen		
<i>Increases</i>	<i>Decreases</i>	<i>Markedly decreased or absent</i>
<i>(Because liver is excreting lot of conjugated bilirubin in the intestine with the bile, so, more urobilinogen is formed. Part of it is reabsorbed and goes to general circulation and thus urine urobilinogen is increased).</i>	<i>(Because, damaged liver cells are producing and excreting less of conjugated bilirubin and thus less urobilinogen is formed).</i>	<i>(Because of obstruction the conjugated bilirubin is not released into the intestine and thus no urobilinogen is formed).</i>
6. Faecal stercobilinogen (normal 25–250 mg/day).		
<ul style="list-style-type: none"> • <i>Markedly increased</i> (because of more formation as described above). • So faeces are <i>dark brown</i> in colour. 	<ul style="list-style-type: none"> • <i>Reduced</i> (because of less formation as described above). • So stools are <i>pale</i> in colour. 	<ul style="list-style-type: none"> • <i>Absent</i> (when obstruction is complete). • So stools are <i>clay</i> coloured.
7. Faecal fat level		
Normal, i.e. 5–6% of total intake/day (as bile is present in gut for normal digestion of fats).	<i>Increased up to 40–50% (because of deficiency of bile in the intestine, emulsification and absorption of fat is inadequate. This produces bulky, pale, greasy and foul smelling faeces, called steatorrhoea).</i>	<i>Increased</i>
8. Specific blood tests		
<ul style="list-style-type: none"> • <i>Peripheral blood film</i> shows signs of haemolysis, i.e. anaemia, reticulocytosis and abnormal RBCs. • <i>Plasma albumin, globulin and A/G ratio</i>: normal. • <i>Serum alkaline phosphatase</i>: normal, i.e. 5–13 KA units/100 ml (because excreted in bile). • <i>Liver function tests</i> Normal (as liver is healthy). 	<p>Normal</p> <p>Albumin is decreased due to less synthesis by damaged liver, globulin increases and A/G ratio decreases.</p> <p>Increased (because less excretion in bile)</p> <p>Impaired (as liver is damaged).</p>	<p>Normal</p> <p>Normal</p> <p>Markedly increased (because not excreted in bile).</p> <p>Normal or mildly impaired.</p>

Physiological jaundice of newborn.

Physiological jaundice of newborn is also called neonatal jaundice.

Mechanism of production.

A hyperbilirubinaemia producing jaundice may be seen normally in the newborn. It appears within 2–5 days of birth and usually disappears in 2 weeks. Its mechanism of production includes:

- **Excessive destruction of RBCs**

occurs in first few days after birth causing increase in serum bilirubin.

- **Hepatic immaturity**

in the first few (7–10) days after birth also contributes to increased serum bilirubin. In the fetus, bilirubin is removed from circulation by the placenta. Immediately after birth, the liver has to take up this work which takes 7–10 days to mature and fully conjugate the bilirubin.

Prevention and treatment.

- **Prevention.**

Neonatal jaundice can be prevented by administration of hepatic microsomal enzyme inducers (e.g. phenobarbital) to the pregnant mother or newborn. The microsomal enzyme inducers increase the activity of glucuronyl transferase in liver.

- **Treatment.**

Normal jaundice can be effectively treated by *phototherapy*. Exposure of the skin to white light causes photoisomerization of bilirubin to water-soluble *lumirubin* which can be rapidly excreted in bile without requiring any conjugation. Thus, phototherapy is of value in treating infants with jaundice, irrespective of its cause.

Applied Aspects

Kernicterus

Unconjugated bilirubin because of its hydrophobic property can cross the blood–brain barrier. When concentration of unconjugated bilirubin in plasma exceeds that which can be tightly bound to albumin (20–25 mg/dL), it enters into the central nervous system and thus results in kernicterus or encephalopathy. The basal ganglia of CNS are mainly affected. For details see page 947

Congenital nonhaemolytic jaundice (Crigler–Najjar syndrome type I and II):

Crigler–Najjar syndrome type I

is a rare autosomal recessive disorder which occurs due to mutation of gene encoding bilirubin UGT activity. The disease is characterized by raised serum bilirubin levels (usually exceed 20 mg/dL). The disease is fatal and phenobarbitol has no effect on formation of bilirubin. Liver transplantation is the only treatment.

Crigler–Najjar syndrome type II.

In this, some activity of the enzyme is retained, therefore in these patients, serum bilirubin level does not exceed 20 mg/dL and responds to phototherapy and phenobarbitol.

- **Gilbert syndrome** is also caused by mutation in genes encoding bilirubin-UGT, but 30% enzyme activity persists. Therefore no harmful effects.
- **Dubin–Johnson syndrome** is a benign autosomal recessive disorder with conjugated hyperbilirubinaemia either in childhood or in adult. It occurs due to mutation in the gene encoding MRP-2 (the protein involved in secretion of bilirubin in the bile).
- **Rotor syndrome** is a rare benign condition which may be occurring due to abnormality in hepatic storage of bilirubin, characterized by chronic conjugate hyperbilirubinaemia.
- **Toxic hyperbilirubinaemia** occurs due to toxin-induced liver dysfunctions, caused by chloroform, aceta-aminophen, viral hepatitis and mushroom poisoning.

Anaemias

Definition and classification

Definition

Anaemia is not a single disease but a group of disorders in which haemoglobin concentration of blood is below the normal range for the age and sex of the subject. Therefore, anaemia is labelled when

haemoglobin concentration is less than:

- 13 g/dL in adult males,
- 11.5 g/dL in adult females,
- 15 g/dL in newborn, and
- 9.5 g/dL at 3 months of age.

Low RBC count (*less than 4 million/mm³*) is usually, but not always associated with low haemoglobin levels in anaemia.

Grading of anaemia, depending upon the level of haemoglobin, has somewhat arbitrarily been made as:

- Mild anaemia—Hb 8–10 g/dL
- Moderate anaemia—Hb 6–8 g/dL and
- Severe anaemia—Hb below 6 g/dL.

Classification

Aetiological (Whitby's) classification.

Types of anaemia depending upon the causative mechanism are:

A. Deficiency anaemias

- Iron deficiency anaemia,
- Megaloblastic anaemia (pernicious anaemia) due to deficiency of vitamin B₁₂,
- Megaloblastic anaemia due to deficiency of folic acid and
- Protein and vitamin C deficiency can also cause anaemia.

B. Blood loss anaemias.

or haemorrhagic anaemias are commonly known and can be:

- *Acute posthaemorrhagic anaemia* as in accidents, and

- *Chronic posthaemorrhagic anaemia*

C. Haemolytic anaemias.

These are relatively uncommon and occur in conditions associated with increased destruction of red blood cells. These can be:

1. Hereditary haemolytic anaemias,

e.g. as seen in:

- Thalassaemia (see page 148),
- Sickle cell anaemia (see page 147),
- Hereditary spherocytosis (see page 151) and
- Glucose 6-phosphate dehydrogenase (G6PD) deficiency (see page 152).

2. Acquired haemolytic anaemias

such as:

Immuno-haemolytic anaemia (due to antibodies against RBCs),

- Microangiopathic haemolytic anaemia (due to mechanical damage to RBCs,
- Haemolytic anaemia due to direct toxic effects (e.g. in malaria, snake venom, toxic effects of drugs and chemicals),
- Haemolytic anaemia in splenomegaly and
- Haemolytic anaemia in paroxysmal nocturnal haemoglobinuria (PNH).

D. Aplastic anaemia.

It occurs due to failure of bone marrow to produce RBCs. It is of two main types:

- Primary aplastic anaemia, and
- Secondary aplastic anaemia.

E. Anaemia due to chronic diseases.

It is seen in tuberculosis, chronic infections, malignancies, chronic lung diseases. The mechanism of causation of anaemia is complex. The tissue

macrophages are believed to become activated so that RBCs are removed from the blood faster than they can be formed in bone marrow.

Morphological (Wintrobe's) classification.

Based on the mean cell volume (MCV), i.e. cell size and the mean corpuscular haemoglobin concentration (MCHC), i.e. haemoglobin saturation of RBCs, the anaemias can be classified as:

1. Normocytic normochromic anaemias.

These are characterized by normal MCV (78–94 μm^3) and normal MCHC (30–38%). Such a morphological picture is seen in:

- Acute posthaemorrhagic anaemia,
- Haemolytic anaemias and
- Aplastic anaemias.

2. Microcytic hypochromic anaemias.

These are characterized by reduced MCV (<78 μm^3) and reduced MCHC (<30%). Examples of such anaemias are:

- Iron deficiency anaemia,
- Chronic posthaemorrhagic anaemia,
- Sideroblastic anaemia and
- Thalassaemia.

3. Macrocytic normochromic anaemia

is characterized by increased MCV (>94 μm^3) and normal MCHC (30–38%). Examples are:

- Megaloblastic anaemia (pernicious anaemia) is due to deficiency of vitamin. B₁₂, and
- Megaloblastic anaemia due to deficiency of folic acid.

General clinical features of anaemia

Anaemic hypoxia

results due to decreased O₂-carrying capacity of blood in anaemia owing to reduced haemoglobin concentration. The hypoxia brings about several cardiorespiratory compensatory responses. So, general clinical features (symptoms and signs) in patients with anaemia are due to those caused by:

- Resulting tissue hypoxia, and
- Resulting compensatory mechanisms.

Haemoglobin level at which symptoms and signs of anaemia develop depends upon three main factors:

- *Speed of onset of anaemia.* Rapidly progressive anaemia causes more symptoms than anaemia of slow onset.
- *Severity of anaemia.* Mild anaemia usually produces no symptoms. Severe anaemia (Hb < 6 g/dL) of rapid onset produces significant clinical features.
- *Age of the patient.* Young patients tolerate anaemia quite well vis-à-vis elderly patients and develop less marked features.

General clinical manifestations of anaemia

which occur either due to tissue hypoxia or due to compensatory mechanisms are:

- *Generalized muscular weakness*, tiredness and easy fatigability occur due to muscle hypoxia.
- *Pallor* of skin and mucous membranes (buccal and pharyngeal mucous membrane, conjunctiva, lips, ear lobes, palm and nail bed) occurs due to deficiency of red coloured haemoglobin in the blood.
- *Respiratory symptoms* such as breathlessness with increased rate and force of respiration occur due to compensatory stimulation of respiratory centre.
- *Cardiovascular manifestations* such as palpitation, tachycardia and cardiac murmurs occur as a result of compensatory mechanisms increasing the cardiac output. In very severe cases of anaemia, features

of cardiac failure and angina pectoris may also occur.

- **Central nervous system (CNS) manifestations** due to cerebral hypoxia include lethargy, headache, faintness especially on exertion, tinnitus, restlessness, confusion and drowsiness.
- **Ocular manifestations** include visual disturbances and retinal haemorrhages and cotton wool spots.
- **Gastrointestinal system symptoms** include anorexia, flatulence, nausea, constipation. In pernicious anaemia, there occurs atrophy of papillae on the tongue.
- **Reproductive system** involvement occurs in females in the form of menstrual disturbances such as amenorrhoea and menorrhagia and loss of libido.
- **Renal system** involvement may occur in severe anaemia causing disturbances of renal function and albumin urea.
- **Basal metabolic rate (BMR)** is increased in severe anaemia.

Description of different types of anaemias

Deficiency anaemias

Deficiency anaemias are quite common and occur due to deficiency of factors necessary for erythropoiesis. These include:

- Iron deficiency anaemia,
- Megaloblastic anaemia due to vitamin B₁₂ deficiency (pernicious anaemia),
- Megaloblastic anaemia due to folic acid deficiency,
- Anaemia due to protein deficiency and
- Anaemia due to vitamin C deficiency.

Iron deficiency anaemia

Iron deficiency anaemia is the commonest nutritional deficiency disorder

present throughout the world, but its prevalence is higher in the developing countries. In India, iron deficiency is the commonest cause of anaemia. Iron deficiency anaemia is much more common:

- In women between 20–45 years than in men.
- At periods of active growth in infancy, childhood and adolescence.

Before discussing the different aspects of iron deficiency anaemia, it will be worthwhile to discuss about normal iron metabolism.

Iron metabolism

Iron is one of important metals present in the human body. The body of a healthy adult contains 4–5 g (72–90 mmol) of iron in the following forms:

- *Haemoglobin* contains about 70% of the total body iron (2.5 g or 45 mmol).
- *Storage iron* amounts to about 20–23% of total body iron (1.5 g, i.e. 18–27 mmol). Two-third of the iron is stored as ferritin and one-third as haemosiderin.
- *Myoglobin* (myohaemoglobin) present in the red muscles contain about 5% of the total body iron (0.2 g or 3.6 mmol)
- *Intracellular enzymes* account for less than 0.1 g (1.8 mmol), i.e. about 2–3% of total body iron. The iron containing enzymes include cytochrome oxidase, catalase and peroxidase cytochrome.

Daily requirement and dietary sources of iron

Daily requirement.

Only 10% of the dietary intake of iron is absorbed. Therefore, daily requirement in adult males is 5–10 mg/day and in females is 20 mg/day (to compensate the menstrual loss). Pregnant and lactating women require about 40 mg of iron per day.

Dietary sources.

Foodstuffs vary both in their iron content and availability of iron for absorption into the body. The dietary sources of iron are meat, liver, egg, leafy vegetables, whole wheat and jaggery. The iron in foods of animal

origin is better absorbed than iron in foods of vegetable origin.

Absorption of iron

- Absorption occurs mainly in the duodenum and upper jejunum.
- Normally, about 10% of the 15–20 mg iron ingested each day is actually absorbed in healthy adult male. This absorption is more in menstruating women.

Mechanism of iron absorption.

Mechanism of iron absorption for the purpose of understanding can be described under three headings:

- A. Transport of iron across the brush border of enterocyte
- B. Fate of iron in the enterocyte, and
- C. Transport of iron in the plasma.

A. Transport of iron across brush border of enterocyte.

In the diet, iron may be present as haem (derived from meat) or nonhaem iron.

1. **Absorption of haem iron.** Haem iron is the iron present in myoglobin, haemoglobin and related compounds. From these compounds, the haem is released by proteolytic enzymes in the gut. From the lumen, the haem is transported inside the enterocyte across the brush-border membrane by an unidentified *haem transport* protein. Inside the cell, the ferrous iron (Fe^{2+}) is released from the haem by the enzyme haemoxygenase. The fate of Fe^{2+} so released is as that of nonhaem Fe^{2+} as given (Fig. 3.2-24). Haem iron absorption is not affected by other dietary constituents.

2. **Absorption of nonhaem iron.** Most of the dietary nonhaem iron is present in ferric form (Fe^{3+}), whereas iron can be absorbed more efficiently in ferrous form (Fe^{2+}).

- Iron has got tendency to form insoluble complexes with dietary phytates, phosphates and dietary fibres. These complexes are more soluble at low pH. Gastric HCl

tends to break insoluble iron complex apart and thus facilitates iron absorption. This explains the occurrence of iron deficiency anaemia in patients with deficient gastric acid secretion (achlorhydria).

- Ascorbic acid and other reducing agents promote iron absorption by reducing ferric iron to ferrous form and also by preventing iron from forming insoluble iron complexes within the chyme.
- Ferrous iron (Fe^{2+}) is transported across the brush border by the *iron transport protein*, i.e. proton coupled divalent metal transporter (DMT-1) present on the cell membrane (Fig. 3.2-24). This protein is not specific for iron, as it can transport a large variety of divalent cations. Once inside the enterocyte, the fate of nonhaem ferrous iron is the same as that of haem iron.

FIGURE 3.2-24 Absorption of iron. Haem is carried across brush border of enterocyte by a haem transport protein (HT), and Fe^{2+} of nonhaem iron by iron transport protein (IT). Inside the enterocyte, some iron binds to ferritin and some crosses the basolateral membrane by active transport process (AT). In the blood, iron binds to the transport protein transferrin (TF).

B. Fate of iron in the enterocyte.

As shown in Fig. 3.2-24, in the cytosol of enterocyte, the free ferrous iron (Fe^{2+}) has two fates:

- A part of Fe^{2+} , depending upon the body's requirement, is actively transported across the basolateral membranes of the enterocytes into the interstitium, from where it enters the blood. Across the basolateral membrane of enterocytes the transport is carried out by another protein called iron regulating protein-I (IREG-I).
- Rest of the ferrous iron is oxidized to ferric form and bound to apoferritin forming ferritin. It is difficult to release iron from this storage form, and in general the ferritin stays in the enterocyte until the cell is sloughed off at the tip of villus.

C. Transport of iron in the blood.

Normally, the iron absorbed into the blood binds with a beta globulin (apotransferrin) to form the transferrin and is transported in this form in the plasma. Iron combines loosely in the globulin apotransferrin and can be released easily to enter any of the tissue cells at any point in the body.

Factors affecting absorption of iron.

Factors affecting absorption of iron from the gut are:

1. *Form of dietary iron*

- *Haem iron.* Iron may be present as haem iron or nonhaem iron forming about 10–15% of the iron present in diet of animal origin, is relatively unaffected by the composition of diet. Haem is absorbed directly, i.e. without splitting off of iron *from protoporphyrin*.
- In *nonhaem iron* the ferrous (Fe^{2+}) form is better absorbed than ferric (Fe^{3+}) form. Therefore, reducing agents such as vitamin C enhance iron absorption by converting ferric into ferrous.

2. *Meat and fish* in the diet considerably enhance absorption of nonhaem iron. The exact mechanism is, however, unknown.

3. *Human breast milk* improves the iron absorption.

4. *The acid gastric juice* (HCl from stomach) favours absorption of nonhaem iron by causing its solubilization and reduction. Therefore, absorption of ferric iron is impaired in subjects with gastrectomy or achlorhydria.

5. *Dietary factors inhibiting nonhaem iron* absorption are:

- *Phytates* in foods (cereals) reduce iron absorption by forming insoluble iron salts.

- *Phosphates*, calcium, egg white and bovine milk proteins inhibit iron absorption.
- *Phenols* present in legumes, tea, coffee and wine cause poor absorption of iron.

6. *Iron stores in the body* affect iron absorption as:

- *Decrease* in iron store of the body (e.g. in iron deficiency anaemia or when erythropoiesis is increased due to hypoxia) enhance iron absorption.
- *An increase in iron storage* in the body reduces iron absorption by the gut mucosa.

Storage of iron in the body.

In the body, iron is stored in two forms, the ferritin and the haemosiderin.

Storage of iron as ferritin.

The iron released into the tissues by apotransferrin combines with the protein apoferritin to form the *ferritin*. Thus, iron is stored as ferritin in the cells of the body. Maximum amount of iron is stored in the hepatocytes of liver and cells of reticuloendothelial system. In other cells of the body only a small amount of iron is stored.

Storage of iron as haemosiderin.

When the intake of iron in the diet is in extremely large quantities, some amount of iron is also stored as a compound *haemosiderin* in reticuloendothelial cells. The haemosiderin is highly insoluble and thus represents a more stable form of storage iron than the ferritin. Therefore, iron exchanges mostly with the ferritin, since exchange with haemosiderin is very slow.

Regulation of body iron.

Regulation of body iron, i.e. iron balance in the body is unique in that it is achieved by control of absorption rather than by control of excretion.

Regulation of mucosal absorption has been explained by mucosal block theory.

Mucosal block theory of absorption.

This theory states that:

- Iron absorption is increased when body iron stores are depleted or when erythropoiesis is increased, and decreased under the reverse conditions.
- As compared to normal conditions (Fig. 3.2-25A), in iron deficiency states, a larger percentage of dietary iron enters the circulation and a smaller amount forms ferritin in the epithelial cells (Fig. 3.2-25B).
- In the presence of iron overload, more ferritin is formed in the enterocytes and shed with these cells in the stools (Fig. 3.2-25C).

FIGURE 3.2-25 Mucosal block theory of regulation of iron absorption: **A**, normally (say, e.g. equal amount (3⁺) of iron is bound to form ferritin and enters the blood across basolateral membrane; **B**, in iron deficiency states, less iron forms ferritin (e.g. 1⁺) and more enters the blood, e.g. 5⁺; and **C**, in iron overload, more ferritin is formed (5⁺) and less enters the blood 1⁺.

The details of the regulatory processes involved remain obscure. However, following views have been put forward to explain the mucosal block theory.

1. **Saturation of apoferritin and apotransferrin.** Most of the iron in the body is stored as ferritin, which is formed by a combination of iron with the protein apoferritin present in the cytoplasm of the body cells. When essentially all apoferritin in the body is saturated with iron, it becomes difficult for the transferrin to release its iron to the tissue cells. Consequently the whole of the apotransferrin is saturated with iron and thus the mucosal cells are loaded with the transferrin. Because of the unavailability of the apotransferrin, the mucosal cells are not able to take up any more luminal iron. Mucosal cells have a lifespan of 3–4 days, at the end of which they get sloughed off into the intestine. Mucosal transferrin (containing iron) is also lost with it and the body gets rid of excess of iron.
2. **Decreased rate of apoferritin synthesis.** When body has excess of iron, due to feedback mechanism, the rate of apoferritin synthesis in the liver is also decreased and thus less iron is absorbed by the intestinal cells.
3. **Role of specific iron receptors in the brush border.** Recently it has been proposed that the absorption of iron by the enterocytes is determined by the presence of receptors on the brush border. Iron receptors in brush border preparations of the small intestine are inversely related to the level of body iron stores. Iron deficient animals show an increase in the number of receptor population, which can be reversed by iron loading.

Conclusion.

The current understanding of the regulation of body iron is still in a state of flux with following conclusions:

- The control seems to reside primarily in the need-based transfer of iron from the enterocyte to the portal blood.
- Some control is also exerted at the level of uptake of iron from the intestinal lumen.
- In cases of iron overload, some iron can be transported from the plasma to the enterocytes. This iron is lost when the enterocytes are shed into the lumen. In this way, the intestine serves to excrete excess iron in a bid to prevent accumulation of excessive iron in the body. Thus, the statement that iron content of the body is regulated only by absorption is also true, only to a limited extent.

The iron cycle.

The iron cycle refers to the continuous exchange of iron between the plasma and RBCs. The steps of iron cycles are (Fig. 3.2-26):

- From the plasma, the iron is transported into bone marrow as transferrin.
- In the bone marrow, the transferrin binds to the specific transferrin receptors present on the surface of intermediate normoblasts.
- In the intermediate normoblasts, the iron is incorporated into the haemoglobin. The mature RBCs containing haemoglobin are then released into the plasma.
- RBCs, after their death (on completion of lifespan), are engulfed by macrophages.
- After phagocytosis, the red cell membrane is lysed and haem is released from the haemoglobin. By the haemoxy genase reaction, iron is liberated from the haem.
- Macrophages lining the sinuses of liver and spleen release iron back into the plasma where it binds with the apotransferrin to form transferrin, thus completing the iron cycle. Each day, about 30 mg of iron goes through this cycle. In addition, about 2 mg iron enters the plasma from the diet also.

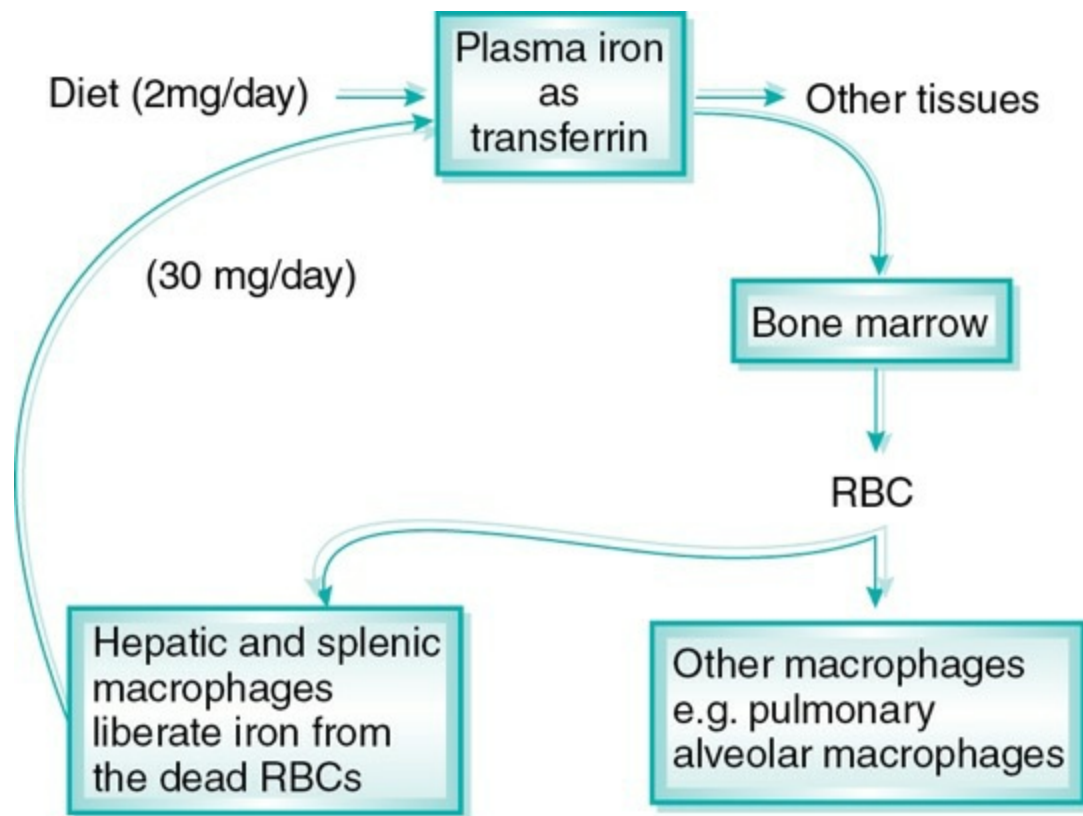

FIGURE 3.2-26 Iron cycle.

Role of iron in the body.

Iron is utilized in the synthesis of:

- *Haemoglobin* in the RBCs (main role),
- *Myoglobin* in the muscles, and
- *Cytochromes* the intracellular enzymes.

Uptake of the iron by tissues

- *RBCs* are the main takers of iron (about 30 mg/day)
- *Other tissues* take up about less than 2 mg iron each day as follows:
 - *Liver*. Out of the tissues other than RBCs, liver takes up the largest amount of iron.
 - *Intestinal mucosal cells*. Iron is stored as transferrin in the intestinal mucosal cells which regulate the iron absorption as discussed above.
 - *Skeletal muscles*. Iron is utilized to produce myoglobin by the muscles.

- *Proliferating cells of the body.* Iron is utilized for synthesis of enzymes cytochrome and catalases, which are required in excess by the proliferating cells of the body.

Applied Aspects

Iron deficiency results in iron deficiency anaemia.

Iron excess. Iron overload may occur when its absorption exceeds its excretion. Such a condition occurs due to:

- *Excessive intake* of iron, and
- *Idiopathic* or congenital failure of mucosal feedback mechanism controlling iron absorption.
- *Excessive* destruction of erythrocytes may also be associated with siderosis.

The excess of iron in the body results in accumulation of hemosiderin in the tissues producing the so-called *haemosiderosis*. Excess of hemosiderin damages the tissues and produces the condition of *haemochromatosis*.

Haemochromatosis may be hereditary or acquired.

The hereditary or primary haemochromatosis occurs due to mutation of HFE gene located on chromosome-6. The individual with homogeneous mutated HFE gene absorbs excess amounts of iron because normally the HFE gene inhibits expression of the transporter responsible for iron intake. Haemochromatosis is characterized by:

- Pigmentation of the skin,
- Diabetes due to pancreatic damage (bronze diabetes),
- Cirrhosis of liver,
- Carcinoma of the liver and
- Atrophy of gonads.

Causes of iron deficiency anaemia

Causes of iron deficiency vary with age, sex and country of residence of patient. In general, the causes of iron deficiency anaemia can be grouped

as:

1. Inadequate dietary intake of iron

as in:

- Milk fed infants,
- Poor economic status individuals,
- Anorexia, e.g. in pregnancy and.
- Elderly individuals due to atrophy and poor dentition

2. Increased loss of iron

(as blood loss) from the body, e.g.

- *Uterine bleeding in females* in the form of excessive menstruation, repeated miscarriages, postmenopausal bleeding, etc.
- *Gastrointestinal bleeding* due to peptic ulcer, haemorrhoids, ulcerative colitis, etc.
- *Renal tract bleeding*, e.g. haematuria.
- *Nasal bleeding*, i.e. repeated epistaxis.
- *Bleeding from lungs* as haemoptysis.

3. Increased demand of iron

as in:

- Infancy, childhood and adolescence,
- Menstruating females and
- Pregnant females.

4. Decreased absorption

of iron, as seen in:

- Partial or total gastrectomy,

- Achlorhydria and
- Intestinal malabsorption diseases.

Clinical features, laboratory findings and treatment

Clinical features of anaemia

1. *General features of anaemia*

See page 157.

2. *Characteristic features of iron deficiency anaemia* are in the form of the following epithelial tissue changes:

- *Nails* become dry, soft and spoon shaped (koilonychia).
- *Tongue* becomes angry red (atrophic glossitis).
- *Mouth* may show angular stomatitis.
- *Oesophagus* may develop thin membranous webs at the postcricoid area leading to dysphagia (Plummer–Vinson syndrome).

Laboratory findings

1. Blood picture and red cell indices

- *Haemoglobin* concentration is decreased.
- RBCs are hypochromic (deficient in haemoglobin) and microcytic (smaller in size). They show anisocytosis and poikilocytosis.
- *Red cell indices* like MCV, MCH and MCHC are decreased.

2. Bone marrow findings

are:

- Marrow cellularity: erythroid hyperplasia,
- Erythropoiesis: normoblastic and
- Marrow iron: deficient reticuloendothelial iron stores and absence of siderotic iron granules.

3. Biochemical findings

- Serum iron decreases, often under 50 µg/dL (normal 60–160 µg/dL).
- Serum bilirubin less than 0.4 mg/dL.
- Serum ferritin is less than 30 µg/dL indicating poor tissue iron stores.
- Total iron-binding capacity (TIBC) is increased.

Treatment.

Treatment of iron deficiency anaemia consists of:

- Oral administration of Fe²⁺ salts, and
- Correction of causative factor if possible.

Megaloblastic anaemia

Megaloblastic anaemias are characterized by abnormally large cells of erythrocyte series. These are caused by defective DNA synthesis due to deficiency of vitamin B₁₂ and/or folic acid (folate).

Aetiological types

I. Megaloblastic anaemia due to vitamin B₁₂ deficiency.

Salient features of vitamin B₁₂ and intrinsic factor of Castle should be understood before discussing other aspects of anaemia due to vitamin B₁₂ deficiency (see page 142).

Causes of vitamin B₁₂ deficiency

are:

1. *Inadequate dietary intake* may occur in:

- Strict vegetarians, and
- Breast-fed infants.

2. *Malabsorption of vitamin B12* is more often the cause of deficiency and may be due to:

- *Gastric causes* leading to deficiency of intrinsic factors such as an autoimmune cause of failure of secretion of intrinsic factor (Addisonian pernicious anaemia), gastrectomy and congenital lack of intrinsic factor.
- *Intestinal causes* which are associated with decreased vitamin B₁₂ absorption are tropical sprue, ileal resection, Crohn's disease, fish tapeworm infestation and intestinal blind loop syndrome.

Addisonian pernicious anaemia.

Aetiology. Addisonian pernicious anaemia is the term which is used specifically for the megaloblastic anaemia due to vitamin B₁₂ deficiency occurring as a result of failure of secretion of intrinsic factor by the stomach owing to an autoimmune atrophy of gastric mucosa. Thus, pernicious anaemia is an autoimmune disease and in about 50% of patients, antibodies to intrinsic factor can be demonstrated. The disease is rare before the age of 30 years, occurs mainly between 45 and 65 years and affects females more frequently than males.

Features of pernicious anaemia

include:

- *Features of megaloblastic anaemia* (described on page 162), and
- *Specific features* of pernicious anaemia are:
- Anti-intrinsic factor antibodies in serum (present in 50% cases) and

- Abnormal vitamin B₁₂ absorption test corrected by addition of intrinsic factor (Schilling test).

Treatment

of pernicious anaemia consists of regular administration of vitamin B₁₂ by intramuscular route:

II. Megaloblastic anaemia due to folate deficiency

Salient features of folic acid.

and its role in erythropoiesis (see page 143).

Causes of folate deficiency.

are:

1. *Inadequate dietary intake* due to poor intake of vegetables as seen in poor people, infants and alcoholics.
2. *Malabsorption*, e.g. in coeliac disease, tropical sprue and Crohn's disease.
3. *Increased demand* as occurs in:
 - Physiological conditions such as pregnancy, lactation and infancy and
 - Pathological conditions of cell proliferation, such as increased haematopoiesis (as in haemolysis) and malignancies.
4. *Effect of drugs* such as: certain anticonvulsants (e.g. phenytoin), contraceptive pills and certain cytotoxic drugs (e.g. methotrexate).
5. *Excess urinary folate loss*, e.g. in active liver disease and congestive heart failure.

Features of folate deficiency anaemia.

include:

- *Features of megaloblastic anaemia, and*
- *Specific features of folate deficiency are:*
- Low serum folate levels and
- Low red cell folate levels.

Clinical features of megaloblastic anaemia

A. General features of anaemia

See page 157.

B. Characteristic features of megaloblastic anaemia

1. Blood picture and red cell indices

- *Haemoglobin* level is low.
- RBCs are larger in size (macrocytosis) but contain a normal concentration of haemoglobin (normochromia).
- *MCV* increases to 95–160 μm^3 (normal 78–94 μm^3).
- *MCH* increases to 50 pg (normal 28–32 pg).
- *MCHC* usually normal ($35 \pm 3\%$) because both *MCV* and *MCH* increase. In late stages, *MCHC* may decrease.
- *Peripheral smear* shows nucleated RBCs with marked anisocytosis and poikilocytosis.
- *Reticulocyte count* increases to more than 5% (normal less than 1%).
- *Lifespan of RBCs* is decreased.
- *WBCs and platelets* decrease because of encroachment of megaloblastic tissue.

2. Bone marrow picture

- Bone marrow shows *megaloblastic hyperplasia* characterized by presence

of:

- 70% proerythroblasts and early normoblasts (normal 30%), and
- 30% intermediate and late normoblasts (normal 70%).
- *Marrow iron.* Prussian blue staining for iron in the marrow shows an increase in the number and size of iron granules in the erythroid precursors.

3. Biochemical finding

- *Serum bilirubin* increases more than 1 mg/dL (normal 0.2–0.8 mg/dL) due to excessive destruction of RBCs in spleen, liver and bone marrow.
- *Urine urobilinogen* excretion may increase due to increased serum bilirubin.
- *Serum iron and ferritin* is usually increased because iron is not utilized by immature RBCs.
- *Serum vitamin B₁₂* levels are decreased (normal 150–350 pg/ml) in patients with megaloblastic anaemia due to vitamin B₁₂ deficiency.
- *Serum folate levels* are decreased in patients with megaloblastic anaemia due to folic acid deficiency.
- *Red cell folate levels* are a more reliable indicator of tissue stores of folate than serum. In folic acid deficiency, red cell folate levels are decreased.

4. Schilling test

is performed in two stages:

In the first stage, a large intramuscular dose of vitamin B₁₂ is given to saturate the plasma transport protein. Thereafter, radiolabelled vitamin B₁₂ is administered orally, and 24 h urine samples are collected to detect vitamin B₁₂. Normally more than 7% of the dose is present in the urine and patients with impaired absorption will have less than 3% of the dose.

The second stage of Schilling test is performed to detect pernicious

anaemia due to lack of intrinsic factor. Radiolabelled vitamin B₁₂ along with intrinsic factor is administered. Combined use of vitamin B₁₂ and intrinsic factor should correct abnormally low absorption due to lack of intrinsic factor. Therefore, urine vitamin B₁₂ level will be improved.

MORPHOLOGY, LIFESPAN, FUNCTIONS AND VARIATIONS IN COUNTS OF WBCs

- Neutrophils
- Eosinophils
- Basophils
- Lymphocytes

- Monocytes

APPLIED ASPECTS

- Disorders of phagocytic functions
- Leukaemoid reactions
- Leukaemias

White blood cells types and their counts

White blood cells (WBCs) or leucocytes are so named since they are colourless in contrast to the red colour of the RBCs. These are nucleated cells which play an important role in the defence mechanism of the body.

The leucocytes of the peripheral blood are of two main varieties, distinguished by the presence or absence of granules. These are: granulocytes and nongranulocytes.

Types of white blood cells

Granulocytes

White blood cells with granules in their cytoplasm are called granulocytes. Depending upon the colour of granules, granulocytes are further divided into three types:

Neutrophils. They contain granules which take both acidic and basic stain.

Eosinophils. They contain granules which take acidic stain.

Basophils. They contain granules which take basic stain.

Agranulocytes

White blood cells that do not contain granules in their cytoplasm are called agranulocytes. These are of two types:

- Lymphocytes and
- Monocytes.

Normal WBC counts

Total leucocyte count

Total leucocyte count (TLC) varies with age as:

- **Adults:** 4000–11,000/mm³ of blood.
- **At birth,** in full-term infant: 10,000–25,000/mm³ of blood.
- **Infants** up to 1 year of age: 6000–16,000/mm³ of blood.
- **Children,** 4–7 years of age: 5000–15,000/mm³ of blood.
- **Children,** 8–12 years of age: 4500–13,500/mm³ of blood.

Differential and absolute leucocyte count

Differential leucocyte count (DLC) and absolute count in normal adults are shown in [Table 3.3-1](#).

TABLE 3.3-1

Differential Leucocytes Count and Absolute Count in Normal Adults

WBCs	Differential count (%)	Absolute count (per mm ³)
Granulocytes		
• Neutrophils	40–75	2000–7500
• Eosinophils	1–6	40–440
• Basophils	0–1	0–100
Agranulocytes		
• Lymphocytes	20–40	1500–4000
• Monocytes	2–10	500–800

Clinical significance of differential and absolute counts

The differential leucocyte count (DLC) tells us if there is an increase or decrease in a particular type of leucocyte, because in different diseases, one or the other type of cells shows an increase or decrease in its numbers. The differential count is done in 100–200 cells, and tells only a relative increase or decrease in a particular variety of cells, with a corresponding decrease or increase in the other types of cells. For example, an increase in the percentage of neutrophils would be associated with a decrease in percentage of lymphocytes, thus giving an impression of lymphocytopenia. But if the TLC is taken into account, the absolute lymphocyte count could be within a normal range. Therefore, DLC alone is not of much importance and so is never done as an isolated test, but always it is part of full blood counts, including TLC and then calculating absolute count.

Variations in WBCs count

Leucocytosis

Leucocytosis refers to increase in total WBC count above $11,000/\text{mm}^3$.

Physiological causes of leucocytosis

are:

1. **Age.** In newborn babies up to the age of 1 year, the WBC count is higher. At birth, the WBC count is about $18,000/\text{mm}^3$, which drops gradually to the adult level.
2. **Exercise.** The WBC count is increased after exercise.
3. **After food intake,** the WBC count is raised.
4. **Mental stress** and emotional conditions like anxiety are associated with raised WBC count.
5. **Pregnancy.** At full-term pregnancy, the WBC count is $12,000\text{--}15,000/\text{mm}^3$.
6. **Exposure to low temperature** also causes leucocytosis.

Pathological causes of leucocytosis

are:

1. Acute bacterial infections especially by pyogenic organisms,
2. Acute haemorrhage,
3. Burns,
4. Postoperative period,
5. Tuberculosis and
6. Glandular fever.

Leucopenia

Leucopenia refers to decrease in the total WBC count below $4000/\text{mm}^3$.

Causes of leucopenia

are:

1. Infections by nonpyogenic bacteria, especially typhoid fever and paratyphoid fever,
2. Viral infections such as influenza, smallpox, mumps, etc.,
3. Protozoal infections,
4. Starvation and malnutrition,
5. Aplasia of bone marrow and
6. Bone marrow depression due to:
 - Drugs such as chloromycetin and cytotoxic drugs used in malignant diseases.
 - Repeated exposure to X-rays or radiations.
 - Chemical poisons like arsenic, dinitrophenol and antimony.

Leukaemia

Leukaemia is a malignant disease of the blood in which there occurs an increase in the total WBC count associated with the presence of immature WBCs in the peripheral blood. Total WBC count is usually above $50,000/\text{mm}^3$, and may be as high as $100,000\text{--}300,000/\text{mm}^3$ (see page 177).

Formation of white blood cells

The process of development and maturation of white blood cells (leucocytes), called *leucopoiesis*, is a part of haemopoiesis (formation of blood cells). All the blood cells develop from the so-called pluripotent *haemopoietic stem cells (PHSCs)*. The stem cells after a series of divisions differentiate into *progenitor cells*, which are also called as colony-forming units (CFU) (for details see page 138).

Leucopoiesis can be discussed under two headings:

- Formation of granulocytes (granulopoiesis) and monocytes and

- Formation of lymphocytes (lymphopoiesis).

Formation of granulocytes and monocytes

The granulocytes and monocytes are formed in the bone marrow from the colony-forming unit called CFU-GM (colony-forming unit granulocytes and monocytes): The progenitor cells (CFU-GM) forming different cells are further named as:

- CFU-G are neutrophil-forming units,
- CFU-EO refers to eosinophil-forming units,
- CFU-Ba are basophil-forming units and
- CFU-M refers to monocyte-forming units.

The development of granulocytes through various stages is called *myeloid series* and development of monocytes through various stages is called *monocyte–macrophage series*.

Myeloid series

Some facts about granulopoiesis

- The cells of myeloid series include myeloblast (most primitive precursor), promyelocytes, myelocytes, metamyelocytes, band forms and segmented granulocyte (mature form). These cells can be grouped together in two pools:
- *Proliferative or mitotic pool* is formed by the myeloblast, promyelocyte and myelocyte; and
- *Mature or postmitotic pool* includes the metamyelocytes, band forms and segmented granulocytes.
- The process of granulopoiesis takes about 12 days.
- Granulocytes are formed and stored in the bone marrow. When need arises, they are released in circulation. Normally, about three times as

many granulocytes are stored in the bone marrow as circulated in the peripheral blood.

Features of the cells of myeloid series (fig. 3.3-1)

FIGURE 3.3-1 Granulopoiesis and features of the cells of myeloid series and monocyte–macrophage series.

1. Myeloblast.

It is the earliest recognizable cell of the granulocyte series. Myeloblasts form about 2% of the total marrow cells. Its features are:

- *Size.* Myeloblast varies in diameter from 16 to 20 μm .

- *Cytoplasm* is basophilic, present as thin rim around the nucleus and is devoid of granules.
- *Nucleus* is large (nearly filling the cells), round to oval, has fine chromatin and contains 2–5 well-defined pale nucleoli.
- *Mitosis* is marked (+++).

2. Promyelocytes.

Myeloblasts progress into the promyelocyte which has following features:

- *Size* varies from 14 to 18 μm .
- *Cytoplasm* increases in amount and is characterized by the presence of *azurophil granules*. These granules are also called *primary nonspecific granules* and these give a positive reaction with the peroxidase stain.
- *Nucleus* is round or oval, slightly small than the nucleus of myeloblast and having fine chromatin, which is condensed. The nucleoli are present but are less prominent and fewer than those in the myeloblast.
- *Mitosis* is a characteristic feature (+++).

3. Myelocyte,

also called myelocyte proper, is the next cell in myeloid series. Its features are:

- *Size* varies from 12 to 16 μm .
- *Cytoplasm* is characterized by the presence of *specific (secondary) granules* and accordingly the cell can be identified at this stage as:
 - Neutrophil myelocyte,
 - Eosinophil myelocyte and
 - Basophil myelocyte.

The primary granules are also present at this stage but

their formation is stopped.

- *Nucleus* is eccentric, round to oval, having coarse nuclear chromatin and no nucleoli.
- *Mitosis* continues up to this stage. Multiplication of these cells is maximum.

4. Metamyelocyte

has the following features:

- *Size* varies from 10 to 14 μm .
- *Cytoplasm* increases in amount and becomes more liquid. Both primary and secondary granules are present. Depending upon the features of secondary granules, the metamyelocytes are distinguished as:
 - Neutrophil metamyelocyte,
 - Eosinophil metamyelocyte and
 - Basophil metamyelocyte.
- *Nucleus* decreases in size becomes indented and lobed (horseshoe shape). The nuclear chromatin is dense and clumped. Nucleoli are absent.
- *Mitosis* stops at this stage.

5. Band or stab form

refers to juvenile granulocytes which has the following features:

- *Size* is slightly smaller than metamyelocyte.
- *Cytoplasm* is pink and contains fine evenly distributed granules.
- *Nucleus* is characterized by further condensation of chromatin and transformation of nucleus shape into a band configuration (deeply indented V-shaped) of uniform thickness which may be twisted.

6. Mature granulocytes

ultimately formed are neutrophils, eosinophils and basophils. Their morphological features are described on page 168.

Monocyte–macrophage series (fig. 3.3-1)

The monocyte–macrophage series of cells basically form a part of myeloid series along with the granulocytes and are thus formed in the bone marrow. These are described separately because of the different morphological stages which include: monoblast, promonocytes and monocyte.

1. Monoblast.

It is a large cell similar in structure to the myeloblast from which it cannot be distinguished on morphological grounds alone. Therefore, it is preferable to call the earliest precursor of granulocytic series as *myelomonoblast*.

2. Promonocyte.

It is a young monocyte about 20 μm in diameter. Its *nucleus* is large, indented (often kidney shaped) and contains one nucleolus. The nuclear chromatin is arranged in a loose network. The *cytoplasm* is basophilic and contains *no azurophilic granules*, but may have fine granules which are larger than those in mature monocyte.

3. Monocyte.

Morphological features of a mature monocyte are described on page 176. These resemble metamyelocytes and are best distinguished by the presence of fine chromatin. In metamyelocytes, the chromatin is dense and clumped.

From the bone marrow, the monocytes migrate into the spleen and the lymphoid tissues in considerable numbers. The transformed stages of these cells in various tissues are called *tissue macrophages* and form a part of *tissue–macrophage system*, which was previously known as *reticuloendothelial system*.

Formation of lymphocytes

Lymphocytes are formed from the *lymphocyte stem cells*, which are formed from the pluripotent haemopoietic stem cells (PHSC) in the bone marrow (Fig. 3.2-9). The lymphocyte stem cells migrate into the thymus

and peripheral lymphoid tissues, where they proliferate and mature into lymphocytes. In humans, the bone marrow and thymus form the primary lymphopoietic *organs*, where lymphoid stem cells undergo spontaneous division independent of antigenic stimulation. The tissues that actively produce lymphocytes from the germinal centres of lymphoid follicles as a response to antigenic stimulation constitute the so-called *secondary or reactive lymphoid tissue*. It is comprised by the:

- Lymph nodes,
- Spleen and
- Gut-associated lymphoid tissue (GALT).

FIGURE 3.3-2 Formation of lymphoid series cells.

Lymphoid series

The maturation stages of lymphoid series are (Fig. 3.3-2):

1. Lymphoblast.

It is the earliest recognizable cell of the lymphoid series. It is an actively dividing cell and resembles the myeloblast morphologically, except for the following minor differences:

- The nucleus contains fewer nucleoli (1–2) compared with the myeloblast (2–5),
- Nuclear chromatin is slightly clumped and stippled compared with fine meshwork in myeloblast and
- Nuclear membrane is fairly dense compared with that of the

myeloblast.

2. Prolymphocyte

is the intermediate stage between the lymphoblast and mature lymphocyte. Its features are:

- *Diameter* is 9–18 μm .
- *Nucleus* is round to indented, with slightly stippled or coarse chromatin and may have 0–1 nucleoli.
- *Cytoplasm* is scanty and nongranular.

3. Lymphocytes.

Prolymphocytes mature successively into large lymphocyte and small lymphocyte, both of which are found in the circulation.

- Then some lymphocytes enter thymus, where they are processed and come out as T lymphocytes. In thymus, a factor called *thymosin* plays an important role in the processing.
- Some lymphocytes are processed in the liver (in fetal life) and bone marrow (after birth). These come out as B *lymphocytes*. The word B comes from 'bursa of Fabricius', which is the site of B cell processing in birds. Morphological features of large and small lymphocytes are described on page 175.

Regulation of leucopoiesis

The constancy of leucocyte count suggests an efficient feedback mechanism to control their production and release (Fig. 3.3-3). During tissue injury and inflammation, bacterial toxins, products of injury, etc. cause a great increase in the rate of production and release of leucocytes. Thus, unlike erythropoiesis, the products of dead and dying white cells themselves control leucopoiesis. The substances that stimulate or inhibit the process of leucopoiesis are complex and include the following:

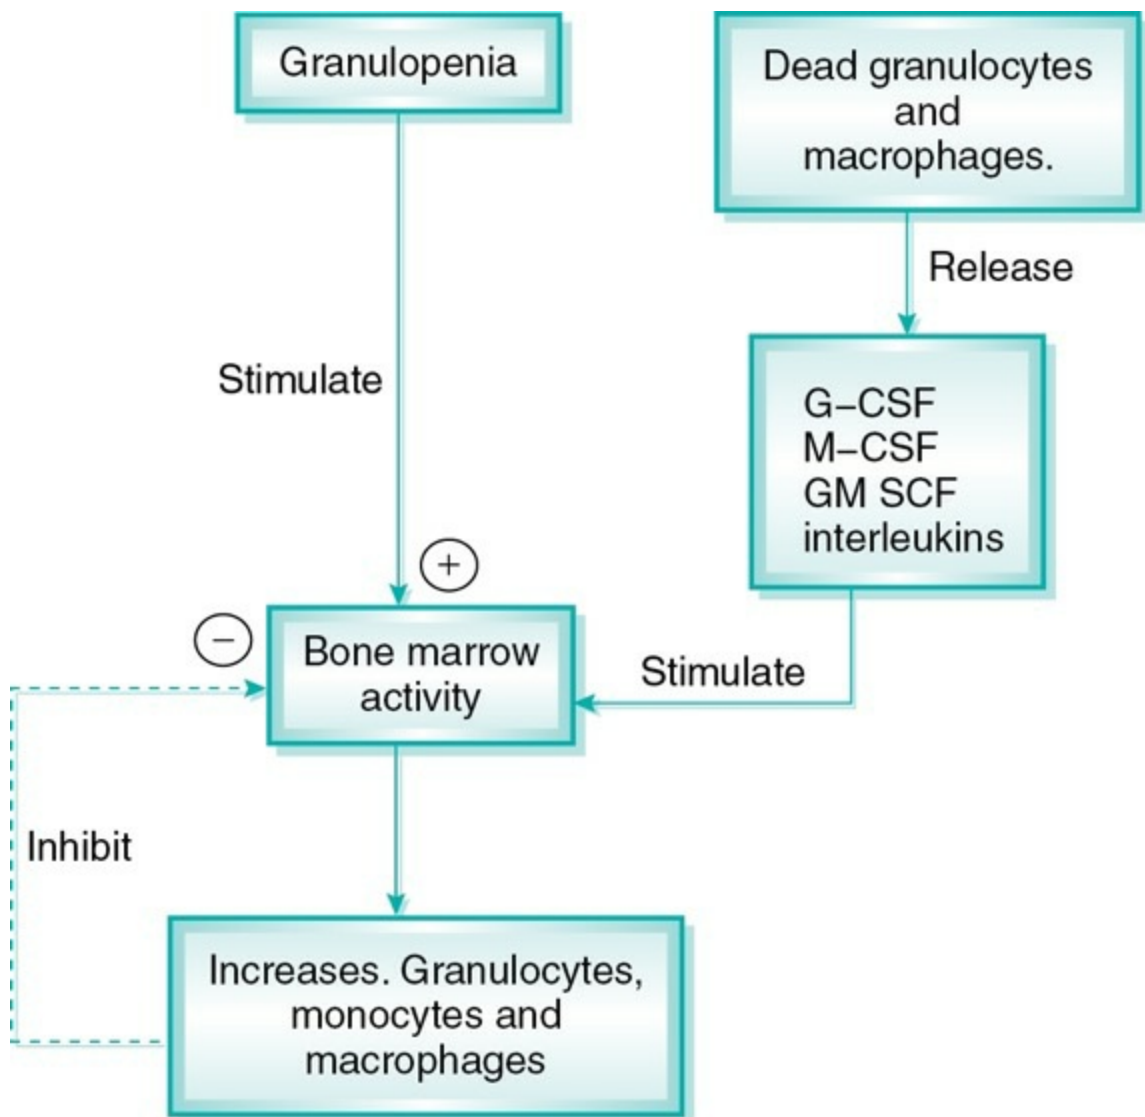

FIGURE 3.3-3 Schematic diagram of regulation of leucopoiesis.

Role of cytokines

The cytokines that control the formation of different types of granulocytes are called *colony-stimulating factors (CSFs)*. The CSFs are glycoproteins formed by monocytes and T lymphocytes and include:

- *G-CSF* which stimulates granulocyte precursors,
- *M-CSF* which stimulates monocytic precursors and
- *GM-CSF* which stimulates both the granulocyte and monocytic precursors.
- The cytokines that control lymphocyte formation are called *interleukins*, e.g. IL-1, IL-3, etc. Interleukins are formed by monocytes, macrophages

and endothelial cells (see page 196).

Role of prostaglandins

Prostaglandins formed by monocytes, *lactoferrin* and possibly some other agents also play a role in control of leucopoiesis.

Morphology, functions, lifespan and variations in counts of WBCs

Morphological features of various types of WBCs, as studied under microscope with Leishman's staining and haematoxylin-eosin stain (Fig. 3.3-4), are summarized below along with their functions and variations in their counts.

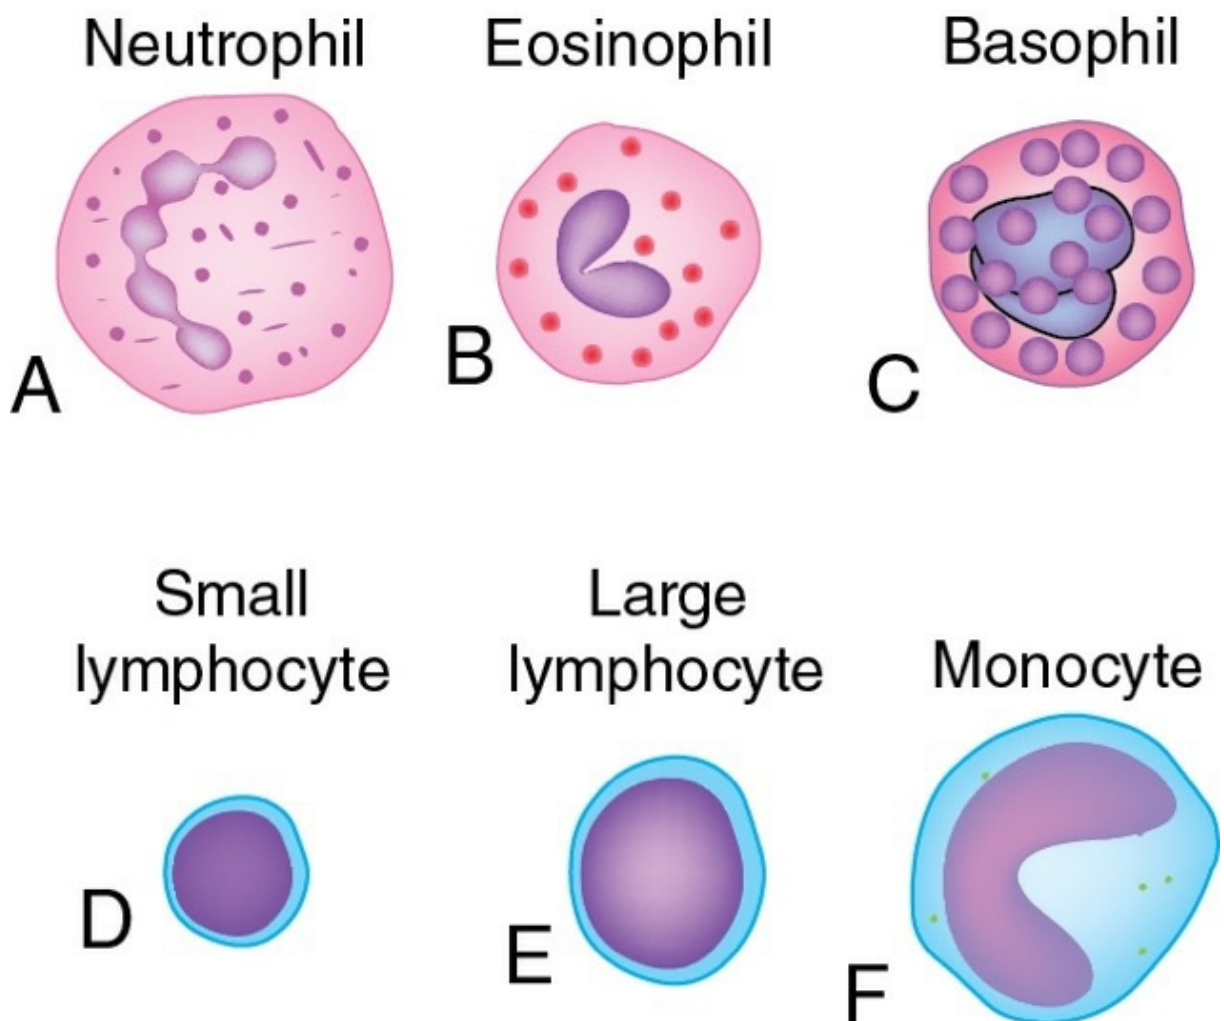

FIGURE 3.3-4 Morphological features of white blood cells: **A**, neutrophil; **B**, eosinophil; **C**, basophil; **D**, small lymphocyte; **E**, large lymphocyte; and **F**, monocyte.

Neutrophils

Morphological features

The polymorphonuclear neutrophils, commonly called polymorphs or neutrophils, have the following morphological features (Fig. 3.3-4A):

- **Diameter.** Diameter of a neutrophil varies from 10 to 14 μm .
- **Nucleus.** A young neutrophil has a single horseshoe-shaped nucleus, which becomes lobed as the cell grows. Nucleus of a mature neutrophil is purple in colour and multilobed (2–6 lobes), that is why a neutrophil is also called polymorphonuclear leucocyte. The lobes of the nucleus are connected by chromatin filaments, seen clearly through the cytoplasm.
- **Cytoplasm.** Cytoplasm of neutrophil is pale bluish in colour and full of fine (pinpoint) granules.
- Granules take both acidic and basic stain and look violet–pink in colour.
- Granules are *lysosomal* in origin and contain a variety of enzymes that include glycosidases, sulphatases, phosphatases, nucleases and proteolytic enzymes. They can thus lyse any type of substance.
- In addition, the granules liberate histamine and peroxidase enzyme which help in killing the ingested bacteria.

Kinetics, lifespan and fate of neutrophils

- The neutrophils released from the bone marrow enter the circulation. In blood, they exist in two equal populations:
- The *circulating pool* comprises 50% cells, which are

circulating in the blood at any instant, and

- The *marginal pool* is constituted by the rest of 50% of cells, which remain margined or sidelined, i.e. sticking to the endothelial cells of closed capillaries, venules, small veins and sinusoids.

There is a rapid exchange between the two pools.

- For every neutrophil in blood, there are about a 100 mature neutrophils held in the bone marrow as reserve. These are released in the circulation when required. The stimulus for their release comes from the dead leucocytes, which release a granulocyte-inducing factor, and also by the hormone cortisol.
- Following their release from the bone marrow, granulocytes remain in circulating blood for 8–10 h and then they enter the tissues. After migration into tissues, they never return to the bloodstream. In the tissues, they are either destroyed during phagocytosis or die due to senescence after 4–5 days. The dead neutrophils are taken up by the macrophages. In cases of severe infection, lifespan of neutrophils may become as short as few hours.
- A huge number of neutrophils is also eliminated daily, mainly into the intestine and out via faeces and to some extent into the respiratory secretions.
- *Old senile neutrophils* are characterized by:
 - Loss of motility,
 - Poorly stained granules,
 - Increased nuclear lobulation and
 - Easy breakability while making blood smear.

Functions

The neutrophils along with monocytes constitute the first line of defence against microorganisms, viruses and other injurious agents that enter the body. Neutrophils subserve this role by the following mechanisms:

1. **Phagocytosis.** The neutrophils engulf the foreign particles or bacteria, digest them and ultimately may kill them by a process called phagocytosis. Various steps of phagocytosis are described below in detail.
2. **Reaction of Inflammation.** The neutrophils also release leucotrienes, prostaglandins, thromboxanes, etc. that bring about the reactions of inflammation like vasodilatation and oedema.
3. **Febrile Response.** The neutrophils contain a fever-producing substance called *endogenous pyrogen*, which is an important mediator of febrile response to the bacterial pyrogens.

Phagocytosis

Phagocytosis (cell eating) refers to the process of engulfment and destruction of solid particulate material by the cells. The cells performing this function are called phagocytes. In addition to neutrophils, the monocytes and fixed tissue macrophages also work as phagocytes. The process of phagocytosis involves the following steps:

1. Margination.

The normal axial blood flow consists of central stream of cells (leucocytes and RBCs) and peripheral cell-free layer of plasma close to vessel walls. In the area of infection, the neutrophils get *marginated*, i.e. get attached towards the capillary endothelium and start rolling along its surface. This process is called *margination* or *pavementing*. The margination is caused by binding of the *selectins* (cell adhesion molecules) present on the endothelial cells with the carbohydrate molecules present on the surface of neutrophils. The endothelial selectins are markedly increased in the areas where there is inflammation ([Fig. 3.3-5A](#)).

FIGURE 3.3-5 Stages of phagocytosis: **A**, margination; **B**, diapedesis; **C**, chemotaxis; **D**, opsonization; **E**, engulfment; **F**, formation of phagolysosome; and **G**, degranulation.

2. Emigration and diapedesis.

The margined neutrophils are emigrated in a large number from the blood at the site of *infection* caused by the foreign microorganism. They are motile and move by diapedesis into the tissues by passing through the junction between the endothelial cells of the blood vessels (Fig. 3.3-5B). The diapedesis of neutrophils is brought about by microtubules, microfilaments and interaction of actin with myosin-I on the inner side of the cell membrane.

3. Chemotaxis.

Chemotaxis refers to the process by which the neutrophils are attracted towards bacteria at the site of inflammation. The process of chemotaxis is mediated by the chemotactic agents called *chemokines*, which are released at the infected area. There are various types of chemokines, and they include:

- Leukotriene B₄ (LTB₄) and
- Components of the complement system (C_{5a}) and cytokines

(polypeptides from lymphocytes and monocytes).

The chemoattractants increase the adhesive nature of neutrophils, which form clumps surrounding the infected area (Fig. 3.3-5C).

4. Opsonization (attachment stage).

Opsonization refers to the process of coating of bacteria by the *opsonins* by which bacteria become tasty to the phagocytes. The principal opsonins are naturally acting factors in the serum and include IgG opsonin and opsonin fragment of complement protein. As shown in Fig. 3.3-5D, the opsonized bacteria are easily bound to the surface of phagocyte (attachment stage). This process triggers G protein-mediated responses, increases motor activity of the cell, exocytosis and respiratory bursts.

5. Engulfment stage.

The increased motor activity of neutrophils leads to prompt ingestion of bacteria by endocytosis. The neutrophils project *pseudopodia* in all directions around the opsonized particle, which is bound to the surface of neutrophil (Fig. 3.3-5E). Pseudopodia meet each other on opposite side and fuse. This creates an enclosed chamber with engulfed material. It breaks away from the membrane forming a *phagocytic vesicle*. Then the lysosomes of the cell fuse with the phagocytic vesicle to form a *phagolysosome* or phagosome (Fig. 3.3-5F).

6. Secretion (degranulation) stage.

Once the bacteria are engulfed, the lysosomes pour their enzymes into the vesicle and also in interstitial space (Fig. 3.3-5G). This process is called degranulation. There are large number of proteolytic enzymes, especially geared up for digesting the bacteria. In addition, lysosomes of macrophages also contain lipases which can digest the thick lipid membranes possessed by certain bacteria.

7. Killing or degradation stage.

The neutrophils and macrophages contain *bactericidal agents* (defensins α and β), which can kill most of the bacteria even when lysosomal enzymes fail to digest them. The bactericidal substance accomplishes the killing process by the following mechanisms:

- **Oxygen-dependent bactericidal mechanism,**

which is mediated by oxidizing agents (superoxides, H_2O , etc.) formed by the membrane-bound enzyme NADPH oxidase which leads to sharp increase in O_2 intake (respiratory burst) and O_2^- is generated by the following reaction:

O_2^- (free radical) is formed by the addition of one electron to O_2 . Two O_2^- react with two H^+ to form H_2O_2 . This reaction is catalysed by the enzyme superoxide dismutase (SOD1) present in the cytoplasm.

O_2^- and H_2O_2 (oxidants) both are bactericidal agents, but H_2O_2 is converted by the enzyme catalase into H_2O and O_2 .

- Neutrophils also discharge another enzyme known as myeloperoxidase, which converts Cl^- , Br^- , I^- and CN^- to their corresponding acids (HOCl, HOBr, HOI, etc). These acids are also potent oxidants.

• Oxygen-independent bactericidal mechanism

works through lysosomal hydrolases, defensins and cationic protein. Elastases. and metalloproteinases attack directly the collagen, and other proteinases destroy the membrane of invading bacteria.

Note: In congenital myeloperoxidase deficiency, there is reduction of microbial killing power of neutrophils due to nonformation of hypochlorous acid.

Important Notes

- Phagocytosis is completed after the stage of killing is over.
- A neutrophil can usually phagocytose 5–20 bacteria, before it itself becomes inactivated or dead.
- Neutrophils are not capable of phagocytosing particles much larger than bacteria.
- Neutrophils killed by the toxins released from the bacteria are collected in the centre of infected area. These are called pus cells and together

with plasma leaked from the blood vessels, liquefied tissue cells and red blood cells escaped from the damaged capillaries constitute the pus.

Defective phagocytic functions

Defective phagocytic functions make the patients prone to recurrent infections. The following abnormalities may be associated with defective phagocytic functions.

1. Defective chemotaxis

occurs in the following conditions:

- Lazy leucocyte syndrome, a rare congenital abnormality.
- Corticosteroid therapy,
- Aspirin ingestion,
- Alcoholism and
- Myeloid leukaemia

2. Defective phagocytosis

due to lack of opsonization occurs in:

- Hypogammaglobulinaemia,
- Hypocomplementaemia,
- After splenectomy and
- In sickle cell disease.

3. Defective killing by phagocytes

occurs in:

- *Chronic granulomatous diseases of childhood*. In this condition, there is failure to generate superoxide radical (O_2^-) in both neutrophils and monocytes, leading to inability to kill the phagocytosed bacteria.
- *Chediak-Higashi syndrome* is an autosomal recessive disorder

associated with reduced chemotaxis and phagolysosomal fusion.

- ***Congenital myeloperoxidase deficiency.*** During phagocytosis, enzyme NADPH oxidase and myeloperoxidase are mainly responsible for killing of invading organism. Myeloperoxidase helps catalysing the formation of oxidants. Therefore, due to its deficiency, microbial killing power is reduced but not absent, because most of the oxygen-dependent bactericidal mechanism remain intact.
- ***Rheumatoid arthritis:*** In this disease, the enzyme NADPH in the neutrophils may cause local destruction of the host tissue.
- ***Severe congenital glucose-6-phosphate deficiency*** leads to failure in NADPH production, thus O_2^- generation. Multiple infections occur in this condition due to defective killing of organisms.
- ***Amyotrophic lateral sclerosis,*** mutation of SOD-encoding gene, results in defective absence of SOD. In this disease, there is accumulation of O_2^- molecule in motor neurons which destroy them.

4. Neutrophil hypomotility

is associated with decreased phagocytosis. In this condition, actin present in the neutrophils do not polymerize normally; therefore, neutrophils move slowly.

Inflammation

Inflammation

is a reaction or tissue change complex brought about by the substances released from the injured tissue or in response to foreign substances such as bacteria. Inflammation is characterized by redness, swelling and tenderness or pain. It includes sequence of reactions (Fig. 3.3-6):

- Vasodilatation of local blood vessels,
- Leakage of large quantity of fluid into the interstitial spaces (due to increased capillary permeability and its clotting due to leakage of fibrinogen and other clotting factors),
- Migration of large number of granulocytes and monocytes into the tissue and

- Swelling of the tissue.

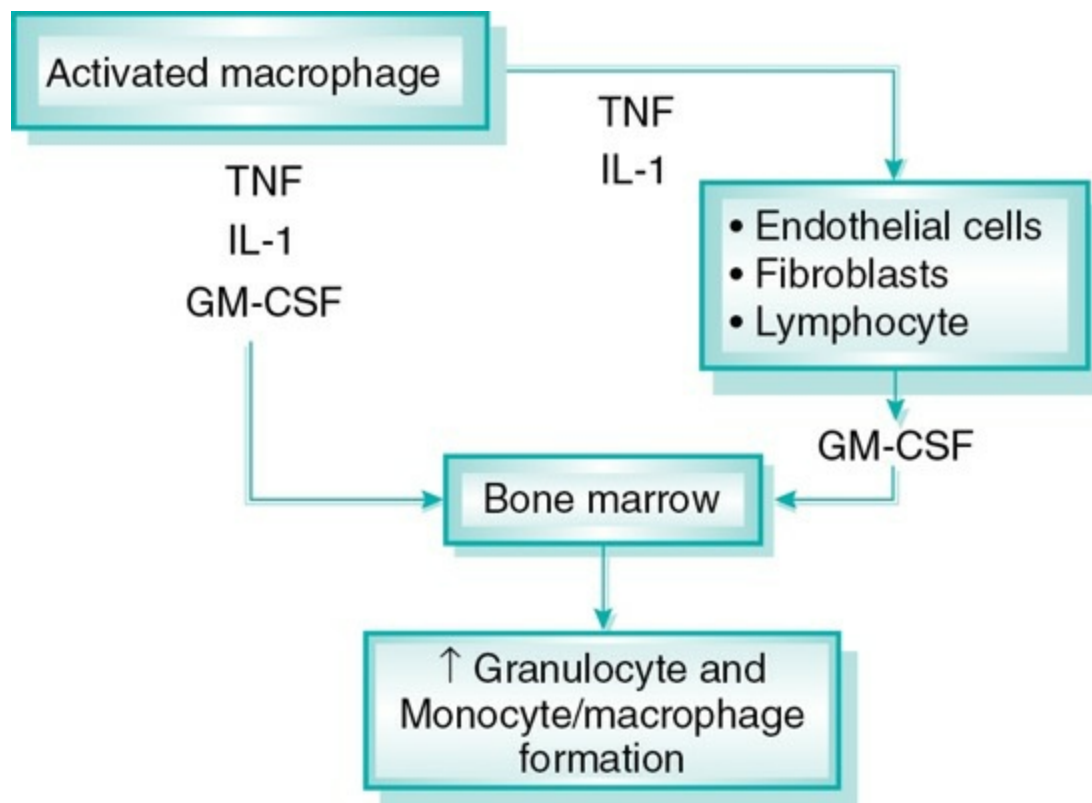

FIGURE 3.3-6 Sequence of events during inflammation.

The substances released from the injured tissues include histamine, serotonin, prostaglandins, lymphokines, reaction products of complement and clotting system.

In inflammation, tissue macrophages are the first line of defence against infection. Within an hour or so, neutrophil from the blood invade the inflamed area. Therefore,

- Within few hours, there is an acute increase in neutrophil count (neutrophilia) that may go up to 4000–5000/ μL .
- Along with neutrophils, monocytes also enter into inflamed tissue and enlarge to become macrophages. As pointed out earlier, macrophages can phagocytize about five times more bacteria and larger particles (including even neutrophil and necrotic tissue).
- The next reaction is increased production of granulocytes and monocytes in the bone marrow as a result of stimulation of GM-progenitor cells, due to the release of colony-stimulating factors (GM-CSF). A powerful feedback mechanism to remove the cause of

inflammation is provided by GM-CSF, along with TNF and interleukin-1.

Walling-off effect of inflammation

is to wall off the area of injury from remaining tissue. This effect is brought about by blockage of tissue spaces and lymphatics by clotting of tissue fluid by fibrinogen. The walling-off process is important for delaying the spread of infection.

Important Note

- **Nuclear factor-kB (NF-kB)** is a transcription factor that plays a key role in the inflammatory response. *NF-kB normally exists as bound form to $I_{kB\alpha}$ (inactive state) in the cytoplasm of the cell.* The stimuli such as cytokines, oxidants, viruses, etc. separate NF-kB from $I_{kB\alpha}$. Free NF-kB enters into the nucleus and gets bound to DNA of genes, responsible for inflammatory mediators and causing increase in their production and secretion.
- **Glucocorticoids:** *The anti-inflammatory action of glucocorticoids is by increasing the production of $I_{kB\alpha}$ to inhibit NF-kB activity.*

Variations in counts

Neutrophilia

Neutrophilia refers to increase in the circulating neutrophil counts (absolute count $> 10,000/\text{mm}^3$). It is the commonest cause of leucocytosis.

Causes

Physiological causes of neutrophilia are:

- Newborn babies,
- After exercise,
- After meals,
- Pregnancy,
- Menstruation,

- Parturition,
- Lactation,
- Mental stress and emotional stress and
- After injection of epinephrine.

Pathological causes of neutrophilia are:

- Acute pyogenic bacterial infections,
- Noninfective inflammatory conditions like gout and acute rheumatic fever,
- Acute tissue destruction as in:
 - Burns,
 - Postoperatively and
 - Myocardial infarction.
- Acute haemorrhage,
- Myoproliferative disorders like polycythaemia vera,
- Poisoning by chemicals and drugs like lead, mercury, etc.
- Poisoning by insect venom and
- Intoxicating conditions like uraemia and diabetic ketoacidosis.

Neutropenia

Decrease in neutrophil count is known as neutropenia (absolute count < 2500/ mm³).

Causes of neutropenia

- Typhoid and paratyphoid fever,
- Malaria,

- Aplasia of bone marrow and
- Bone marrow depression due to:
- Drugs such as chloromycetin and cytotoxic drugs used in malignant diseases,
- Repeated exposure to X-rays and radiations and
- Chemical poisons like arsenic.

Arneth count

Counting the number of neutrophils with different nuclear lobes and expressing the count as percentage of cells with different number of nuclear lobes is called Arneth or Cooke's–Arneth count. Different stages with normal count are shown in [Fig. 3.3-7](#) and [Table 3.3-2](#).

FIGURE 3.3-7 Stages of Cooke's–Arneth count.

TABLE 3.3-2
Cooke's–Arneth Count

Stage	Nuclear lobes	Normal count (%)
• Stage I (N_1)	1 (the nucleus is C-shaped)	5–10
• Stage II (N_2)	2 lobes are connected by a filament	20–30
• Stage III (N_3)	3 lobes connected by chromatin filament	40–50
• Stage IV (N_4)	4 lobes connected by chromatin filament	10–15
• Stage V (N_5)	5 lobes or more	3–5

Clinical significance.

The Arneth count is useful in judging the rate of formation of neutrophils. The neutrophils enter the bloodstream mostly as bilobed cells, but the number of lobes increases to 5 or more by the end of their short lifespan of 8–10 h. The three-lobed cells are fully mature and functionally the most efficient. Thus, the presence of younger cells (shift to the left) and more mature cells (shift to the right) in the blood can provide important information about the rate of formation and release of neutrophils from the bone marrow.

- ***In left shift*** (more younger cells), $N_1 + N_2 + N_3$ is more than 80%. It indicates hyperactive bone marrow (high rate of formation).
- ***In right shift*** (more mature cells), $N_4 + N_5$ is more than 20%. It indicates hypoactive bone marrow (slow rate of formation).

Variations in neutrophil morphology

Some of the variations seen in morphology of neutrophils are:

1. ***Variations in granules.*** Heavy, dark staining and coarse toxic granules are the characteristics of bacterial infections.
2. ***Formation of vacuoles in cytoplasm.*** Cytoplasmic vacuolation may develop in bacterial infections such as in septicaemia.
3. ***Formation of dohle bodies in cytoplasm.*** Dohle bodies are small, round or oval patches, 2–3 μm in size seen in the cytoplasm of neutrophils (Fig. 3.3-8A) in patients with bacterial infections.
4. ***Presence of sex chromatin with nuclear lobes.*** Sex chromatin is a normal finding seen in 2–3% of neutrophils in females. It consists of a drumstick appendage of chromatin about 1 μm across, and attached to one of the nuclear lobes by a thin chromatin strand (Fig. 3.3-8B). Their presence is indicative of 2X chromosomes.
5. ***Hypersegmented neutrophils.*** Presence of hypersegmented (more than 5 nuclear lobes) neutrophils in the peripheral blood (Fig. 3.3-8C) is called a *shift-to-right*. It is indicative of a hypoactive bone marrow, as seen in megaloblastic anaemia and uraemia.

6. ***Band and star form neutrophil.*** Presence of band and star form neutrophils, i.e. premature neutrophils with decreased nuclear lobes (Fig. 3.3-1) in the peripheral blood is called *shift-to-left*. It is indicative of hyperactive bone marrow, as seen in severe infections and leukaemias.

7. ***Pelger–Huet Anomaly.*** It is an inherited disorder in which majority of the neutrophils have decreased number of nuclear segments (1–2) and coarsely staining chromatin. The nuclei appear rod-like, dumb-bell or spectacle-like (Fig. 3.3-8D).

FIGURE 3.3-8 Some variations in neutrophil morphology: **A**, Dohle bodies; **B**, female sex chromatin; **C**, hypersegmented neutrophil; and **D**, hereditary Pelger–Huet anomaly.

Eosinophils

Morphological features

Morphological features of eosinophils (Fig. 3.3-4B) are:

- **Diameter.** Diameter of eosinophils is similar to neutrophils, i.e. 10–14 μm .
- **Nucleus.** Nucleus is purple in colour and is bilobed in 85% of the cells. The two lobes are connected by the chromatin strands and thus look *spectacle shaped*. The remaining 15% of the eosinophils have trilobed nucleus.
- **Cytoplasm.** Cytoplasm is acidophilic and appears bright pink in colour.
- It contains coarse, deep red-staining granules which do not cover the nucleus.
- The granules in eosinophils contain basic protein and stain more intensely for peroxidase than granules in the neutrophils.
- The granules contain histamine, lysosomal enzymes and eosinophil chemotactic factor of anaphylaxis (ECF-A).

Functions of eosinophils

1. Mild phagocytosis.

Eosinophils are not very motile and thus have very mild phagocytic activity. Like neutrophils, eosinophils are attracted towards the endothelial cells by selectins and enter the tissue by diapedesis.

2. Role in parasitic infestations.

They play an important role in the defence mechanism of body, especially in *parasitic infestations*. Eosinophils act through the following lethal substances present in their granules:

- **Major basic protein (MBP)** makes up about 50% of the mass of large granules. It is a highly *larvicidal* polypeptide. Because of this, eosinophils are able to damage the parasitic *larvae*, which are large to be engulfed by phagocytosis.
- **Eosinophil cationic protein (ECP)** is a potent bactericidal and major

destroyer of helminths. It is about 10 times more potent than MBP in destroying helminths by means of complete disintegration. It is also a neurotoxin.

- *Eosinophil peroxidase* is capable of destroying helminths, bacteria and tumour cells.
- *Eosinophil-derived neurotoxin* is capable of destroying the nerve fibres.

3. Role in allergic reaction.

The eosinophils increase in number in allergic conditions like bronchial asthma and hay fever.

- They are capable of *detoxifying* inflammation-inducing substances (released by mast cells and basophils) like histamine and bradykinin.
- They inhibit mast cell degranulation.
- They phagocytose and destroy antigen–antibody complexes and thus prevent spread of local inflammatory process.
- *Arylsulphatase B*, present in the fine granules of eosinophils, has the ability of inactivating sulphur-containing leukotrienes that tissue mast cells liberate in immediate hypersensitivity reactions.
- *Lysophospholipase* is an unusual membrane-bound protein present in the eosinophils, which forms crystals called *Charcot-Leyden crystals* in the pulmonary secretions of patients with bronchial asthma.

4. Role in immunity.

The eosinophils are present in abundance in the mucosa of respiratory tract, gastrointestinal tract and urinary tract, where they probably provide mucosal immunity.

Variation in counts

Eosinophilia

Eosinophilia refers to increase in the eosinophil count (absolute count > 500/mm³).

Causes

of eosinophilia are:

- Allergic conditions like bronchial asthma and hay fever,
- Tropical pulmonary eosinophilia,
- Parasitic infestation, e.g. intestinal worms like hookworm, roundworm and tapeworm,
- Skin diseases like urticarial and
- Scarlet fever.

Eosinopenia

Eosinopenia is the decrease in eosinophil count (absolute count < 50/mm³).

Causes

of eosinopenia are:

- ACTH and steroid therapy,
- Stressful conditions and
- Acute pyogenic infections.

Basophils

Morphological features (fig. 3.3-4C)

- **Diameter.** Diameter of a basophil is similar to neutrophil and eosinophil, i.e. 10–14 μm.
- **Nucleus.** Nucleus of basophils is irregular, may be bilobed or trilobed, and its boundary is not clearly defined because of overcrowding with coarse granules.
- **Cytoplasm.** Cytoplasm of basophils is slightly basophilic and appears blue. It is full of granules.

- Granules of basophils are very coarse and stain deep purple or blue with basic (methylene) dye.
- Granules are in plenty and completely fill the cell and overload the nucleus.
- The granules of basophils contain heparin, histamine and 5-HT.

Functions

1. Mild phagocytosis.

Basophils have very mild phagocytic function.

2. Role in allergic reaction.

Basophils also enter into the tissue and release cytokine and inflammatory mediators such as histamine, bradykinin, slow-reacting substances of anaphylaxis (SRS-A) and serotonin (5HT). These substances, in turn cause local vascular and tissue reactions that cause allergic manifestations by binding of specific antigen to cell-fixed IgE molecules (for details see page 201).

3. Role in preventing spread of allergic inflammatory process.

Basophils also release eosinophil chemotactic factor that causes eosinophils to migrate towards the inflamed allergic tissue. Eosinophils then phagocytose and destroy the antigen–antibody complexes and prevent spread of local inflammatory process.

4. Release of heparin.

Basophils release heparin in the blood which:

- Prevents clotting of the blood and
- Activates the enzyme lipoprotein lipase which removes fat particles from the blood after a fatty meal.

Variation in counts

Basophilia

Basophilia refers to increase in the basophil count (absolute count > 100/mm³).

Causes of basophilia are:

- Viral infections, e.g. influenza, small pox and chicken pox,
- Allergic diseases and
- Chronic myeloid leukaemia.

Basopenia

Decrease in basophil count is called basopenia

Causes of basopenia are:

- Corticosteroid therapy,
- Drug-induced reactions and
- Acute pyogenic infections.

Mast cells

Mast cells are large tissue cells resembling the basophils. These are present in bone marrow and immediately outside the capillaries in the skin. Mast cells are granulated cells of connective tissue; their granules contain proteoglycans, histamine and many proteases.

Functions.

Mast cells play role in allergic reactions similar to the basophils.

- When allergens bind to the surface of mast cell coated with Ig G molecules, the degranulation of mast cells occurs and thus involved in inflammatory responses.
- Mast cells also play an important role in acquired immunity; they release TNF- α in response to bacterial product by antibody-independent mechanism.

Lymphocytes

Morphological features

There are two types of lymphocytes large and small having almost

similar structure. Majority of lymphocytes in peripheral blood are small, but large lymphocytes are also found. Morphological features of lymphocytes are:

- **Diameter.** Diameter of large lymphocytes varies from 12 to 16 μm and that of small lymphocytes from 7 to 10 μm (Figs. 3.3-4D and E).
- **Nucleus.** Lymphocytes have a large, round and single nucleus, which almost completely fills the cell. It stains deeply blue, giving an *ink-spot appearance*. Nuclear chromatin is coarsely clumped and shapeless.
- **Cytoplasm.** The cytoplasm is scanty, i.e. its amount is always less than that of nucleus. It is seen as a crescent of clear light blue colour around the nucleus. Cytoplasm does not contain visible granules.

Functional subtypes

Based on their developmental background, lifespan and functions, the small lymphocytes have been broadly classified into three subtypes (Fig. 3.3-9):

1. **B lymphocytes**, which are processed in the bone marrow, are concerned with the humoral immunity.
2. **T lymphocytes**, which are processed in the thymus and concerned with the cellular immunity.
3. **Natural killer (NK) cells** are lymphocyte-like cells that nonspecifically kill any cell that is coated with immunoglobulin IgG. This phenomenon is called *antigen-dependent cell-mediated cytotoxicity (ADCC)*. Thus, NK cells provide *innate immunity*. They are highly cytotoxic against tumour cells and virus-infected cells.

FIGURE 3.3-9 Processing of stem cells in thymus and bone marrow to become immunocompetent T and B lymphocytes.

The aforementioned functional subtypes of lymphocytes are not morphologically distinguishable, but they have distinctive surface molecules that are identifiable by immunochemical methods. The NK cells lack identifying surface markers.

Kinetics, lifespan and fate of lymphocytes

- After processing, the T lymphocytes (processed in the thymus) and B lymphocytes (processed in the bone marrow; B stands for 'bursa of Fabricius', the site of B cell processing in birds) enter the circulation where they are present in an approximately 70:30 ratio.
- Many of the lymphocytes remain in circulation for a few hours, then leak out through the venules and settle in the *peripheral lymphoid*

tissues, which include lymph nodes, spleen, gut-associated lymphoid tissue (GALT) and lymphoid tissue associated with respiratory and urinary tracts. At any given time, only about 2% of the body lymphocytes are in the peripheral lymphoid tissue.

- Some of the lymphocytes re-enter the blood circulation through the lymphatics, draining the peripheral lymphoid tissues. In this manner, they recirculate for months or years. Thus, the lymphocytes have a lifespan of months or a year depending upon body's need for these cells.

Functions

Lymphocytes play an important role in immunity. *Immunity* is the capacity of human body to resist all types of microorganisms and toxins that tend to damage the tissue or organ. Functionally, the lymphocytes are classified into two types: the B lymphocytes and T lymphocytes.

Functions of B lymphocytes

B lymphocytes as well as their derivatives, the plasma cells, are responsible for the development of *humoral immunity* also called antibody-mediated immunity (AMI). B lymphocytes produce antibodies (gamma globulins), which circulate in the blood and constitute the humoral immunity. Humoral immunity is the major mechanism of defence against the invading organisms, especially the bacteria. Antibodies fight against the invading organisms:

- By direct action,
- By making them inactive by agglutination, precipitation, neutralization or lysis and
- Through complement system.

Functions of T lymphocytes

T lymphocytes are responsible for the development of *cellular immunity*, also called cell-mediated immunity (CMI) or T cell immunity. CMI plays an important defensive role against:

- Viral infections,
- Some bacterial infections and

- Tumour cells.

T lymphocytes are associated primarily with two main functions in immune mechanism:

1. *Cellular immune reactions and hypersensitivity Reactions*

- Cellular immune reactions are mediated by the T lymphocyte such as cytotoxic or killer T cells (CD3⁺) and CD8⁺ T cells.
- Hypersensitivity reaction is mediated by CD4⁺ T cells.

2. *Immunoregulatory function.* The CD4⁺ helper cells regulate the immune mechanism by regulating the function of other T cells, B cells and haemopoietic stem cells.

For details of the role of lymphocytes in immunity, see page 182.

Variations in count

Lymphocytosis

Lymphocytosis refers to increase in the lymphocyte count (absolute count > 4000/mm³).

Physiological causes of lymphocytosis are:

- *In healthy infants and young children*, the lymphocytes count is usually high (about 60% in DLC) while the TLC is normal (relative lymphocytosis).
- *In females*, during menstruation lymphocytes are increased.

Pathological causes of lymphocytosis are:

- Chronic infections like tuberculosis, hepatitis and whooping cough.
- Viral infections like chicken pox,
- Autoimmune diseases like thyrotoxicosis,
- Infectious mononucleosis and

- Lymphatic leukaemia (most common cause of lymphocytes $> 10,000/\text{mm}^3$).

Lymphopenia

Lymphopenia or lymphocytopenia refers to decrease in the lymphocyte count (absolute count below $1500/\text{mm}^3$).

Causes of lymphopenia are:

- Patients on corticosteroid and immunosuppressive therapy,
- Hypoplastic bone marrow,
- Widespread irradiation and
- Acquired immunodeficiency syndrome (AIDS, see page 203).

Monocytes

Morphological features (fig. 3.3-4F)

Diameter. The monocyte is the largest mature leucocyte in the peripheral blood measuring some 12–20 μm in diameter.

Nucleus. The nucleus of monocyte is large, single and eccentric in position, i.e. present on one side of the cell. It may be notched, or indented, i.e. horseshoe or kidney shaped. It may appear oval or rounded in side view. Nucleus has characteristically fine reticulated chromatin network.

Cytoplasm. The cytoplasm is abundant, pale blue and usually clear (no granules); sometimes, it may contain fine purple, dust-like granules called *azur granules* which may be few or numerous.

Kinetics, lifespan and fate of monocytes

- The kinetics of monocytes is less well understood than that of granulocytes.
- After release from the bone marrow, the monocytes remain in circulation for 10–20 to over 40 h and then they leave the blood to enter the extravascular tissues.
- In the tissues, the monocytes get converted to macrophages and form the part of so-called *tissue macrophage system* (reticuloendothelial

system). In the tissues, they can live for months or even years unless destroyed while performing the phagocytic function.

Functions

1. Role in defence mechanism.

Monocytes along with neutrophils play important role in the body's defence mechanism. Their main function is *phagocytosis*. Monocytes after entering in the tissue get converted to macrophages. These are more powerful phagocytes than neutrophils and are capable of phagocytosing as many as 100 bacteria. They also have the ability to engulf large particles such as red blood cells and malarial parasites.

The process of phagocytosis by monocytes is similar to that described in neutrophils (see page 169).

2. Precursor of tissue macrophages.

Monocytes are the precursors of tissue macrophages. The mature monocytes stay in the blood only for few (10–20) hours. Then they leave the blood to enter the extravascular tissue and get converted into tissue macrophages (for details see page 179).

3. Role in tumour immunity.

Monocytes may also kill tumour cells after sensitization by lymphocytes.

4. Synthesis of biological substances.

Monocytes synthesize complement and other biologically important substances.

Variations in count

Monocytosis

A rise in the blood monocytes above $800/\text{mm}^3$ is termed as monocytosis.

Causes

of monocytosis are:

1. *Certain bacterial infections* such as tuberculosis, syphilis and subacute bacterial endocarditis,
2. *Infectious mononucleosis* or the so-called glandular fever,

3. *Viral infections,*

4. *Protozoal and rickettsial infections, e.g. malaria and kala-azar,*

5. *Haemopoietic disorders* like monocytic leukaemia and myeloproliferative disorders and

6. *Collagen vascular disorder.*

Monocytopenia

Monocytopenia refers to decrease in the monocyte count.

Causes.

Monocytopenia is rare. It may be seen in hypoplastic bone marrow.

Applied aspects

Leukaemoid reactions

Leukaemoid reaction refers to a reactive excessive leukocytosis in the peripheral blood resembling that of leukaemia in a subject who does not have leukaemia. In spite of confusing blood picture, the leukaemoid reactions are characterized by:

- Absence of the clinical features of leukaemia such as splenomegaly, lymphadenopathy and haemorrhages and
- Presence of the features of underlying disorders causing leukaemoid reaction, such as infections, intoxication and malignant diseases.

Types of leukaemoid reactions

Leukaemoid reaction may be myeloid or lymphoid.

1. Myeloid leukaemoid reaction

is characterized by *leucocytosis*, usually moderate, not exceeding 100,000/mm³. In majority of the cases, the granulocyte series is involved.

2. Lymphoid leukaemoid reaction

is also characterized by moderate leucocytosis. TLC usually does not exceed 100,000/mm³. The DLC reveals mostly mature lymphocytes

simulating the blood picture seen in the chronic lymphoid leukaemia.

Leukaemias

Leukaemias constitute a group of malignant diseases of the blood in which there occurs an increase in the total WBC count associated with the presence of immature WBCs in the peripheral blood. The total WBC count is usually above $50,000/\text{mm}^3$ and may be as high as $100,000$ – $300,000/\text{mm}^3$.

- The proliferation of leukaemic cells takes place primarily in the bone marrow and in certain form in the lymphoid tissues.
- There are associated features of:
- Bone marrow failure (e.g. anaemia and thrombocytopenia) and
- Involvement of other organs (e.g. liver, spleen, lymph nodes, meninges, brain, skin, etc.)

Types of leukaemias

Leukaemias account for 4% of all cancer deaths. Leukaemias are classified on the basis of cell types predominantly into *myeloid* (involving cells derived from the myeloid stem cells) and *lymphoid* (involving the cells derived from lymphoid stem cells). On the basis of natural history of disease each variety can be divided into *acute* and *chronic* types. In this way, the main types of leukaemias are:

1. *Acute myeloblastic leukaemia (AML)*,
2. *Acute lymphoblastic leukaemia (ALL)*,
3. *Chronic myeloid leukaemia (CML)*,
4. *Chronic lymphoid leukaemia (CLL) and*
5. *Hairy cell leukaemia (HCL) which is an unusual variant of lymphoid neoplasia.*

OTHER IMMUNE MECHANISM-RELATED ASPECTS

- Immune tolerance
- Immune modulation
- Tissue Transplantation
- Autoimmunity
- Hypersensitivity
- Immunodeficiency diseases

Introduction

Immunity refers to resistance of the body to pathogens and their toxic products. Various aspects in relation to the immune mechanisms which need detailed discussion are introduced briefly:

Types of immunity.

Immunity primarily is of two types: innate immunity which is present by birth, and acquired or adaptive immunity which is achieved during the lifetime by the individual.

Antigens.

Antigens are substances that can stimulate an immune response in the body.

Antibodies.

Antibodies or immunoglobulins (Igs) are gamma globulins which are produced in response to antigenic stimulation.

Immune system.

The immune system that constitutes the body's defence system consists of lymphoid organs, reticuloendothelial components and the various types of immunological cells distributed throughout the body.

Immune response.

The immune system of the body responds to an antigen by two ways:

- *Humoral or antibody-mediated immunity (AMI)* which is mediated by antibodies produced by plasma cells, and
- *Cell-mediated immunity (CMI)* which is mediated directly by the sensitized lymphocytes.

Immune tolerance.

Immune tolerance refers to the inability of a host to express a specific immunological response to an antigen.

Autoimmunity.

Refers to the condition when the body's immune response gets directed towards its own tissues which are normally exempted as self.

Immunomodulation.

Refers to process of modifying the body's immune response. It may be in the form of:

- *Immunoenhancement (immunopotentialion)*, i.e. to enhance the antibody or cell-mediated immune response against an antigen, and
- *Immunosuppression*, i.e. to reduce the body's immune response against the antigens.

Hypersensitivity.

Refers to an abnormal immune response which produces physiological or histopathological damage in the host.

Architecture (components) of immune system

The immune system which constitutes the body's defence system consists of immunological cells distributed in to two main components:

1. Mononuclear phagocytic system, and
2. Lymphoid component.

Mononuclear phagocytic system

Mononuclear phagocytic system (MPS), also known as *tissue-macrophage system*, is the new name given to the system previously called as *reticuloendothelial system (RES)*.

Formation of mononuclear phagocytic system.

The monocytes enter the blood from the bone marrow and circulate for about 3 days. From the blood, the monocytes migrate into the tissue where they attain maturity, i.e. they increase in size and a large number of lysosomes and mitochondria develop in their cytoplasm. In this way, they acquire the ability to phagocytose and thus get converted to macrophages. The macrophages wander through tissues (*mobile macrophages*) and perform scavenger functions of eliminating microorganisms and other foreign particles that invade the tissues. Some of these macrophages become attached to certain tissues in the body (*fixed macrophages*) and remain there for several months. These tissue macrophages scattered in different parts of the body combinedly constitute the *tissue macrophage system* or the so-called *mononuclear phagocytic system (MPS)*. The tissue macrophage system includes the macrophages present at the following sites in the body:

- Macrophages lining the sinusoids of liver (Kupffer cells),
- Spleen,
- Bone marrow (littoral cells),
- Lymph nodes,
- Lungs (pulmonary alveolar macrophages or PAM, also called dust cells),
- Connective tissue (histiocytes),
- Pleura and peritoneum,
- Subcutaneous tissue,
- Bones (osteoclasts) and
- Central nervous system (microglial cells).

Constituent cells of mononuclear phagocytic system.

The term mononuclear phagocytic system was coined in 1960 to include the following constituents:

- Precursor cells of the monocyte series from bone marrow,
- Promonocytes from the bone marrow,
- Monocytes from the bone marrow and blood and
- Tissue macrophages present in the above-cited sites in the body.

The MPS does not include the following cells which were included in the reticuloendothelial system (RES):

- Reticulum cells of the spleen and lymph nodes,
- Endothelial cells and
- Fibroblasts.

Functions of mononuclear phagocytic system.

The MPS functions as a physiological unit, i.e. if any part of it is put out of action, the rest of the system undergoes compensatory hypertrophy and makes up the deficiency. The MPS plays the following roles in the body:

1. Role in inflammation and healing.

The cells of MPS ingest cell debris, broken down RBCs, fibrin and bacteria from the inflamed area and promote healing process.

2. Role in defence against the bacteria invading the body tissues.

These cells ingest the invading bacteria and are thus concerned with the defence of the body against the bacteria. During infection, these cells rapidly increase in number resulting in enlargement of the organs which are rich in these cells, e.g. spleen, lymph nodes, etc.

3. Role in the immune response

played by MPS:

- The cells of MPS ingest and process the antigen entering the body. The processing of antigen is essential before an antigen can evoke cell-mediated immunity (CMI) or stimulate antibody formation in plasma

cells.

- The cells of MPS have receptors for immunoglobulins and complements, so these are very efficient in phagocytosing the antigen-antibody complement complexes.

4. Role in removal of old RBCs.

The aged RBCs or those damaged by the action of antibodies are removed by the cells of MPS in different organs like spleen, bone marrow, liver, etc.

5. Role in removal of old WBCs and platelets.

Like RBCs, WBCs and platelets are also removed by the cells of MPS system.

6. Storage function.

The cells of MPS store excess lipids and mucoprotein and become swollen.

Lymphoid organs

The lymphoid component of the immune system consists of a network of lymphoid organs, tissues and cells and the product of these cells.

Lymphoid organs can be classified into:

A. *Central or primary lymphoid organs*, which include:

I. Thymus, and

II. Bursa equivalent (fetal liver and bone marrow); and

B. *Peripheral lymphoid organs*, which include:

I. Lymph nodes,

II. Spleen and

III. Mucosa-associated lymphoid tissues (MALT).

Primary (central) lymphoid tissues

Thymus

The thymus gland is a complex lymphoreticular organ located in mediastinum just above the heart. It consists of two (right and left) encapsulated lobes joined together by a fibrous connective tissue. Each lobe is divided into many lobules. Histologically, each lobule consists of outer *cortex* and inner *medulla*. Both cortex and medulla consist of two types of cells:

- **Epithelial cells.** These cells form a network in which thymocytes and macrophages are found.
- **Thymocytes** refer to the immature lymphocytes predominantly present in the cortex and mature lymphocytes mainly present in the medulla. Lymphocytes produced in the thymus are called thymus-derived lymphocytes or T lymphocytes or simply T cells. Lymphocyte proliferation in thymus is not dependent on antigenic stimulation.

Role of thymus in the immune system

- The main function of the thymus is development of cell-mediated immunity. The stem cells destined to form T lymphocytes leave the bone marrow and migrate to the thymus where they further differentiate.
- The thymus confers immunological competence on the lymphocytes during their stay in the organ. In the thymus, T lymphocytes are educated so that they become capable of mounting a cell-mediated immune response against an appropriate antigen. This is affected under the influence of the thymic microenvironment and several hormones, such as *thymosin* and *thymopoietin* produced by the thymic epithelium.
- The *immunologically competent lymphocytes* migrate from thymus into peripheral lymphoid organs as mature T lymphocytes which are precommitted to their function and antigen specificity. These are selectively seeded into paracortical areas of peripheral lymph nodes and into the white pulp of the spleen around the central arterioles. These regions are known as *thymus-dependent* areas.

Effects of thymectomy

1. *Thymectomy in newborn animals* produces:

- Lymphopenia and atrophy of peripheral lymphoid tissue,
- Suppression of delayed hypersensitivity reactions,
- Failure to reject foreign tissue grafts and
- Markedly increased susceptibility to infections.

2. *Thymectomy in adult animals* produces immune deficiency after a few months, i.e. after the existing pool of immunologically competent lymphocytes is depleted.

The above observations 1 and 2 prove that:

- The thymus is responsible for development of immunologically competent T lymphocytes, and
- The thymus is also responsible for maintenance of an adequate pool of T lymphocytes in adult life.

Bursa equivalent

In humans, the fetal liver and bone marrow appear to be the equivalent of avian bursa of Fabricius. *Bursa of Fabricius* in birds is also a site of lymphocytic proliferation and differentiation. Immunocompetent lymphocytes produced in the bursa are called bursa lymphocytes or B lymphocytes or B cells. The mature B cells migrate from the bursa into outer or superficial cortex of the germinal follicles and medullary cords of lymph nodes and lymphoid follicles of spleen. These sites are known as *bursa-dependent* or *thymus-independent* areas. Following appropriate antigenic stimulation, B lymphocytes transform into plasma cells and secrete antibodies which constitute the *humoral immunity* or *antibody-mediated immunity (AMI)*. Surgical removal of bursa (bursectomy) from newly hatched birds destroys their subsequent ability to produce antibodies but does not affect their ability to produce cell-mediated

immunity (CMI).

Since fetal liver and bone marrow appear to be the mammalian equivalent of the avian bursa of Fabricius, so the bone marrow is the site not only of haemopoiesis but also of initial differentiation of stem cells to B lymphocytes.

Peripheral lymphoid organs

Lymph nodes

The lymph nodes are small bean-shaped or oval structures which form part of the lymphatic network distributed throughout the body.

Structural characteristics of lymph node (fig. 3.4-1)

- *Capsule* of connective tissue covers each lymph node. From the capsule trabeculae penetrate into the lymph node.
- *Afferent lymphatics* enter into each lymph node at its convex surface and drain into the peripheral subcapsular sinus.
- *Efferent lymphatics* leave the lymph node at the concavity (hilum) as a single large lymph vessel.
- *Microscopically*, the lymph node consists of two parts—peripheral cortex and central medulla.

Cortex of the lymph node consists of several rounded aggregates of lymphocytes called *lymphoid follicles*. Each follicle has a pale-staining germinal centre surrounded by small dark-staining area of lymphocytes representing *B-cell area* of the node. Besides proliferating lymphocytes, the follicles contain dendritic macrophages which capture and process the antigens.

- *Paracortex* is the deeper part of cortex, i.e. the zone between the peripheral cortex and the inner medulla and represents the *T-cell area* (*the bursa-independent area*).
- *Medulla* is predominantly composed of cords of plasma cells and some lymphocytes (*medullary cords*). The medullary cords contain B lymphocytes and along with the lymphoid follicles constitute the *bursa-dependent areas* of the lymph node.

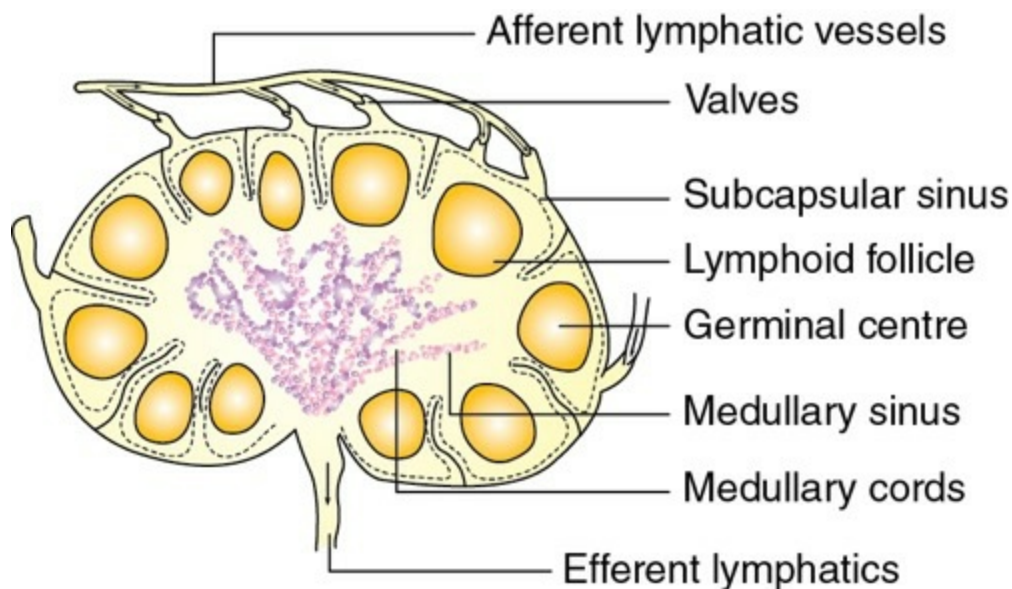

FIGURE 3.4-1 Structure of a lymph node.

Functions of lymph nodes

1. *To mount immune response in the body.* It is the main function of lymph nodes. A bulk of antigens is processed and antibody production occurs in the lymphoid follicles (for details see page 189).
2. *To perform the function of active phagocytosis* for particulate material is another main function of the lymph nodes. The lymph nodes constitute a series of inline filters. Lymph must pass through at least one lymph node before mixing with the bloodstream. Over 99% of the lymph passes through the lymph sinuses, and only 1% penetrates the lymphoid follicles.

Spleen

The spleen is the largest lymphoid organ of the body. Under normal conditions, the average weight of the spleen is about 150 g.

Structural characteristics (fig. 3.4-2)

- **Capsule** of connective tissue surrounds the spleen. From the capsule extend connective tissue *trabeculae* into the pulp of the organ and serve as a supportive network. Unlike some animals like cats and dogs, the capsule of human spleen contains very few smooth muscle fibres; hence, it is not capable of marked contraction.
- **Grossly** on a cut section, the spleen consists of a homogeneous, soft,

dark red mass called *red pulp*. In the red pulp are seen scattered white nodules called *white pulp* (malpighian bodies).

- *Microscopically*, the structural characteristics are:
- ***Red pulp*** consists of the thin-walled *blood sinuses* with *splenic cords* between them. The splenic cords consist of a collection of lymphocytes and macrophages arranged in cords in the fine network of reticular cells and fibres. This finer network forms a filtering bed that filters out red cells, white cells and platelets passing through the red pulp.
- ***White pulp*** consists of lymphocytes surrounding an eccentrically placed central artery. These periarteriolar lymphocytes are mainly *T lymphocytes*. In addition, the white pulp also contains the lymphoid follicles composed principally of *B lymphocytes*.

Blood circulation. Blood enters the spleen by the *splenic artery* which divides into branches that penetrate the splenic tissue via trabeculae. From the trabeculae arise small branches called *central arteries*. Each central artery gives off a number of *penicillar arterioles* which open into large, thin-walled blood *sinusoids*. From the sinusoids the blood is drained into the venous channels. This pattern of circulation is called the *closed circulation*. According to another view, the spleen has an open circulation, i.e. the penicillar arterioles open into the fine network of red pulp. Ultimately, blood is drained into sinusoids and venous channels.

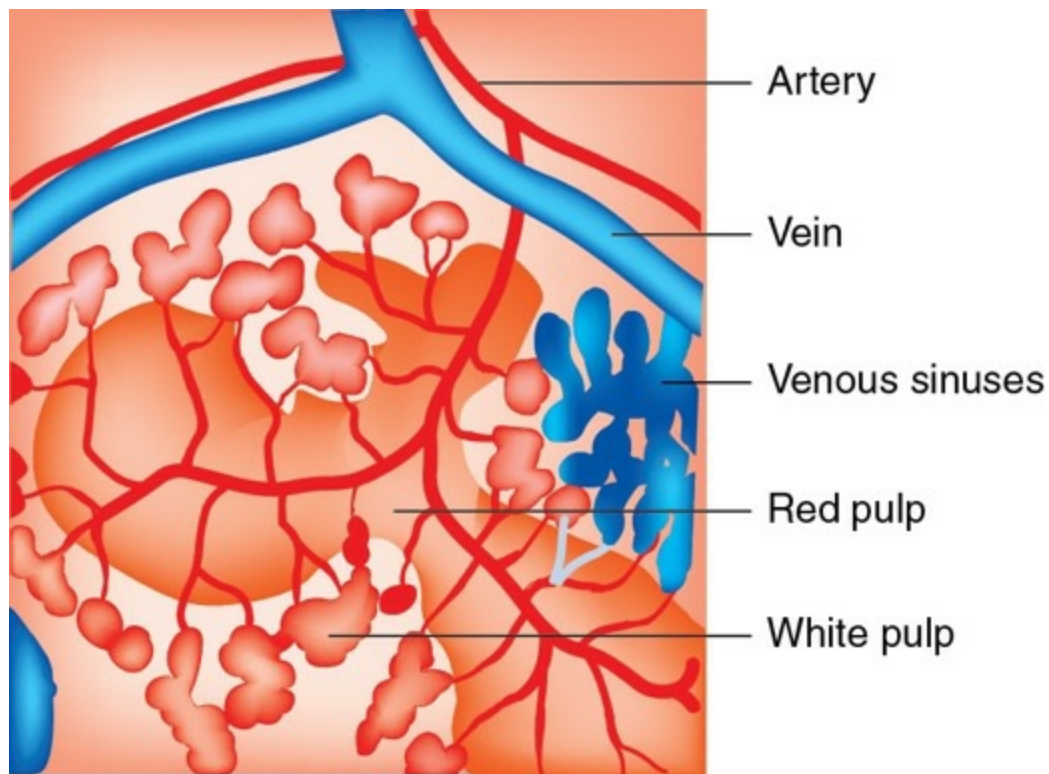

FIGURE 3.4-2 Structure of spleen.

Functions of spleen

1. **Role in immune response.** The spleen constitutes an important component of the defence system. It is an active site for production of T and B lymphocytes and antibodies. Blood-borne antigens entering the spleen are phagocytosed and processed by macrophages and fixed phagocytic mononuclear cells. Presentation of antigens, on the surface of such cells, to the splenic lymphocytes results in the formation of secondary follicles containing germinal centres of dividing and differentiating B cells which ultimately form antibodies. After splenectomy, antibody production continues to occur in other lymphoid organs but the antibody response is delayed and the antibody titre does not rise as high as in normal individuals.

2. **Role in removal of old RBCs, WBCs and platelets.** Tissue macrophages present in the spleen like other components of the *mononuclear phagocytic system (MPS)* play an important role in the removal of old RBCs, WBCs and platelets. The spleen seems to possess a special capability of trapping even mildly damaged erythrocytes. This ability has been attributed to the uniquely slow circulation of RBCs along the splenic cords where RBCs come in close contact with the splenic

macrophages. This ability of spleen to detect and destroy abnormal type of blood cells is called *cutting action of spleen*.

3. **Role in haematopoiesis.** During the 4th and 5th month of fetal life, erythropoiesis occurs in spleen. In postnatal life, under pathological conditions when the entire bone marrow is exhausted, the spleen may become the site of *extramedullary erythropoiesis*.

4. **Role in iron metabolism.** Spleen macrophages have a special ability to recycle iron liberated from the phagocytosed RBCs, for synthesis of fresh haemoglobin in the bone marrow. Other tissue macrophages have this ability much less, and the lung macrophages (PAM) do not have this ability at all.

5. **Role as a reservoir.** Spleen serves as a reservoir for mobilization of RBCs in some animals like cats and dogs. In humans, this function is not important since the splenic capsule lacks smooth muscles and thus cannot contract to any significant degree. However, spleen serves as reservoir for *platelets*. About 30% of the total circulating platelets may be present in the spleen adhering to the reticular cells in the red pulp or endothelial cells of the sinusoids.

6. **Role in regulating portal blood flow.** The vasculature of spleen also plays a role in regulating the portal blood flow.

Mucosa-associated lymphoid tissue

Mucosa-associated lymphoid tissue (MALT) refers to the lymphoid tissue distributed along the mucosa lining the alimentary, respiratory, genitourinary and other surfaces which are constantly exposed to numerous antigens. Tonsils, adenoids and Peyer's patches of small intestine are known as gut-associated lymphoid tissue (GALT). Peyer's patches are small patches of organized lymphoid tissue along the intestine containing B lymphocytes (in germinal centre) and T lymphocytes. They play a primary role in defence against infectious organisms entering via the gastrointestinal tract (GIT).

Immunity

Immunity refers to resistance of the body to pathogens and their toxic products. It can be classified as:

I. *Innate immunity*

1. Nonspecific and

2. Specific innate immunity:

- Species.
- Racial and
- Individual.

II. *Acquired (adaptive) immunity*

1. Active acquired (adaptive) immunity,

- Natural and
- Artificial.

2. Passive acquired (adaptive) immunity

- Natural and
- Artificial.

Innate immunity

- *Innate or natural immunity* is the inborn capacity of the body to offer resistance to pathogens and their toxic products. It is due to genetic and constitutional make up of an individual.
- It may be *specific* (against a particular organism) or *nonspecific*.
- Innate immunity may be:
- *Species immunity*, i.e. resistance to a pathogen shown by

all members of a species.

- *Racial immunity*, i.e. resistance to a pathogen shown by only a particular race within a species.
- *Individual immunity*, i.e. resistance to a pathogen shown by a particular individual within a race.

Mechanisms of innate immunity

1. Mechanical barrier

against invading microorganisms is provided by the intact skin and mucosa in the body.

2. Surface secretions

constitute one of the important mechanisms of innate immunity. These include:

- *Secretions* from the sebaceous glands of skin, which contain both saturated and unsaturated fatty acids that kill many bacteria and fungi.
- *Saliva*, constantly produced in the mouth cavity, has an inhibitory effect on many microorganisms.
- *Gastric juice* and highly acidic environment of stomach may hydrolyse microbial invaders.
- *Tears* poured in the conjunctival sac mechanically wash away the particles and a hydrolytic enzyme, lysozyme present in the tears, can destroy most of the microorganisms.

3. Humoral defence mechanisms

provide innate immunity by the nonspecific microbicidal substances present in the body fluids. A few examples are:

- *Lysozyme* is found in high concentration in most tissue fluids except CSF, sweat and urine. It is a mucolytic enzyme which kills microorganisms by splitting sugars of the structural mucopeptide of their cell wall.

- **Basic polypeptides** containing nonspecific microbicidal activity include leukins, arginine- and lysine-containing proteins protamine and histone.
- **Complements** have lytic and several other effects on foreign substances (see page 192).
- **Interferons** are antiviral substances produced by the cells stimulated by live or killed viruses. α and β interferons are part of innate immunity.

4. Cellular mechanisms of defence

which provide nonspecific innate immunity are:

- **Phagocytes**, i.e. neutrophils and the monocyte–macrophage system cells constitute the most important nonspecific cellular defence against the invading microorganisms (see page 169).
- **Natural killer (NK) cells** refer to a subpopulation of lymphocytes which provide nonspecific cellular defence against viruses, tumour cells and other infected cells (see page 175).
- **Eosinophil granules** contain enzymes and toxic molecules that act against larvae of helminths (see page 173).

Acquired (adaptive) immunity

The resistance that an individual acquires during his lifetime is known as acquired or adaptive immunity. It is antigen specific and may be antibody- or cell mediated. It is of two types: active and passive.

1. Active immunity

Active immunity is acquired by the synthesis of antibodies (humoral immunity) and production of immunocompetent cells (cell-mediated immunity) by the individual's own immune system in response to an antigenic stimulation.

Natural and artificial active immunity.

Active immunity can be induced naturally or artificially.

i. Natural active immunity.

Natural active immunity results either from a subclinical or clinical

infection. For example, a large majority of adults in the developing countries possess natural active immunity to poliomyelitis due to repeated subclinical infections with polio virus during childhood.

ii. Artificial active immunity.

Artificially, active immunity is induced by introducing antigens in the body in the form of vaccines and this process is called *active immunization*. The vaccines are preparations of live or killed microorganisms or their products. Examples of vaccines are:

- Bacterial vaccines
- Live: BCG vaccine for tuberculosis and
- Killed: TAB vaccine for typhoid.
- Bacterial product vaccines
- Tetanus toxoid and
- Diphtheria toxoid.
- Viral vaccines
- Live: Sabin vaccine for poliomyelitis, MMR vaccine for measles, mumps and rubella, and 17 D vaccine for yellow fever.
- Killed: Salk vaccine for poliomyelitis, neural and non-neural vaccines for rabies.

2. Passive immunity

Passive immunity refers to the immunity that is transferred to a recipient in a ready-made form. Here, the individual's immune system does not play an active role.

Natural and artificial passive immunity

i. Natural passive immunity

is the transfer of ready-made antibodies from the mother as:

- *In a fetus*, the IgG antibodies are transferred from the mother through the placenta.
- *After birth*, immunoglobulins are passed to the newborn through breast milk. Human colostrum is rich in IgA antibodies which are resistant to digestion in stomach and small intestine.

Passively transferred antibodies are generally against all common infectious diseases in the locality. These confer immunity on the neonate up to 3 months of age. Therefore, most paediatric infections are more common after the age of 3 months when maternal immunoglobulins disappear. By active immunization of mother during pregnancy, the immune status of the neonate can be improved. Therefore, immunization of pregnant women with tetanus toxoid is recommended in countries where neonatal tetanus is common.

ii. Artificial passive immunity.

Artificially, passive immunity can be transferred to the recipients by injecting ready-made antibodies. This is done by administration of hyperimmune sera of men or animals.

Examples of artificial passive immunity include injection of:

- Antitetanus serum (ATS),
- Antidiphtheric serum (ADS) and
- Antigangrene serum (AGS).

After first administration, the passively administered antibodies are removed by metabolism and following subsequent injections by metabolism and immune elimination. Therefore, immunity conferred is short lived.

Differences between active and passive immunity

Differences between active and passive immunity are summarized in [Table 3.4-1](#).

TABLE 3.4-1

Differences between Active and Passive Immunity

Active immunity	Passive immunity
1. Production	
Antibodies are produced by the body's own immune system in response to antigens introduced naturally or artificially in the body.	Received passively by the host. No participation of host's immune system. It is conferred by administration of ready-made antibodies naturally or artificially in the body.
2. Negative phase	
Negative phase is present in development of active immunity during which the immunity is transiently lowered. This is due to an antigen combining with the pre-existing antibodies and lowering their level.	There is no negative phase in passive immunity, as antigens are not injected.
3. Latent period	
Active immunity develops after a latent period varying from 4 days to 4 weeks. This is the time required for generation of antibodies and immunocompetent cells.	There is no latent period. Passive immunity is effective immediately.
4. Secondary response	
Due to immunological memory, the secondary response, i.e. response to antigen introduced second time, is more enhanced.	There is no immunological memory. Rather subsequent administration of antibodies is less effective due to immune elimination.
5. Duration	
Active immunity is long lasting.	Passive immunity is short lasting.
6. Effectivity	
Active immunity is more effective and confers better protection.	Passive immunity is less effective and provides inferior immunity.
7. Applicability in immunodeficient individuals	
Active immunity is not applicable in immunodeficient individuals.	Passive immunity is applicable in immunodeficient hosts.

Antigens

Definition

Antigen. Antigens are substances that can stimulate an immune response in the body. Most antigens are proteins, but some are carbohydrates, lipids and nucleic acids. The specificity of an antigen is due to specific areas of its molecule called *determinant sites* or *epitopes*. The epitopes can bind to specific binding sites called *paratopes* of the antibody molecule (Fig. 3.4-3). A pure protein can have several epitopes and thus can stimulate formation of many distinct antibodies.

FIGURE 3.4-3 Structure of an antigen.

Hapten or incomplete Antigen is a chemical substance of low molecular weight that cannot induce an immune response by itself. Nevertheless, haptens can produce the immune response when combined with larger molecules (usually proteins), which serve as carriers. For example, the atropine molecule is a hapten and does not produce an immune response, but when it combines with tear proteins it can excite immune response.

In contrast to complete antigens, haptens contain a single epitope.

Some facts about antigenicity

Immunogenicity.

Immunogenicity, i.e. ability of an antigen to stimulate an immune response is determined by:

- Size of molecule,
- Foreignness of molecule,
- Chemical structure of molecule,
- Susceptibility of the substance to the tissue enzymes,
- Genetic constitution of the host and

- Dosage, route and timing of administration.

Antigen specificity.

Antigen specificity is determined by chemical grouping and acid radicals. The antigen specificity is not absolute, i.e. some cross-reactions can occur between antigens which bear stereochemical similarities.

Species specificity.

Tissues of all individuals in a species contain species-specific antigens. However, some degree of cross-reactivity is seen between antigens from related species.

Isospecificity.

Isoantigens are the antigens which are found in some but not all members of a species. On the basis of isoantigens, a species may be divided into different groups. The best example of isoantigens is human blood group antigens on the basis of which all humans can be divided into blood groups A, B, AB and O. Each of these groups may be further divided into Rh-positive and Rh-negative. This carries clinical importance in blood transfusion, isoimmunization during pregnancy and disputed paternity.

Histocompatibility antigens

Histocompatibility antigens refer to the antigens present on the plasma membrane of cells of each individual of a species. These antigens are encoded by genes known as histocompatibility genes which collectively constitute the major histocompatibility complex (MHC). These are located on the short arm of chromosome 6. MHCs present on the surface of leucocytes were previously known as human leucocyte-associated antigens (HLA) and now known as histocompatibility lymphocyte antigen (HLA). These have been studied extensively in organ transplantation. The major histocompatibility antigens in man and mouse are known as HLA and H₂, respectively. No two persons, except identical twins, have the same MHC proteins. No two persons can have the same MHC proteins on plasma membranes of their cells.

Classes of MHC genes- There are three subclasses of MHC genes: class I, II and III.

- *MHC class I* molecules are found on the surface of virtually all the cells of the body excluding red blood cells. The MHC class I refers to the

products of HLA-A, HLA-B and HLA-C loci (Fig. 3.4-4).

- **MHC class II** antigens are encoded by the HLA-DP, HLA-DQ and HLA-DR loci, all of which reside within HLA-D region of HLA complex (Fig. 3.4-4). In man, MHC class II antigens are only found on immunologically reactive cells such as B lymphocytes, macrophages, monocytes and activated T lymphocytes.
- **MHC class III.** The genes coding for the complement components of the classical (C_2 and C_4) and the alternative (properdin factor B) pathways also reside in the MHC genes complex located between MHC class I and class II regions (Fig. 3.4-4).

FIGURE 3.4-4 HLA complex: **A**, showing the location of MHC class I, II and III antigen proteins in HLA complex; and **B**, structure of MHC proteins and their relation to CD_4 and CD_8 .

HLA tissue typing.

Histocompatibility typing or the so-called HLA tissue typing refers to detection of MHC class I and MHC class II antigens. HLA typing is used:

1. To determine HLA compatibility prior to organ/tissue transplantation from one individual to another within a species.
2. For paternity testing.
3. For anthropologic studies.
4. For establishing HLA disease association.

Antibodies

Antibodies or immunoglobulins (Igs) are gamma globulins which are produced in response to antigenic stimulation. These react specifically with the antigens which stimulated their production. All antibodies are immunoglobulins but all immunoglobulins are not antibodies.

Immunoglobulins (Igs) have been divided into five distinct classes or isotypes, namely, IgG, IgA, IgM, IgD and IgE.

Structure of antibody

IgG has been studied extensively and serves as a model of basic structural unit of all Igs. An immunoglobulin is a Y-shaped molecule made of four polypeptide chains: two heavy (H) and two light (L). These are held together by disulphide bonds (Fig. 3.4-5).

FIGURE 3.4-5 Basic structure of an antibody showing the arrangement of heavy and light chains and its variable and constant domains.

Heavy chains

- Heavy (H) chains have a molecular weight of 50,000 Da.
- H chains are structurally and antigenically distinct for each class of Ig and are named as:
 - α (alpha) in IgA,
 - δ (delta) in IgD,
 - ϵ (epsilon) in IgE,
 - γ (gamma) in IgG and
 - μ (mu) in IgM.
- The NH_2 terminal half of each chain has a variable sequence of amino acids and is called the *variable region*. In the heavy chain, it is designated as VH.

- The COOH terminal of each chain has a relatively constant sequence and is called the *constant region*. In the heavy chain, it is designated as CH.
- Two H chains are always identical in a given molecule. In IgG, each H chain contains 440 amino acids.
- Intrachain sulphide bonds fold each chain into incomplete loops. In the heavy chains, there are four loops of 110 amino acids, and each loop forms a globular domain. One domain designated as VH lies in the variable region and CH₁, CH₂ and CH₃ lie in the constant region (Fig. 3.4-5).

Light chains

- Molecular weight of light (L) chains is 25,000 Da.
- L chains are of two types: κ (Kappa) and λ (lambda). A molecule of Ig may have either κ or λ chains but never both together. κ and λ chains occur in a ratio of about 2:1 in human serum.
- Similar to H chains, the variable region of L chains is designated as VL and constant region is designated as CL.
- Like H chains, the L chains are also always identical in a given molecule. In IgG, each L chain contains 220 amino acids.
- In the light chain, there are two loops each containing 110 amino acids. Each loop forms a globular domain. One domain in variable region is designated as VL and the other in the constant region is designated as CL (Fig. 3.4-5).

Fragments of immunoglobulins

1. When treated with enzyme papain.

When treated with enzyme papain, each immunoglobulin splits into three fragments (Fig. 3.4-6A):

- *Fab (fragment antigen binding)* are two identical fragments. Each Fab bears all the variable regions and thus possesses the antigen-binding sites. The portion of the H chains present in the Fab is called Fd piece.

- *Fc (fragment crystallizable)* is the third fragment having a molecular weight of 5000 Da. As the name indicates, it can be crystallized. It lacks the ability to bind to antigen and it serves the following functions:
- Binds complements leading to complement fixation.
- Binds to cell receptors (FcRs).
- Determines placental transfer of Ig.
- Determines skin fixation and catabolic rate.
- Antigenic determinants that distinguish one class of antibody from another are also located on Fc.

FIGURE 3.4-6 Various fragments of an antibody when treated with: A, enzyme papain; B, enzyme pepsin; and C, a reducing agent (mercaptoethanol).

2. Treatment of Ig with enzyme pepsin

- Enzyme pepsin cleaves H chains on the carboxy terminal side of the interchain disulphide bonds of the hinge region. Therefore, two Fab fragments remain united. This fragment is designated as $F(ab)_2$ with two antigen-binding sites. It is about 10% larger than the two Fab fragments obtained from the papain digestion of Ig (Fig. 3.4-6B).
- Pepsin also degrades part of the Fc portion to small peptides and leaves a dimer of the carboxy terminal quarter of the chain, termed pFc (Fig. 3.4-6B).

3. Treatment of Ig with reducing agent.

Treatment of Ig with a reducing agent such as mercaptoethanol, in the presence of urea, reduces disulphide bonds releasing the four peptide chains, two heavy and two light (Fig. 3.4-6C).

Types of immunoglobulins

On the basis of physiochemical and antigenic structure, five distinct classes of immunoglobulins are identified in human serum. These are IgG, IgA, IgM, IgD and IgE.

IgG

Distribution.

IgG is the most abundant class of Ig in the body, constituting approximately 75% of the total body Igs. It is distributed equally between the intravascular and extravascular pools. It is also found in milk, saliva, nasal and bronchial secretions.

Production.

A little IgG is produced during the early stage of primary response to antigen. But, it is the major form of antibody produced during secondary response in which the initial IgM production gives way to IgG production (class switch).

Molecular weight.

IgG is a glycoprotein with a molecular weight of 150,000 Da.

Serum concentration.

of IgG normally is about 12 ng/mL.

Half-life.

of IgG is 21 days.

Subclasses.

There are four subclasses of human IgG: IgG1, IgG2, IgG3 and IgG4, possessing distinct types of heavy chains known as γ_1 , γ_2 , γ_3 and γ_4 , respectively.

Placental transfer.

IgG is the only class of Igs that can cross the placenta and is responsible for protection of the infant during the first few months of life. IgG is also found along with IgA, in milk during the first few weeks after birth, providing additional protection if the infant is breast-fed.

Binding characteristics

of IgG are:

- Macrophages and monocytes bear Fc receptors (FcRs) which bind to the Fc portion of IgG1 and IgG3 in CH₃ domain. Such binding permits these cells to exhibit antibody-dependent cellular toxicity (ADCC).
- IgG usually exhibits high affinity for antigens leading to efficient neutralization of toxins.
- Among NK null cells, a distinct subpopulation of cytotoxic cells has been recognized which also possess FcRs for Fc part of IgG; they are capable of lysing or killing target cells sensitized with IgG and are called killer cells.
- Platelets also possess FcRs for Fc portion of IgG leading to aggregation, degranulation and release of histamine.
- IgG is the only Ig which has the property to fixing guinea pig's skin. Thus, IgG participates in most immunological reactions such as complement fixation, precipitation and neutralization of toxins and viruses.

Catabolism

of IgG is unique in that it varies with its serum concentration, that is, when its level is raised catabolism is rapid.

IgM

Distribution.

IgM constitutes about 10% of the total serum immunoglobulins. In contrast to IgG, IgM, because of its large size, remains almost exclusively in the serum and is not usually found extravascularly in body cavities or secretions.

Production.

Phylogenetically, IgM is the oldest Ig class. It is the only Ig which is produced before birth. It is the predominant Ig produced during primary response. It appears early in the secondary response but its level does not rise significantly thereafter.

Structure.

IgM normally exists as a pentamer consisting of five Ig subunits (Fig. 3.4-7).

- Its heavy chain μ type and light chain κ or λ .
- The $H\mu$ chain has four CH domains rather than three as seen in H chains of IgG.
- H chains are held together by disulphide bonds between CH_3 domains.
- There is an additional peptide chain called the joining (J) chain. The J chain may be largely responsible for the polymerization process, which occurs shortly before the molecule is secreted by plasma cells.

FIGURE 3.4-7 Structure of IgM immunoglobulin.

Molecular weight.

IgM is a glycoprotein with a molecular weight of 9,000,000 Da.

Serum concentration of IgM is 1.2 ng/mL.

Half-life of IgM is about 5 days. Since they are relatively short-lived, their demonstration in the serum indicates recent infection.

Placental transfer.

Pentamer IgM is apparently too large to cross the placenta. As it cannot cross the placental barrier, the presence of IgM in a fetus or newborn indicates intrauterine infection. Its detection is therefore useful for the diagnosis of congenital syphilis, rubella and toxoplasmosis.

Binding characteristics.

IgM contains 10 Fab fragments, and thus 10 antigen-binding sites. Therefore, theoretically, it can bind to 10 antigen molecules. However, practically, IgM is capable of binding to as few as five molecules of antigen.

- IgM is much more efficient than IgG in its ability to fix complement by the classical pathway promoting lysis and death of most Gram-negative bacteria. This greater efficiency is due to the fact that the complement may bind to several Fc regions of pentameric IgM simultaneously, thus initiating a complement cascade and target cell lysis with a single molecule.
- IgM causes effective agglutination but its opsonizing power is rather weak.

IgA

Distribution.

IgA is the second-most abundant class constituting about 15% of human serum Igs where it exists as a *monomeric* Ig. Its more important form is the *dimeric* form, known as *secretory* IgA (SIgA). It is the predominant class of Igs in secretions such as milk, tears, nasal secretions, saliva, lung secretions, genitourinary and gastrointestinal fluids.

Production.

Secretory IgA is synthesized by plasma cells in the subepithelial tissues of the body.

Structure.

The basic structure of IgA is similar to that of IgG. It contains two identical light chains (either κ or λ) and two heavy α chains.

- Secretory IgA is a dimer containing four heavy chains, four light chains and one J chain which is similar to J chain found in pentameric IgM (Fig. 3.4-8). Secretory IgA also possesses an additional structural unit called secretory component (SC) which is attached to the Fc portions of IgA molecules. Due to this secretory component, the SIgA is relatively resistant to digestive enzymes.
- In the intestinal mucosa, the M cells take up the bacterial and viral antigens and pass them onto Peyer's patches (underlying the aggregate lymphoid tissue) and activate B cell lymphocytes, then the lymphocytes infiltrate into the mucosa of gastrointestinal, respiratory, genitourinary, female reproductive tract and also the breast tissue. There these B cells secrete Ig as when exposed to an antigen that initially activates them. The Sc component of IgA antibodies is secreted

by epithelial cells that acts as a receptor for binding to IgA. This thus provides secretory immunity.

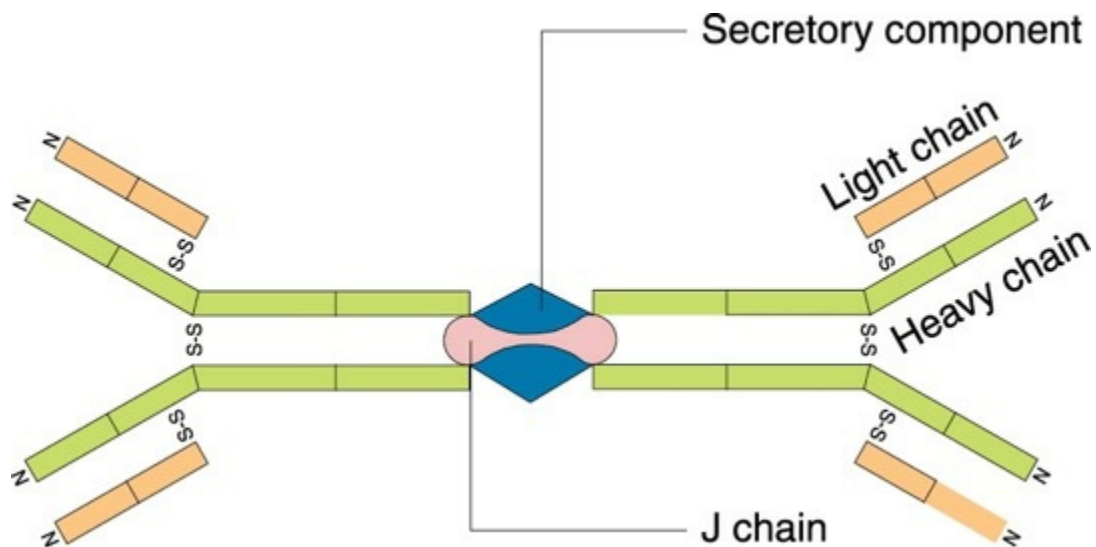

FIGURE 3.4-8 Structure of secretory IgA molecule.

Molecular weight

of IgA is 160,000 Da; while that of SIgA is 385,000 Da.

Serum concentration

of IgA is 2 ng/mL.

Half-life

of IgA is about 6 days.

Binding characteristics.

IgA does not fix complement in the classical pathway but can activate the alternative pathway. It promotes phagocytosis and intracellular killing of microorganisms.

Important Note

- SIgA coats the microbes and inhibits their adherence to the mucosal cells thereby preventing the entry into the body tissues. *Nisseria gonorrhoeae* which produces IgA protease can penetrate the mucosal barrier even in an immune person.

IgD

Structure.

Like other monomeric antibodies, IgD is composed of two light chains (either κ or λ) and two heavy chains designated as δ chains.

Molecular weight

of IgD is 180,000 Da.

Distribution.

IgD is present on the surface of B lymphocytes (which are destined to differentiate into antibody-producing plasma cells) and are known to act as antigen receptors for the B cells.

Serum concentration

of IgD is 0.03 ng/mL.

Half-life

of IgD is about 3 days.

Placental transfer.

It does not cross the placenta.

Binding characteristics.

IgD does not bind complement. Since it is present on the surface of B lymphocytes, it is involved in antigen recognition. Reaction of an antigen with surface immunoglobulin may lead to cell differentiation and antibody synthesis.

IgE

Structure.

Structure of IgE is similar to that of IgG. It consists of two light chains (either κ or λ) and two heavy chains designated as ϵ (epsilon) chain.

Molecular weight of IgE is 190,000 Da.

Production.

IgE is chiefly produced in the lining of the respiratory and intestinal tracts.

Distribution and serum concentration.

Mostly a person's IgE is fixed to the surface of mast cells and basophils. It

is present in extremely low concentration (0.00004 ng/mL) in the serum. However, the serum IgE levels are raised in atopic (type I hypersensitivity) conditions like asthma and hay fever.

Half-life

of IgE is about 2 days.

Heat stability.

In contrast to other Igs, IgE is heat labile and gets inactivated by heating at 56°C for 30 min.

Placental transfer.

It does not cross the placental barrier.

Binding characteristics.

It does not fix complement.

- The Fc portion of IgE binds to the Fc receptors present on the surface of mast cells and basophils leaving antigen-binding sites free to react with specific antigen. When a specific antigen binds with such IgE, the reaction results in the degranulation of mast or basophil cells with the release of pharmacologically active substances such as histamine, slow-reacting substances of anaphylaxis (SRS-A), mast cell chemotactic factor, eosinophil chemotactic factor, etc.
- IgE production is particularly known to be stimulated in parasitic infestation. It has been suggested that mast cell-bound IgE reacts with antigens on the parasite followed by release of histamine. This results in increased vascular permeability followed by influx of plasma and cells (particularly eosinophils) and destruction of parasite.

Summary of characteristic features and functions of immunoglobulins

The characteristic differentiating features of various immunoglobulins are summarized in [Table 3.4-2](#).

TABLE 3.4-2

Characteristic Differentiating Features of Various Immunoglobulins

Feature	IgG	IgA	IgM	IgD	IgE
• <i>Structure characteristics</i> -Structural unit -Heavy chain class -Light chain class	Monomer γ1, γ2, γ3, γ4 k or λ	Monomer SIgA is dimer α1, α2 k or λ	Pentamer μ k or λ	Monomer δ k or λ	Monomer ε
• <i>Additional chain</i>	–	J, SC	J	–	–
• <i>Molecular weight (in kDa)</i>	150	160-385	900	180	190
• <i>Carbohydrate content (%)</i>	3	8	12	13	12
• <i>Serum concentration (ng/mL)</i>	12	2	1.2	0.03	0.00004
• <i>Half-life (days)</i>	21	6	5	3	2
• <i>Secretion from serous membranes</i>	No	Yes (SIgA)	No	No	Yes
• <i>Placental transfer</i>	Yes	No	No	No	No
• <i>Heat stability (56°C)</i>	Yes	Yes	Yes	Yes	No
• <i>Complement fixation</i>	Classical Pathway	Alternative	Classical pathway	None pathway	None pathway
• <i>Binding to tissue</i>	Heterogeneous	None	None	None	Heterogeneous
• <i>Role in the body</i>	Protects the body fluids	Protects the body surfaces	Protects the bloodstream	Role not known	Mediate type I hypersensitivity

From the available information, the specific functions of various immunoglobulins appear as:

- **IgG** protects the body fluids,
- **IgA** protects the body surfaces,
- **IgM** protects the bloodstream,
- **IgE** mediates type I hypersensitivity and
- **IgD's** role is not clearly known.

Development of immune response

Development of an immune response implies *development of acquired active immunity* in the body. The immune system of the body responds to an antigen by two ways:

1. Humoral or antibody-mediated immunity (AMI), and
2. Cell-mediated immunity (CMI).

Development of humoral immunity

The humoral immunity is mediated by antibodies and so is also called antibody-mediated immunity (AMI). The antibodies are produced by plasma cells which in turn are produced by B lymphocytes.

Role of humoral immunity

1. The humoral immunity provides defence against most extracellular bacterial pathogens and viruses that infect through the respiratory and intestinal tract.
2. It participates in immediate hypersensitivity reactions of type I, II and III.
3. Humoral immunity is also associated with certain autoimmune diseases.

Types of humoral immune responses

The antibody response to stimulation by an antigen is of two types (Fig. 3.4-9):

- Primary humoral response, and
- Secondary humoral response.

FIGURE 3.4-9 Response of body immune system to an antigen: **A**, time course of antibody production in primary versus/secondary response; and **B**, serum levels of IgM and IgG antibodies in primary and secondary response.

Primary response

refers to the response of the body's immune system to an antigen which is introduced into the body for the first time. Always there is a latent period varying from 4 days to 4 weeks before the primary response in the form of a rise in the serum antibodies titre can be detected.

Secondary response

refers to the response of the body's immune system to an antigen which is introduced into the body on a second occasion. Such a response occurs more quickly and more abundantly. This is because of the fact that the immune system is liable to retain the memory of a prior antigenic exposure for long periods (immunological memory) and produce

enhanced response when encountered with the same antigen for the second time.

Immune response arch.

The development of immune response can be subdivided using the concept of "Immune Response Arch" into three phases—afferent, processing and effector.

Phases of humoral immune response (figs. 3.4-10, 3.4-11)

1. Antigen processing and presentation

Once the antigen enters the body, it is phagocytosed by the macrophages (nonspecific response). Phagocytosed material is broken down into polypeptide fragments. The antigen polypeptide fragments then combine with the MHC II present in the macrophages and move to the cell surface. This is called *processing of antigen*. The processed antigen is then presented to immunocompetent lymphocytes by the macrophages. So, the macrophages are also called *antigen-presenting cells (APCs)*. Other antigen-presenting cells which can process and present the antigen to lymphocytes are:

- B lymphocytes themselves and
- Dendritic cells present in the skin (Langerhans cells), thymus (medulla), lymph nodes (cortex and paracortex), spleen and other secondary lymphoid organs.

FIGURE 3.4-10 Broad outline of development of humoral immune response: **A**, antigen processing and presentation to immunocompetent cells; **B**, recognition of antigen by the lymphocytes; and **C**, activation of lymphocytes (blast transformation).

FIGURE 3.4-11 Summary of immune response.

2. Recognition of antigen by lymphocytes.

The lymphocytes possess the antigen recognition receptors. These include the membrane-bound (surface) immunoglobulins (mIgs or sIgs) in B lymphocytes and T cell receptors (TCRs) in the T lymphocytes. These receptors serve as specific surface receptors, recognizing and interacting with only a single antigenic determinant on the antigen presented to the lymphocytes. This process of binding of processed antigen to specific receptors on the surface of lymphocytes in technical terms is called *recognition of antigen by lymphocytes*. Thus, many million different T and B lymphocytes, each with the ability to respond to particular antigen, are present in the body.

Important Note

The receptors on circulating T cell (TCRs) are mainly made of α and β polypeptide units, hence called α and β T cells. About 10% of T cell receptors (TCRs) have γ and δ polypeptide units, and they are designated as $\gamma\delta$ T cells.

3. Lymphocyte activation.

The lymphocytes that have combined with antigen are activated, i.e. the lymphocytes become larger and look like a lymphoblast. This is known as *blast transformation*. Activated B lymphocytes and helper T cells (CD₄ cells) play a major role in humoral immunity. The macrophages liberate

IL-1 and cause further activation of B lymphocytes and helper (CD_4T) cells.

Activation of T lymphocytes.

Activation of helper T cells by the processed antigen complex is essential for humoral immunity. The activated helper T cells secrete two substances: interleukins 2 (IL2) and B cell growth factor which further promote proliferation of B lymphocytes and their transformation into plasma cells. This phenomenon is called *T–B cooperation*.

Activation of B lymphocytes.

After receiving cooperation from T helper cells (T–B cooperation), B lymphoblasts proliferate forming clones of cells that respond to this antigen (*clonal selection*). A clone is the population of cells descended by asexual reproduction from a single cell. The B lymphocytes proliferate and transform into two types:

- Plasma cells, and
- Memory B cells.

Role of plasma cells. When a B lymphocyte is converted to a plasma cell, its cytoplasm expands. It is filled with granular endoplasmic reticulum. The plasma cells secrete antibodies.

Role of memory B cells. A small portion of the activated B lymphocytes do not enlarge or undergo blast transformation. Instead, they only proliferate and transform into small-sized memory B cells, which occupy the lymphoid tissue throughout the body. Memory B cells have a long lifespan and remain inactive. When the body is exposed to the same antigen for the second time, they are able to recognize it become active, i.e. they are responsible for secondary response of antibodies.

4. Production of antibodies.

The plasma cells so formed secrete antibodies which are also called immunoglobulins (Igs). Immunoglobulins are actually secreted form of antigen-binding receptors. For structure and class of immunoglobulins, see page 185. The rate of antibody production is very high, i.e. each plasma cell produces about 2000 molecules of antibodies per second. A plasma cell secretes an antibody of a single specificity of a single antibody class and a single light chain type. However, in a primary

antibody response, a plasma cell produces IgM initially and later it may switch onto IgG production.

Theories of antibody production.

The antibody produced in response to an antigen is highly specific, i.e. it reacts only with the antigen which has evoked its production. How this is possible is not known exactly. Various theories have been put forward to explain this immune specificity.

Clonal selection theory put forward by Burne in 1957 is more widely accepted than other theories.

- According to this theory, during immunological development, a large number of B lymphocytes capable of reacting with different antigens are formed. Each specific B cell multiplies and establishes a population of genetically and immunologically identical B cells called a *clone*. An antigen has only to select and stimulate its specific clone. That is why this theory is named clonal selection theory.
- This theory also states that cells with immunological reactivity with self-antigens are eliminated during embryonic life. Such clones are known as forbidden clones. Their persistence or development in the later life leads to autoimmunity.
- The diversity for production of large number of different types of immunoglobulins by human B cells has a genetic basis.

The immunoglobulin molecules possess two types of light chains and eight types of heavy chains. In the heavy chain, there are variable regions (V, D and J segments). The gene responsible for V segment has several hundred coding regions, about 20 for D segment and 4 for J segment. During B cell proliferation, one coding region for each (V, D and J segments) is randomly selected; therefore, about 10^{15} different immunoglobulin molecules are permitted by this mechanism. Similar mechanisms operate for diversity in T cells receptor production.

5. Inactivation of antigen or attack phase or effector phase of immune response.

This is the last phase of immune response and involves the inactivation of antigen by the antibodies. Antibodies act on the invading antigen in two ways:

1. Direct attack on the invading agents.

Because of the bivalent nature of antibody and multiple antigen sites on most of the invading agents, antibodies can inactivate the invading agent by the following reactions:

- **Agglutination.** By this reaction, large number of particles (bacteria or red cells) with antigens on their surface are bound together to form a clump. Clumping increases the susceptibility to phagocytosis.
- **Precipitation.** In this reaction, the antigen–antibody complex forms an insoluble precipitate.
- **Neutralization.** Antibodies cover the toxic sites of antigen and neutralize them.
- **Cytolysis.** Antibodies attach to the membranes of cellular agents thereby causing rupture of cells.

2. Attack on the antigen through complement system

The complement system includes 11 enzymatic proteins which are named as C1 to C9, B and D. All these are present in the blood as plasma proteins. These are also present in the tissue fluid. The complement system acts in three ways (Fig. 3.4-12):

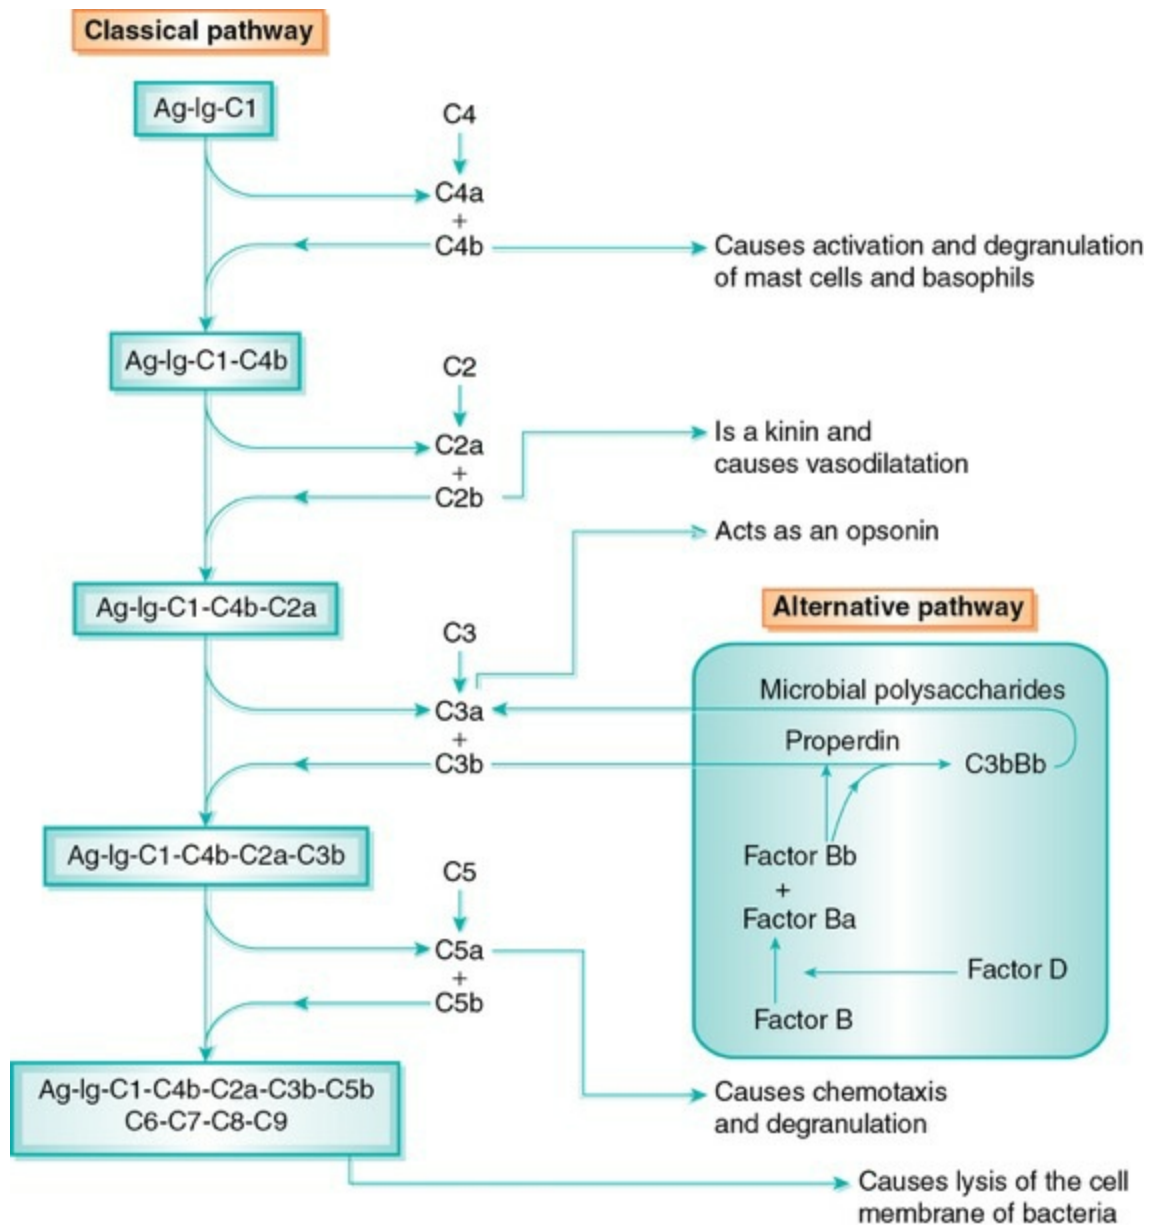

FIGURE 3.4-12 Broad outline of classical and alternative pathway of complement system.

(a) Classical pathway.

This is activated by an antigen–antibody reaction. When an antibody binds with an antigen, a specific reactive site on the constant portion of the antibody becomes uncovered where the protein C1 binds and thus gets activated. The activated C1 in turn activates the other complements in a series of cascade reactions. The products of complement activation cause the following effects:

- **Opsonization.** Opsonization is the coating of antigen by antibody and complement. It helps the neutrophils and macrophages to phagocytose the antigen. The activated C3a product acts as an opsonin.

- **Lysis**, i.e. destruction of bacteria by rupturing the cell membrane. A membrane attack complex is formed by C5b–C6–C7–C8–C9. The cell lysis is brought about by the complement system by inserting proteins called *perforins* into the cell membrane. Perforins make holes in the cell membranes, resulting in free flow of ions and disrupting membrane permeability.
- **Agglutination**, i.e. clumping of bacteria and RBCs.
- **Chemotaxis**, i.e. attraction of leucocytes to the site of antigen–antibody reaction. Chemotaxis is enhanced by C5b–C6–C7 complex.
- **Neutralization**, i.e. covering the toxic sites of antigenic products.
- **Activation and degranulation of mast cells and basophils** is caused by C4b. This releases factors producing vasodilatation and chemotaxis. Vasodilatation increases capillary permeability; therefore, plasma proteins enter the tissues and antigenic products are inactivated.

The antibodies which can fix and thereby activate complements are IgM and IgG. IgA also fixes complements but does so by the *alternative pathway* and not by the *classical pathway*.

(b) Alternative pathway.

In the alternative pathway, the complement system is activated without an antigen–antibody reaction. The alternative or properdin pathway is initiated by binding of the factor I (a protein in circulation) with polysaccharide present in the cell wall of invading organism, i.e. bacteria (endotoxin) and yeast cell wall (zymogen). This binding triggers reactions that activate C3 and C5 which ultimately attack the antigenic products of invading organisms. *Properdin* (a circulating protein) stabilizes the activating enzyme complex that is why the alternative pathway is also called properdin pathway. Because this pathway does not involve an antigen–antibody reaction, it is one of the first line of defence against invading organisms.

(c) Mannose-binding lectin pathway

of complement system is triggered when lectin binds to mannose groups in bacteria.

Development of cellular immune response

The cellular immunity refers to specific acquired immunity which is accomplished by effector T cells and macrophages (Figs. 3.4-11, 3.4-13). It is also called cell-mediated immunity (CMI).

FIGURE 3.4-13 Development of cellular immune response.

Role of cellular immunity

1. Cellular immunity protects the host against fungi, most of the viruses and intracellular bacterial pathogens like *Mycobacterium tuberculosis*, *M. leprae* and *Brucella*.
2. It participates in allograft rejection and graft versus host reaction.
3. CMI participates in delayed hypersensitivity reaction.
4. CMI is also associated with certain autoimmune diseases.

5. It provides immunological surveillance and immunity against cancer (tumour immunity).

Types of cellular immune response

Like humoral immune response, the cellular immune response is also of two types:

- **Primary cellular response** which is produced by initial contact with a foreign antigen, and
- **Secondary cellular response** which is produced when the host is subsequently exposed to the same antigen. The secondary cell-mediated immune response is usually more pronounced and occurs more rapidly. Further, because of the availability of specific memory cells, an increased number of effector cells are produced in secondary response.

Phases of cellular immune response

The development of cellular immune response can be subdivided, using the concept of immune response arch in three phases—afferent phase, processing phase and effector phase.

1. Antigen processing and presentation.

An antigen entering the host body is phagocytosed and degraded into polypeptide fragments by the antigen-processing cells (APCs) which include macrophages and dendritic cells present in the peripheral lymphoid tissue. The antigen polypeptide fragments then become associated with MHC antigen and are expressed on the surface of APC. Two modes of antigen processing are known:

- Processing of Phagocytosed Material, e.g. bacterial antigen, is accomplished by combining with MHC-II molecules, and
- Processing of Antigen Derived Within the Cell, e.g. viral antigens synthesized in infected cell, is accomplished by combining with MHC-I molecules (probably in the endoplasmic reticulum).

2. Recognition of antigen by lymphocytes.

T lymphocytes possess the antigenic recognition receptors known as *T cell receptors* (TCRs). These receptors serve as specific surface receptors

recognizing and interacting with only single antigenic determinant on the antigen presented to lymphocytes. Further, the mature T lymphocytes can be differentiated into two antigenic subtypes depending on the ensemble of their surface antigens: CD4+ cells and CD8+ cells.

- CD8+ cells recognize the combination of foreign antigen and class I MHC antigen, and
- CD4+ cells recognize the combination of foreign antigen and class II MHC antigen.

T lymphocyte differentiation (activation).

CD8+ type of T lymphocytes.

after combining with foreign antigen–MHC-I complex are activated and differentiate into:

- Cytotoxic T cells (T_c cells), and
- Suppressor T cells (T_s cells).

CD4+ type of T lymphocytes

after combining with foreign antigen–MHC-II complex are activated and differentiate into:

- Helper T cells (T_H cells), and
- Delayed type hypersensitivity T cells (T_D cells).

T–T cooperation.

The differentiation of T lymphocytes into T_H, T_C, T_S and T_D cells is interdependent. This interdependence is called T–T cooperation.

Release of differentiated T cells.

The differentiated T lymphocytes so formed are released into the lymph and then enter the blood through which they are distributed throughout the body. They also pass out through capillary walls and enter in tissue fluid. From the tissue fluid they enter back into the lymph, and then to lymphoid tissue and once again into blood. Thus, T lymphocytes circulate again and again throughout the body, sometimes lasting for

months or years.

T lymphocyte memory cells.

are also formed. These spread throughout the lymphoid tissues of entire body. Therefore, on subsequent exposure to the same antigen, release of T cells occurs far more rapidly and much more powerfully than in the first response (secondary response).

4. Attack phase of cell-mediated immunity.

Role of cytotoxic T cells.

Cytotoxic T cells (T_c cells) and natural killer cells (NK cells) are responsible for the attack phase of cell-mediated immunity.

Cytotoxic T cells have some receptor protein on their outer membrane. On the basis of their receptors and functions, cytotoxic T cells are divided into $\alpha\beta$ and $\gamma\delta$ ($\alpha\beta T_c$ and $\gamma\delta T_c$) cells. Cytotoxic T cells bind antigen-bearing cells (target cells) tightly and destroy them by the following mechanisms:

i. *Perforin-mediated killing.* The T_c cells after binding with the target cell secrete a hole-forming protein called *perforin*. The perforins literally punch round holes in the membrane of target cells in the presence of extracellular calcium (calcium-dependent lysis). The pores so formed cause cell death by disrupting cell homeostasis.

ii. *Lysis through cytotoxic substances.* After binding with target cells, the T_c cells enlarge and release cytotoxic substances.

iii. *Induction of apoptosis.* T_c cells secrete tumour necrosis factor B (TNF-B) which increases the Ca²⁺ permeability of antigen-bearing cell. The increased intracellular calcium activates enzymes that cause degradation of nucleus producing apoptosis.

Role of helper T cells (TH cells).

Helper T cells are of two types: T_H¹ and T_H².

i. *Helper T¹ (T_H¹) cells* play their roles by secreting three cytokines:

- *Interleukin 2 (IL-2)* secreted by helper T₁ cells activates the CD8⁺ cells to differentiate into cytotoxic T cells and

suppressor T cells (T–T cooperation).

- γ Interferon ($IFN-\gamma$) has the direct ability to kill antigen-bearing cells.
- Tumour necrosis factor-B ($TNF-B$) can induce apoptosis in antigen-bearing cells.

ii. *Helper T₂ (T_H²) cells* secrete interleukins 4, 5, 6, 10 and 13 and primarily with activation of B lymphocytes produce antibodies (T–B cooperation).

Role of suppressor T lymphocytes (T_s cells)

- Suppressor T cells regulate the activity of cytotoxic T cells. Thus, the cellular immune response is a balance between T_C cells and T_s cells.
- Suppressor T cells also play an important role in preventing the cytotoxic T cells from destroying the body's own tissue along with the invading organism.
- Suppressor T cells also suppress the activities of helper T cells.

Cytokines

Cytokines are small protein molecules which act like hormones to regulate immune response.

Types, cell source and effects.

Types, cell source and effects of various cytokines are summarized in [Table 3.4-3](#). As shown in [Table 3.4-3](#), the cytokines are secreted not only by lymphocytes and macrophages but also by endothelial cells, neuroglial cells and other types of cells. Broadly, cytokines can be grouped as:

- *Interleukins (IL)*. These are the principal cytokines and include IL-1 to IL-13 ([Table 3.4-3](#)).
- *Other cytokines* include:
- Chemokines,

- Growth factors,
- Colony-stimulating factors (CSF),
- Tumour necrotic factors (TNF α and TNF β) and
- Interferons (IFN).

Chemokines are the substances that attract neutrophils and other white blood cells to the area of immune response or inflammation. About 40 chemokines have been identified. The receptors of chemokines are serpentine and act via G proteins. Chemokines also play role in cell growth and angiogenesis.

TABLE 3.4-3

Main Characteristics of Human Interleukins and Other Immunoregulatory Cytokines

Type of cytokine	Cell source	Effects
<i>I. Interleukins (IL)</i>		
IL-1 α and β	Macrophages and other antigen-processing cells (APCs)	i. B cell proliferation, ii. Igs production, iii. Stimulation of T cells and iv. Inflammation fever.
IL-2	Activated helper cells (Th ¹), cytotoxic cells (Tc) and natural killer cells (NK)	i. Proliferation of activated T cell. ii. B cell proliferation, Igs expression.
IL-3	T lymphocytes	Growth of early progenitor cell
IL-4	TH ² and mast cells	i. Eosinophil growth and its function, ii. B cell proliferation, iii. Igs expression, iv. MHC class II expression, v. Proliferation of TH ² and Tc cells and vi. Inhibition of production of inflammatory cytokines.
IL-5	TH ² and mast cells	Growth of eosinophils and its function.
IL-6	Activated TH ² cells APC and other somatic cells	i. Act with IL-I and TNF to stimulate T cells, ii. Proliferation of B cells and Igs production and iii. Stimulates thrombopoiesis.
IL-7	Thymic and bone marrow stromal cells	Lymphopoiesis (T and B cells)
IL-8	Macrophages	Stimulates neutrophil activity and promote their accumulation.
IL-9	From cultured T cells	Stimulates haematopoietic and thymopoietic factors.
IL-10	Activated helper cells (TH ²), TCD8, B lymphocyte and macrophages	i. Inhibition of cytokine production, ii. Stimulates B cells and antibodies production and its functions, iii. Suppresses cell-mediated immunity and

		iv. Causes growth of mast cells.
IL-11	Stroma cells	Stimulates haematopoiesis and thrombopoiesis
IL-12	Macrophages and B cells	Stimulates proliferation of cytotoxic T cells and killer cells (Tc and NK).
IL-13	TH ² cells	Promotes cell-mediated immune response. i. B cell proliferation, IgG expression, class II MHC expression, ii. Proliferation of TH ² , Tc cells and their function and iii. Inhibition of production of inflammatory cytokines
II. Other cytokines	Activated macrophages	i. IL-I type effects and
TNF α		ii. Causes vascular thrombosis and necrosis of tumour cells.
TNF β	Activated Th ¹ cells	Vascular thrombosis and tumour cell necrosis
Interferon (IFN α and β)	Macrophages, neutrophils and other somatic cells	i. Antiviral effects, ii. Stimulates class II MHC cells and iii. Activation of macrophages and NK cells.
IFN- γ	Activated Th ¹ and NK cells	i. Antiviral effect, ii. Activation of class I MHC cells and class II MHC cells and iii. Promotes cell-mediated immunity.
TGF β	Activated T lymphocytes, platelets, macrophages and somatic cells	i. Anti-inflammatory effect by suppressing cytokine production and MHC-II cells, ii. Inhibits proliferation of macrophages and lymphocytes, iii. Proliferation of B cells and iv. Healing (by stimulating fibroblast cells).

Mechanism of action

1. Local effects.

Cytokines act in an *autocrine* (i.e. on the cell that produced them) or *paracrine* (i.e. on the cell close by) manner through their specific receptors.

Receptors of Cytokines have been grouped under the superfamily. The *superfamily* includes receptors of:

- Cytokines,
- Haematopoietic growth factors,
- Prolactin and
- Growth hormone.

The superfamily of receptors has been divided into three *subfamilies*:

- Subfamily I includes receptors for IL-4 and IL-7.
- Subfamily II includes receptors for IL-3, IL-5 and IL-6.
- Subfamily III includes receptors of IL-2 and other cytokines and related proteins, e.g. IL-2R and Tac antigen.

Systemic effects.

Interleukin-1 (IL-1) affects the various body systems:

- *Central nervous system effect.* It causes fever, slow wave sleep, secretion of CRH and anorexia.
- *Metabolic effects.* It increases hepatic protein synthesis, excretion of sodium and decreases plasma zinc and iron level and also cytochrome P₄₅₀. It also causes lactic acidosis.
- *Haematological effects.* It increases number of circulating neutrophils, colony-stimulating factors and nonspecific resistance.
- *Vascular system effect.* It stimulates leucocyte adherence to the vessel wall, increases synthesis of prostaglandins, releases platelet-activating factor and increases the capillary permeability.

Other immune mechanism-related aspects

Some other aspects related to immune mechanisms which need to be elaborated are:

- Immune tolerance,
- Immune modulation,
- Autoimmunity,
- Hypersensitivity and
- Immunodeficiency diseases.

Immune tolerance

Types of immune tolerance.

Immune tolerance may be defined as a state of unresponsiveness to an antigen. It occurs in two forms: natural and acquired.

1. Natural tolerance

refers to nonresponsiveness to a self-antigen. During embryonic development, when the immune system is immature, any antigen which comes in contact with the immature immune system is recognized as self-antigen. Therefore, it does not evoke any response in later life when body is exposed to the same antigen.

2. Acquired tolerance

means unresponsiveness to a potential antigen. It is of further two types: general and specific.

(i) *General immunological tolerance* results due to impairment of the immune system; hence, there is lack of responsiveness to potential antigens.

(ii) *Specific immunological tolerance* arises when a potential antigen induces a state of unresponsiveness to itself and not to other antigens. This happens when an antigen becomes tolerogenic (tolerogen).

- In some instances, when an antigen is presented at particular concentration, it might induce specific immunological tolerance or unresponsiveness, whereas when presented at some other concentration, it promotes immunity. Therefore, an antigen that induces tolerance is referred to as *tolerogen*.
- Specific acquired tolerance has consequences for the host defences. Presence of tolerogenic epitopes on the pathogens compromises with the ability of the body to resist infections.

Mechanism of tolerance.

Immunotolerance can arise by three possible mechanisms:

- Clonal deletion,
- Clonal anergy and
- Suppression.

1. Clonal deletion.

During embryonic life, clones of B and T cells are formed. These B and T cells possess receptors which recognize the antigens and are selectively deleted or eliminated and therefore, not available to respond on subsequent exposure to that antigen in later life.

2. Clonal anergy.

Clones of B and T cell receptors which recognize self-antigen might remain, but cannot be activated. This is referred as clonal anergy.

3. Suppression.

Clones of B and T cells expressing receptors that recognize self-antigen are preserved and capable for recognition of an antigen when activated. However, an immune response might be inhibited through active suppression.

Factors influencing induction of tolerance.

A number of factors influence induction of immunological tolerance. These are: species, competency of the host, antigen and age of the host.

1. Species.

Immunological tolerance varies from species to species. For example, species like rabbits and mice can be rendered tolerant more rapidly as compared to guinea pigs and chickens.

2. Immunological competency of the host

also effects induction of tolerance. If degree of immunological competency of the host is high, then induction of tolerance is very difficult. On the other hand, newborns and embryos are particularly susceptible for induction of tolerance because their immune system is immature and not very competent.

3. Antigen.

Induction of tolerance also depends upon the antigen (i.e. its physical

nature, dose and its route of administration).

i. *Physical nature of an antigen* refers to the form of an antigen, i.e.

- Aggregated form, or
- Soluble (free form).

For example, human gamma globulin is *heat aggregated* and it is highly immunogenic in mice. But when deaggregated, it becomes tolerogenic. This is probably due to the fact that antigens in the aggregated form are easily phagocytosed by the macrophages and then presented to antibody-forming cells. On the other hand, soluble antigens or deaggregated antigens or free antigens escape phagocytization by the macrophages; therefore, they are not so easily processed and are tolerogenic.

ii. *Dose*. The induction of tolerance is also dose dependent. It has been observed that high doses of antigen tolerize the B cells and minute doses of an antigen when introduced repeatedly tolerize the T cells, but a moderate dose of the same antigen is immunogenic. Dose-dependent tolerance occurs by two ways:

- *Immune paralysis* or *high zone tolerance* occurs when high doses of antigen are introduced. It may be because of depletion of specific clone cells.
- *Low zone tolerance* occurs when a subimmunogenic dose of some thymus-dependent antigen is repeatedly introduced.

iii. *Route of administration* of an antigen also effects the induction of tolerance. An antigen when introduced intravenously, even at its highest concentration, can cause tolerance. This is due to the fact that the antigen has a fast contact with more number of cells and also reaches the spleen, to which the suppressor cells T_s migrate leading to tolerance.

4. Age of the host.

As mentioned above, the immune system competency is related to the age of the host. Therefore, embryo and newborns can develop immune tolerance easily.

Tolerance to fetus.

Fetus is genetically different from the mother and thus it should evoke an immune response in the mother. However, it usually never happens and it is considered to be the best example of immune tolerance. **Various factors which prevent an immunological response in a mother against its fetus are described:**

1. Placenta.

Placenta plays an important role by different ways:

- Immediately after implantation, the trophoblast cells lose their immunogenic capacity due to decrease in MHC antigen density.
- There is formation of mucoprotein coating on the cell surface.
- Anti-MHC antibodies which are produced in the mother get absorbed into the placenta and their entry into fetal circulation is prevented. Thereby, the placenta acts as a shield against the immunological response.

2. Alpha fetoprotein.

During embryonic development, α fetoprotein (AFP) is produced which acts as an immunosuppressive agent.

3. Progesterone.

During pregnancy, high levels of progesterone have an immunosuppressive effect.

4. Fetal T cells.

get activated when the fetus is exposed to mother T cells through the placenta and suppress the mother's T cells.

Immune modulation

Immune modulation refers to modification of the immunological response. It can be either enhanced or suppressed.

Immune enhancement.

Immune enhancement means there is increase in the response in terms of rate, intensity, duration and even induction of response to substances which were earlier nonimmunogenic.

Immunological response can be potentiated by use of certain substances referred to as adjuvants.

Adjuvants.

Adjuvants are the compounds which when introduced along with or mixed with an antigen, nonspecifically enhance or modify the immune response to that antigen. The first adjuvant was discovered by Freund hence known as Freund's adjuvant. Their contribution in enhancement of response is basically achieved by two ways:

- i. *More and prolonged production* of antibodies, and
- ii. *Increasing the number of effector* cells.

Mechanism of action. Adjuvants act by the following ways:

- They alter the distribution and persistence of an antigen in the host.
- They stimulate lymphocyte number nonspecifically.
- They activate macrophages.

Types. Adjuvants are of two main types:

i. *Incomplete adjuvants.* Substances like aluminium hydroxide, aluminium phosphate and certain mineral oils (lanolin oil) act as incomplete adjuvants. When an aqueous solution of an antigen is mixed with mineral oil, an emulsion is formed, which serves as a depot for that antigen causing slow and prolonged release of the antigen.

ii. *Complete adjuvant.* The cell walls of certain bacteria like tubercular bacilli and Gram-negative bacilli (e.g. diphtheria and of whooping cough) act as complete adjuvants because the constituents of the cell wall convert the soluble antigen into insoluble and particulate form which can be easily phagocytosed by macrophages. A typical example of a complete adjuvant is *killed mycobacterium bacilli*.

Adverse effects of adjuvants are delayed hypersensitivity reactions in human beings (see page 202) and formation of local granuloma

(inflammatory reaction, at the site of inoculation).

Immune suppression.

Immune suppression refers to reduction in the immunological response. It is of two types:

1. Specific immune suppression or immune tolerance.

(See page 197).

2. Nonspecific immune suppression.

It is caused by immunosuppressive agents which inhibit the immune response of macrophages and B and T cells leading to either lowered phagocytosing capacity of the macrophages or production of antibodies and lymphokines.

Immunosuppressive agents

refer to methods or substances causing immunosuppression. These have been grouped as physical, chemical and biological agents.

A. Physical immunosuppressive agents

(methods):

1. **Irradiations.** This is the most common method for prolonged survival of transplants. Irradiations cause breakage in the nucleic acid chains of replicating cells.

2. **Surgical procedures** like thymectomy, splenectomy and thoracic duct drainage.

- **Thymectomy.** Removal of fetal thymus gland ensures absolute depletion of mature T cells but the effect of thymectomy decreases with age. Therefore, this method is not usually applicable.
- **Splenectomy.** Though most of the antibodies are formed in the spleen, but splenectomy has little effect in adult life (because other peripheral organs—lymph nodes—can compensate for absence of spleen).

- *Thoracic duct drainage* is another method of immune suppression first used in humans during heart transplant. In this, the thoracic duct is cannulated and lymph is drained for many days, leading to decrease in size and weight of lymph node and depletion of lymphocyte (lymphopaenia).

B. Chemical methods

are nonspecific suppressants and have limited effectiveness. This group includes the following drugs:

1. *Corticosteroids* suppress the immune response by the following ways:

- They impair the maturation of activated cells.
- They suppress the production of antibodies.
- Have an anti-inflammatory effect and diminish the responsiveness of B and T lymphocytes.
- They also inhibit production of IL-1 and IL-2.

Corticoids, though commonly used, have limited effectiveness due to their side effects, as prolonged use leads to hypertension, bone necrosis, cataract and mental disturbances.

2. *Cyclosporin or tacrolimus (FK-506)* has been widely used as an immunosuppressive drug in organ transplants. This acts by inhibiting the production of IL-2. Normally, activation of T cell receptor increases intracellular calcium (Ca^{2+}) that activates calcineurin via calmodulin. Calcineurin in turn dephosphorylates the transcription factor NF-AT that moves into the nucleus and increases the gene coding activity for IL-2. The drugs cyclosporin (Csp) and tacrolimus (Tcl) prevent dephosphorylation of NF-AT (Fig. 3.4-14). It also has adverse effects on the liver and kidney.

3. *Cytotoxic drugs* such as *azathioprine* and *cyclophosphamide* act on

various stages of nucleic acid synthesis and thus prevent replication of lymphocyte. *Methotrexate*, an antagonist of folic acid, produces competitive inhibition of an enzyme reductase (essential for synthesis of DNA). This drug is a known anticancer drug.

FIGURE 3.4-14 Mechanism of action of cyclosporine C and tacrolimus in T lymphocytes.

C. Biological methods

include:

1. *Antigen-induced suppression.* This method is used for desensitization against an allergen. In this method, if the body is exposed to small doses of antigen for long time, then it can develop resistance to that antigen.

2. *Antibody-induced suppression*. This method of immunosuppression is used in pregnant mothers (Rh -ve) to prevent sensitization against Rh antigen (from fetus) by injecting anti-D after expulsion of placenta.

3. *Antilymphocytic serum* is used for depletion of T cell population. In this method, antilymphocytic serum is prepared from horse by injecting human lymphocytes. The antibodies present in the horse serum destroy body T cell pool, but antibody production remains normal. The main drawback of this method is that the ability to fight against viral infection is tremendously decreased.

Tissue transplantation

Tissue transplantation refers to the transplant of a tissue or whole organ from one part of same individual to another part or to another individual. When tissues such as skin and kidney are transplanted from a donor to a recipient of the same species, the transplant is usually taken up for some time, but then becomes necrotic and is rejected. The grafts are rejected because the recipient produces an immune reaction against the grafted tissue (foreign tissue).

Types of grafts

Different types of grafts are:

- *Autografts*. When a graft tissue is taken from one part of the body and transplanted to another part of the body of same individual.
- *Isograft*. When transplanted tissue is taken from the identical twins.
- *Allograft*. When transplanted tissue is taken from an individual and grafted to another person of same species.
- *Xenograft*. When the transplanted tissue is taken from an individual of a different species (i.e taken from an animal and grafted to human).

Rejection of grafts.

In autografts and isografts, the antigens are of the same type as in recipients; therefore, the transplanted tissue is taken up easily if blood supply is adequate. On the other hand, in xenografts, an immune response always occurs and within few weeks the graft is rejected. The organs or tissue like skin, kidney, liver, heart, bone marrow and lung transplanted as allografts are taken up safely if proper matching is done

and after transplantation proper immunosuppressive therapy is carried out.

Tissue typing.

The human leucocyte antigen (HLA) complex is mainly responsible for graft rejection. Six of these antigens are present on the cell membrane of each person. There are more than trillion possible combinations.

Therefore, development of significant immunity against any one of these antigens can cause graft rejection. The tissue type matching between siblings, parent of a recipient is more successful for transplantation.

Prevention of graft rejection

can be achieved by suppressing the immune system of the recipient. For details see page 199.

Autoimmunity

During fetal life, when many antigens are presented to the immune system, they are recognized as self-antigens and antibodies and cytotoxic T cells are not produced.

Therefore, tolerance to self-antigen is produced. However, sometimes body starts producing antibodies or T cells against self-antigen (own cells or tissue) leading to an autoimmune disease. Therefore autoimmunity may be defined as immune response to self-antigen.

Mechanism of autoimmunity.

The possible mechanisms involved in development of autoimmunity are:

1. Forbidden clones.

According to clonal selection theory, antibody-forming lymphocytes are formed against different antigens. In fetal life, lymphocytes are also formed against self-antigens, but get depleted. The clones of these cells are called forbidden clones and hence an immune response does not occur against self-antigen. However, persistence of these clones or their development in later life by some mutations leads to autoimmunity.

2. Hidden antigen or sequestered antigen.

Certain self-antigens are present in the close system and never exposed to the immune system during fetal life. These are known as hidden antigens or sequestered antigens, e.g. *lens protein* being enclosed by its capsule does not come in contact with blood; therefore, immunological

tolerance against such antigens does not develop. When such antigens in later life are somehow exposed to the immune system (accidental leak of lens protein during cataract surgery), this leads to an immune response and damages the other eye also. Another example of a hidden antigen is *sperm antigen*. Injury to testes or viral infections (mumps) leads to leakage of sperm proteins into the circulation and thus evokes an immune response against one's own testes and orchitis occurs.

3. Neoantigen or altered antigen.

Certain cells of the body undergo alterations due to exposure to irradiations, drugs, sunlight, etc. and start producing an immune response.

4. Cross-reacting antigen.

Although antibodies are highly specific for a particular antigen, but in some cases they cross-react with other cells or body tissue. This phenomenon is called as *molecular mimicry* and these antigens are called cross-reacting antigens. For example, in rheumatic heart disease, the heart is damaged by antibodies formed against streptococci.

5. Mutations.

The body immune system becomes competent for self-antigen by certain mutations.

6. Unbalanced activity of helper and suppressor T cells.

It has been observed that optimum antibody response always depends upon the balance activity of helper (TH) and suppressor T cells. If somehow the activity of these cells is altered, i.e. overactivity of TH cells and underactivity of Ts cells, then it may result in autoimmunity.

Autoimmune diseases.

Common autoimmune diseases include:

1. *Autoimmune anaemia*. For example:

- Haemolytic anaemia. Antibodies react with one's own RBCs.
- Pernicious anaemia. Antibodies react against gastric

mucosa.

2. *Thrombocytopenic purpura*. Autoantibodies react with self-platelets.
3. *Graves' disease*. Autoantibodies bind to thyroid cells and stimulate them.
4. *Hashimoto's disease*. T cells react against the antigen on the thyroid cells.
5. *Insulin-dependent diabetes mellitus*. Antibodies damage the β cells (insulin producing cells) of the pancreas.
6. *Rheumatoid arthritis*. Antibodies damage the joints.
7. *Rheumatic fever*. Antibodies cross-react with valves of the heart.

Hypersensitivity

Hypersensitivity is an abnormal response which produces physiological or histopathological damage in the host. There are five types of hypersensitivity reactions:

- Type I (anaphylaxis or IgE mediated)
- Type II (antibody-mediated cytotoxicity),
- Type III (immune complex-mediated disorders) and
- Type IV (delayed type or T cell-mediated hypersensitivity).
- Type V (stimulatory).

The characteristic features of each hypersensitivity reaction are given in [Table 3.4-4](#).

TABLE 3.4-4
Characteristics of Hypersensitivity Reactions

Characteristics	Type I	Type II	Type III	Type IV
1. Time of onset of reaction	1/2–8 h	5–12 h	3–8 h (peak 48–72 h)	24–48 h
2. Reaction mediators	IgE, histamine, serotonin, SRS-A, etc.	IgG, IgM and complement	IgG, IgM, neutrophils, eosinophils, lysosomal enzymes	T lymphocytes, macrophages and lymphokines
3. Response to intradermal injection of antigen (allergen)	Wheal and flare	–	Erythema and oedema	Erythema and induration
4. Passive transfer with	Serum	Serum	Serum	T cells
5. Samples	<ul style="list-style-type: none"> • Anaphylaxis • Asthma • Hay fever • Allergic with food and insect bite 	<ul style="list-style-type: none"> • Transfusion reactions (incompatibility reaction) • Haemolytic disease of newborn • Drug-induced allergies 	<ul style="list-style-type: none"> • Arthus reaction • Serum sickness 	<ul style="list-style-type: none"> • Tuberculin test • Contact dermatitis • Graft rejection

Type I hypersensitivity or anaphylaxis.

It is mediated by IgE antibodies and occurs due to mast cells degranulation resulting in release of histamine and many other vasoactive substances. Type I reaction (anaphylaxis) depends on the amount of histamine release and route of stimulating antigen. It occurs in two forms: local anaphylaxis and generalized anaphylaxis.

- **Local anaphylaxis** occurs when an antigen called as allergen is administered locally in smaller dose. Examples of local anaphylaxis are asthma and hay fever.
- **Systemic or generalized anaphylaxis** is a shock-like condition. It occurs in individuals who are intensely allergic and when an antigen is administered in large amount or through systemic route.

Mechanism of type I hypersensitivity.

In type I hypersensitivity reaction, the individual first comes in contact with an antigen and antibodies (IgE) are produced which get bound to mast cells or to fixed basophils. The specific IgE antibodies are fixed to mast cell surface by its Fc portion. After second exposure, the allergen passes on to these sensitized cells (IgE-fixed mast cells) and get attached onto the Fab site of IgE molecule attached to mast cell. Antigen–antibody binding triggers the degranulation of mast cells and releases pharmacologically active chemicals (histamine, serotonin, bradykinin and slow-reacting substances of anaphylaxis) causing vasodilatation, sensory nerve ending stimulation, etc. The individuals susceptible to type I hypersensitivity reaction are called *atopic* and reaction is known as *atopy*. Example of type I hypersensitivity includes allergic rhinitis and atopic dermatitis.

Type II hypersensitivity or antibody-mediated autotoxicity.

It is an immediate reaction in which antigen-bearing cells are damaged. The mechanism involved in this reaction is either complement- or antibody-mediated cytotoxicity.

Examples.

Type II hypersensitivity is most commonly seen in:

- Incompatible blood transfusion.
- Autoimmune haemolytic anaemia and
- Haemolytic disease of the newborn. When antibodies react with the cells on which these antigens are present, i.e. RBCs get damaged.

Type III hypersensitivity (immune complex-mediated hypersensitivity).

Monocytes and macrophages are efficient in binding and removal of antigen–antibody complexes. When the body is exposed repeatedly to an antigen, which is not cell bound (free, small and soluble), then the body faces great difficulty, because the antigen–antibody complexes formation occurs in the serum and subsequently get deposited in the normal body tissue. Complement system is also activated (particularly C3a and C5a), which is cytotoxic for monocytes, macrophages and even nearby normal tissue where the antigen–antibody complexes are deposited.

Glomerulonephritis is the best example of type III hypersensitivity reaction.

Type IV or delayed hypersensitivity.

Delayed hypersensitivity is the cell-mediated reaction in tissues of a sensitized individual. The reaction is due to sensitization of T lymphocytes and not by antibodies or by B lymphocytes. The reaction starts after several hours (48–72 h). Two types of delayed hypersensitivity reactions are recognized: tuberculin (infection) type and contact dermatitis.

Tuberculin test.

In this test, a small dose of tuberculin, or purified protein derivative from *Mycobacterium tuberculosis*, is injected intradermally in an individual sensitized earlier by tubercular protein by infection or by immunization.

Within 48–72 h an inflammatory reaction of 5 mm diameter appears at the site of injection. The inflammatory reaction is recognized by

erythema (increased blood flow) and induration (due to infiltration with large number of T lymphocytes and macrophages).

Contact dermatitis.

is type IV hypersensitivity reaction. Hypersensitivity against various chemicals in the forms of ointments, dyes, cosmetics, etc. is tested by *patch test*.

- **Patch test.** In this test, a patch of an allergen is applied to the skin under a dressing. If itching occurs within 4–5 h and local reaction in the form of redness and induration appears within 24 h, then the test is positive.

Type V or stimulatory hypersensitivity.

Over the last few years, type V hypersensitivity has been added to the original four types. In this reaction, an antibiotic can act as a stimulant to target cell or organ. An example is long-acting thyrostimulatory (LATS) antibody, a feature of Grave's disease. The LATS antibody is directed towards a portion of TSH receptor in the thyroid and mimics the function of thyroid stimulatory hormone.

Immunodeficiency diseases

Immunodeficiency diseases occur when the body defence mechanisms are impaired. The defect may lie in one or more of the following components of the immune system:

- Lymphocytes (B and T) and natural killer (NK) cells,
- Phagocytic cells and
- Complement proteins.

Immunodeficiency diseases may be classified as primary or secondary.

Primary immunodeficiency

Primary immunodeficiency occurs due to defect in the development of the immune system. Various primary immunodeficiency syndromes are as under:

1. Humoral immune deficiency

(due to B cell defect) may manifest as:

X-linked agammaglobulinaemia is the first immune deficiency disorder recognized by Bruton in 1952, hence also known as Bruton's disease. It is seen in males but sporadic cases are found in females. The basic defect in this disorder is failure of premature B cells to differentiate into mature B cells. The disease is characterized by:

- Recurrent infections with pyogenic bacteria.
- Tonsils and adenoids are atrophied.
- Lymph node biopsy reveals depletion of bursa-dependent areas.
- B cells are either absent or remarkably decreased.
- Serum immunoglobulins (all the five classes) are absent.

2. Cellular immunodeficiencies

occur due to defect in T cells and manifest as:

- Thymic hypoplasia (Di George syndrome), and
- Purine nucleoside phosphorylase (PNP) deficiency.

i. *Thymic hypoplasia or Di George syndrome* results due to a congenital malformation affecting third and fourth pharyngeal pouches from where thymus develops. Defective or nondevelopment of thymus T cells are deficient or absent in circulation. The disease is characterized by:

- Thymus is hypoplastic.
- In lymph nodes and in spleen, thymus-dependent areas are absent.
- Infants with this defect are susceptible to viral and intracellular bacterial infections.
- B cells are normal.
- Immunoglobulin levels are normal.

ii. *Purine nucleoside phosphorylase (PNP) deficiency*. Due to gene defect in chromosome 14, PNP enzyme is lacking resulting in defective metabolism of cytosine and inosine to purine which is essential for T cell proliferation. Therefore, a patient with this disorder shows decreased cell-mediated immunity.

3. Combined immunodeficiencies

occur due to defect in both B and T cells. This defect may manifest as *severe combined immunodeficiency diseases* (SCID). Many distinct patterns have been described:

- Agammaglobulinaemia,
- Adenosine deaminase deficiency and
- Reticular dysgenesis.

4. Complement immune deficiency disorder.

In this disorder, complement proteins are deficient due to genetic defect resulting in lack of various complement functions like phagocytosis, antibody killing of bacteria, lysis of virus, tumour cells and histamine release by mast cells.

5. Phagocytic disorders

lead to increased susceptibility to infections.

Secondary immunodeficiency disease.

Acquired deficiencies of immunological response mechanisms can occur secondarily to number of diseases. Secondary immunodeficiency is more common than the primary immunodeficiency. Acquired immune deficiency syndrome (AIDS) is the most important.

AIDS, i.e. acquired immune deficiency syndrome is characterized by reduction in the number of helper T cells because of infection by human immunodeficiency virus (HIV). AIDS was first of all detected in the USA in 1981. HIV is of two types, HIV-1 and HIV-2.

Spread of disease.

AIDS is a major worldwide life-threatening disease spreading rapidly. Daily about 8500 persons get infected with HIV. The high-risk groups include: sex workers, drug addicts, homosexual males, persons with

extramarital relations and recipients of unscreened blood transfusion.

Transmission.

There are mainly three routes of transmission:

1. *Parenteral route* is through blood contact involving:

- Unscreened blood transfusion,
- Tattooing,
- Use of infected razors, syringes, needles, etc.,
- Use of poorly sterilized dental instruments and
- Organ transplants.

2. *Sexual route* accounts for about 85% of HIV infection due to multiple sex partners, sex workers, homosexuality and artificial insemination. The virus is present in sufficient concentration in the semen and vaginal secretions of the infected person.

3. *Transplacental route*. Infection can be transmitted from infected mother to her fetus (vertical transmission) across the placenta and also to the infant through breast milk (perinatal transmission).

AIDS does not spread through mosquito bites, hugging, kissing and sharing meals.

Structure of HIV.

HIV is a retrovirus having rounded outline and consists of (Fig. 3.4-15):

- *The core* has two single strands of genomic RNA, enzyme reverse transcriptase and protein P-15 associated with genomic RNA. Genomic RNA is surrounded by two coverings:
- Inner covering is cone shaped consisting of P-24, and
- Outer covering of P-17.

- **Genome** has two types of genes—overlapping and split genes (8 in HIV-1 and 9 in HIV-II). Virus is surrounded by *host-derived envelop with spikes containing* protein components complementary to CD₄ or T₄ receptors present on the surface of helper T cells, monocytes, macrophages and some other nerve cells.

FIGURE 3.4-15 Schematic diagram of structure of HIV.

Virus multiplication.

When virus comes in contact with the cells having receptors of T₄ antigen (helper T cells, monocytes, macrophages and some nerve cells), it sticks to the receptor site and then passes into the cell. Then free genomic RNA synthesizes a copy DNA with help of enzyme reverse transcriptase and biochemicals of the host.

- The copy DNA forms complement strand and the duplex attaches to the host DNA in the form of *provirus*. Provirus may multiply with host cell and ultimately forms *genomic RNA* and messenger RNA.
- The messenger RNA synthesizes viral proteins. Then genomic RNA and viral proteins are packed to form virions and these bud off from the host cell, get covered by an envelope and attack a new host cell.

- The infected host cell ultimately gets killed leading to reduction in number of cells belonging to the immune system.

Incubation period.

Varies from 2 to 10 years (commonly 27–28 months). The first 2–6 months are called *window period* because in this period tests are negative. Then onwards HIV positivity is indicated by:

- Presence of P24,
- Antiviral antibodies and
- Reduction in number of T cells.

Signs and symptoms

are mostly of opportunistic infections due to decreased immunity. They include:

- Repeated episodes of diarrhoea,
- Unexplained weight loss,
- Prolonged cough, night sweating, continuous fever for more than 1 month,
- Tuberculosis, candidiasis of mouth and oesophagus,
- Brain damage and
- Ulcers, Kaposi sarcoma (cancer of skin and lymph nodes).

HIV tests.

Laboratory tests employed for diagnosis of HIV infection may be classified into three groups:

A. **Screening tests** are used to screen antibodies against HIV. The most commonly used test is ELISA (enzyme-linked immune sorbent assay) test. It is highly sensitive. For negativity, it is 100% correct but for a positive test there is a 5–6% chance of false positive.

B. **Supplement tests.** These tests also detect antibodies against HIV and are recommended for validation of positive tests on screening. The

commonly employed test is *western blot assay*. It is a highly sensitive and specific assay for culturing blood and testing plasma for virus.

C. Confirmatory tests. These tests confirm HIV infection in an individual who is seropositive. These tests include:

- Virus isolation,
- Detection of P24 antigen and
- Detection of viral nucleic acid by polymerase chain reaction.

Treatment.

Triple drug treatment is employed which includes:

- Protease inhibitor,
- Reverse transcriptase inhibitor, and
- AZT (azidothymidine).
- Interleukins are added to make the treatment more effective.

Prevention.

Preventive measures against HIV infection include:

- **Education.** National AIDS Control Organization (NACO) has been set up under the Ministry of Health and Family Welfare. Awareness is being imparted through all means of publicity and by NGOs in schools, colleges, factories, farms, etc.
- **Screening** is compulsorily carried out in case of blood donors, organ donors, semen donors, foreigners and sex workers.
- **AIDS-positive** persons are advised to prevent sexual contacts and pregnancy.
- Ban on prostitution.

- *Safer sex* with single partner, use of condoms and barrier creams.
- Use of disposable syringes, needles, blood bags and I/V sets.
- *Proper sterilization* of razors, blades and dental equipment by using 70% alcohol, 35% sodium hypochloride, 5% formaldehyde, boiling for 15 min or autoclaving.

CHAPTER

3.5

Platelets, haemostasis and blood coagulation

PLATELETS

- Structure and composition
- Properties and functions
- Normal count and variations
- Formation of platelets
- Lifespan and fate of platelets

HAEMOSTASIS

- Vasoconstriction
- Formation of temporary platelet plug
- Formation of definitive haemostatic plug

BLOOD COAGULATION

- Clotting factors
- Mechanism of coagulation
- Role of calcium in blood coagulation
- Role of vitamin K, liver and vascular wall in haemostasis and coagulation
- Thrombosis

ANTIHAEMOSTATIC MECHANISMS

- Antihaemostatic mechanisms

- Anticoagulants

BLEEDING DISORDERS

- Classification
- Purpura
- Haemophilia
- Disseminated intravascular coagulation
- Tests in bleeding disorders

Platelets

Structure and composition

Platelets (small plates), also known as thrombocytes (thrombo = clot; cytes = cells), are the third types of blood cells having the following features:

- *Size*. Platelets are the smallest blood cells varying in diameter from 2 to 4 μm , with an average volume of 5.8 μm^3 .
- *Shape and colour*. Platelets are colourless, spherical or oval discoid structures.
- *Leishman staining* shows a platelet consists of a faint bluish cytoplasm containing reddish-purple granules.
- *Nucleus* is absent in the platelets, and therefore, these cannot reproduce.

Electron microscopic structure.

Under an electron microscope, a platelet shows the following structural and compositional characteristics (Fig 3.5-1):

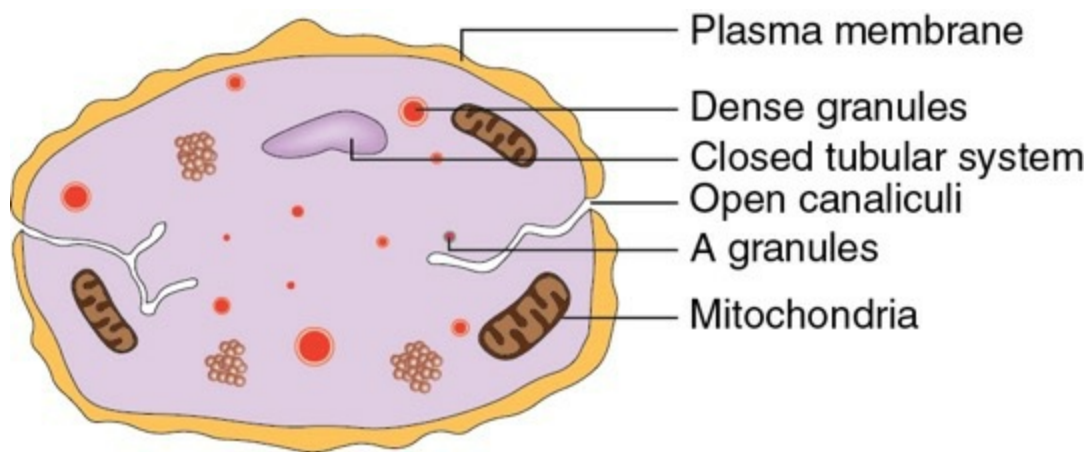

FIGURE 3.5-1 Ultra structure of a platelet.

1. Cell membrane.

Each platelet is enclosed in a 6 nm thick trilaminar membrane identical to plasma membrane of tissue cells. It consists of lipids (phospholipids, cholesterol and glycolipids), carbohydrates, proteins and glycoproteins. Its salient features are:

- **Glycoproteins** forming the surface coat of the platelet membrane prevent adherence of platelets to normal endothelium, but accelerate the adherence of platelets to collagen and damaged endothelium in injured blood vessels.
- **Phospholipids** of the platelet membrane contain platelet factor-3, which plays an activating role at several points in the blood clotting process.
- **Invagination** of the surface membrane forms the so-called *canalicular system* or the *surface connecting system*.
- **Receptors** present on the platelet membrane are meant for combining with specific substances like collagen, fibrinogen ADP and the von Willebrand factor in vessel walls.
- **Precursors** of various substances like thromboxane A_2 , prostaglandins, leukotrienes and platelet factors 3 and 4 are also present in the platelet membrane.

2. Microtubules.

Microtubules are made up of polymerized proteins called tubulins. These

form a compact bundle which is present immediately beneath the platelet membrane and encircles the whole cytoplasm. These are responsible for maintenance of the discoid shape of circulating platelets.

3. Cytoplasm.

Cytoplasm of the platelets contains Golgi apparatus, endoplasmic reticulum, few mitochondria, microtubules, microvesicles, filaments, granules, glycogen, lysosomes, proteins, enzymes and hormonal substances. The role of some of the active factors is described:

- *Endoplasmic reticulum and Golgi apparatus.* These structures synthesize various enzymes and store large quantities of calcium.
- *Mitochondria.* These are capable of forming ATP and ADP.
- *Contractile proteins* include actin, myosin and thrombosthenin. Actin and myosin molecules are similar to those of contractile proteins of the muscles. Contractile proteins can cause the platelet to contract and are thus responsible for the clot retraction.
- *Other proteins* present in the cytoplasm are:
 - *Fibrin stabilizing factor.* It is an important protein having a role in blood coagulation.
 - *Platelet-derived growth factor.* It causes growth of vascular endothelial cells, vascular smooth muscle cells and fibroblasts; and thus is involved in the repair of damaged blood vessels.
 - *Von Willebrand factor (VWF)* is a large, circulating protein molecule produced by the endothelial cells of the vessel wall. It plays an important role in platelet adherence.
- *Granules.* Two types of granules are present in the cytoplasm of platelets.
 - *Dense granules* contain substances (like phospholipids,

triglycerides, cholesterol) ATP, ADP and serotonin (5HT). Platelets cannot synthesize 5HT, so they obtain their 5HT while passing through GIT.

- *α-granules* contain secreted proteins such as clotting factors and platelet-derived growth factor (PDGF).
- *Enzymes* present in the cytoplasm of platelets include adenosine triphosphatase and the enzyme necessary for synthesis of prostaglandins. Prostaglandins act as local hormones and have local vascular and tissue reactions.

Properties and functions

Properties of platelets (fig 3.5-2)

1. Adhesiveness.

Platelets possess the property of adhesiveness, i.e. when they come in contact with any wet or rough surface, they are activated and stick to the surface. Factors responsible for adhesiveness are collagen, thrombin, ADP, thromboxane A₂, calcium ions and the von Willebrand factor.

Whenever there is injury to the vessel wall, platelets adhere to the exposed collagen and the von Willebrand factor, to their receptors present on the platelet membrane.

FIGURE 3.5-2 Properties of platelets: **A**, adhesiveness; **B**, aggregation; and **C**, formation of haemostatic plug.

2. Aggregation.

Platelets have the property to aggregate, i.e. they stick to each other. This is due to ADP and thromboxane A_2 . Platelet binding causes their activation which results in release of contents of the granules. The released ADP acts on ADP receptors on the platelet membrane and produces further accumulation of platelets (platelet aggregation). Platelet aggregation is also fostered by the platelet-activating factor (PAF), cytokines (secreted by platelets), neutrophils and monocytes. The platelet-activating factor acts via a G protein-coupled receptor (GPCR).

Note: In human beings, there are different types of ADP receptors (P_2Y_1 , P_2Y_2 and P_2X_1).

3. Agglutination.

Clumping together of platelets is called agglutination. This occurs due to

the action of some platelet agglutinins.

Functions of platelets.

When activated, platelets perform the following functions:

1. Role in haemostasis.

Haemostasis refers to spontaneous arrest of bleeding from an injured blood vessel. Process of haemostasis is discussed in detail on page 208. Platelets play following roles in haemostasis:

- *Vasoconstriction* is induced by the serotonin (5HT) and other vasoconstrictors secreted by the platelets.
- *Temporary haemostatic plug* is formed by the platelets due to their properties of adhesiveness and aggregation.
- *Definitive haemostatic plug* formation process is also initiated by platelets.

2. Role in clot formation.

Process of clot formation involves a complex series of events (described on page 209). Platelets play an important role in the formation of the intrinsic prothrombin activator which is responsible for the onset of blood clotting.

3. Role in clot retraction.

Process of clot retraction is described on page 213. Contractions of contractile proteins (actin, myosin and thrombosthenin) present in the platelets play an important role in clot retraction.

4. Role in repair of injured blood vessels.

The platelet-derived growth factor (PDGF) present in the cytoplasm of platelets plays an important role in the repair of endothelium and other structures of the injured/damaged blood vessels.

Important Note

- Platelet-derived growth factor (PDGF) is also produced by macrophages and endothelial cells. It is made up of two subunits α and β .

5. Role in defence mechanism.

Platelets, due to their property of agglutination are capable of phagocytosis. These are particularly helpful in phagocytosis of carbon particles, viruses and immune complexes.

6. Transport and storage function.

Platelets can take up 5HT against the concentration gradient when they pass from the GIT. The 5HT is stored in the platelets and transported to the site of injury, where it is released.

Normal count and variations

Normal count.

Normal platelet count ranges from 1.5 to 4.5 lakh/ μ L with an average count of 2.5 lakh/ μ L.

Physiological variations

1. **Age.** Platelet count is less in infants (1–2 lakh/ μ L). Adult levels are reached by the third month after birth.
2. **Sex.** Normally there is no difference in the platelet counts of males and females. However, during menstruation the count is reduced in females.
3. **After meals** the platelet count is slightly increased.
4. **After strenuous muscular exercise** platelets may increase.
5. **At high altitude** the platelet count increases.

Pathological variations

A. Thrombocytosis.

An increase in the number of platelets more than 4.5 lakh/ μ L is called thrombocytosis.

Causes of thrombocytosis. Platelet count is increased:

1. After splenectomy,
2. After:

- Haemorrhage,
- Severe injury,
- Major surgical operation and
- Parturition.

3. In myeloproliferative disorders such as:

- Chronic myeloid leukaemia,
- Polycythemia vera and
- Myelofibrosis.

B. Thrombocytopenia.

Decrease in the number of platelets below 1.5 lakh/ μ L is called thrombocytopenia.

Causes of thrombocytopenia are:

1. Idiopathic thrombocytopenic purpura
2. Bone marrow depression due to:
 - Effects of various cytotoxic drugs,
 - Whole body irradiation and
 - Hypoplastic and aplastic anaemia.
3. Acute leukaemia or secondary deposits of malignancy in the bone marrow.
4. In infections like smallpox, chicken pox, scarlet fever, typhoid and dengue fever.
5. In hypersplenism.

6. Intoxaemia, septicaemia and uraemia.

Formation of platelets

Formation or development of platelets is called *thrombopoiesis*. The platelets are produced in the bone marrow. The pluripotent stem cell destined to form platelets is converted into colony forming units called Meg-CFU, which develop into platelets after passing through various stages.

Stages in platelet production (fig 3.5-3)

1. Megakaryoblast.

The earliest recognizable precursor of platelets in the bone marrow is megakaryoblast. It arises from Meg-CFU by a process of differentiation.

- *Diameter* of megakaryoblast is about 20–30 μm ,
- *Cytoplasm* is small, blue and nongranular, and
- *Nucleus* is large, oval or kidney-shaped with several nucleoli.

FIGURE 3.5-3 Stages of thrombopoiesis.

2. Promegakaryocyte.

Promegakaryocyte is formed from the megakaryoblast. A megakaryoblast undergoes endo-reduplication of nuclear chromatin, i.e. nuclear chromatin replicates repeatedly in multiples of two without division of the cell. Ultimately, a large cell containing up to 32 times the normal diploid content of nuclear DNA is formed when further nuclear replication ceases and the cytoplasm becomes granular. The granules are intensely basophilic.

3. Megakaryocyte.

A promegakaryocyte matures into a megakaryocyte with the following features:

- *Diameter.* Mature megakaryocyte is a large cell, 30–90 μm in diameter.
- *Nucleus.* Megakaryocyte has single multilobed (4–16 lobes) nucleus with coarsely clumped chromatin.
- *Cytoplasm* is abundant, light blue in colour and contains red–purple granules.
- *Cell margin* is irregular and shows many pseudopodia. Platelets are formed from pseudopodia of megakaryocyte cytoplasm which get detached into the blood stream. Each megakaryocyte may form upto 4000 platelets. The formation of platelets from the stem cell takes about 10 days.

Control of thrombopoiesis.

Thrombopoiesis seems to be regulated by the following humoral factors:

- Thrombopoietin, and
- Megakaryocyte-colony stimulating activity (Meg-CSA).

Thrombopoietin

promotes maturation of megakaryocytes and is a circulating protein produced by the liver and kidney. Thrombopoietin acts through its receptors present on platelets and controls the platelet production by feedback mechanism, i.e. when the number of platelet count is low, less will bind to the platelets and more will be available for platelet production. On the other hand, when the number of platelets is high, more will bind to the receptors and less will be available for stimulation of platelet production.

Megakaryocyte colony-stimulating factor (Meg-CSF)

controls the production of megakaryocytes.

Lifespan and fate of platelets.

Lifespan of platelets varies from 8 to 12 days with an average of 10 days. Platelets are destroyed by the tissue macrophage system in the spleen. Therefore:

- *Splenomegaly* causes reduction in the platelet count, and

- *Splenectomy* is followed by an increase in platelet count.

Haemostasis

Haemostasis refers to spontaneous arrest or prevention of bleeding from injured/damaged vessels by the physiological process. The process of haemostasis is initiated immediately following an injury/damage to the blood vessel. It involves three main steps (Fig 3.5-4):

- Vasoconstriction,
- Formation of temporary haemostatic plug and
- Formation of the definitive haemostatic clot.

FIGURE 3.5-4 Steps of haemostasis.

1. Vasoconstriction.

Vasoconstriction plays an important role in the process of haemostasis. It is induced as:

Initial vasoconstriction.

affects several centimetres in both the directions from the site of injury and occurs immediately following injury to the vessels. The degree of spasm is proportionate to the degree of trauma to the blood vessel. The vasoconstriction may be intense enough to stop the bleeding from small vessels. Initial vasoconstriction is caused by the direct effect of injury on the vascular smooth muscles. It is transient and is maintained for several minutes or even hours by humoral facilitation.

Humoral facilitation of vasoconstriction.

Following an injury/damage to the wall of blood vessel, the platelets get adhered to the damaged endothelium and exposed collagen. These platelets immediately release 5HT and other vasoconstrictors which augment the initial vasoconstriction. The vasoconstriction so induced is, thus, purely a local phenomenon. Usually arterioles and small arteries respond by vasoconstriction and decrease the loss of blood from the damaged blood vessel.

2. Formation of temporary haemostatic plug.

Formation of a temporary haemostatic plug by the platelets at the site of injury involves following steps:

Platelet adhesion.

Following injury, platelets come in contact with damaged collagen fibres and endothelial cells of the vessel wall and change their characteristics. That is, they begin to swell and assume irregular forms with large numbers of pseudopodia protruding from the surface. The contractile proteins of the platelets contract forcibly and cause release of granules that contain multiple factors. They become sticky and therefore adhere to the collagen of damaged cell walls and to the damaged endothelium.

Platelets activation.

The platelets secrete large quantities of ADP and thromboxane A_2 which

act on the nearby platelets and cause their activation. Stickiness of these additional platelets causes them to adhere to originally activated platelets. In this way, a vicious cycle is initiated which leads to activation and adherence of a large number of platelets.

Platelets aggregation.

The large numbers of activated sticky platelets stick to each other forming platelets aggregation. Platelets aggregation is also increased by *platelet-activating factor* (PAF), a cytokine secreted by neutrophils, monocytes and platelet cell membrane lipids.

Platelet aggregation initiates a series of reactions which result in the formation of thromboxane A_2 and prostacyclin from the platelet membrane phospholipids.

Formation of temporary haemostatic plug.

The platelets adherence and aggregation ultimately leads to the formation of the platelet plug. At first, it is a fairly loose plug, but is successful in blocking the blood loss if the vascular opening is small.

Inhibition of further plug formation.

Prostacyclin formed from the membrane phospholipids inhibit thromboxane formation, and thus curtail the process of further plug formation. This reaction keeps the platelets plug localized, i.e. prevents intravascular spread of plug.

3. Formation of definitive haemostatic plug.

The temporary platelet plug is converted into the definitive haemostatic plug by the process of clot formation (blood coagulation), which involves a complex series of events (see page 210). Platelets play an important role in the formation of the intrinsic prothrombin activator which is responsible for initiating the process of clot formation (page 211). The blood clot formed at the site of injury results in a tight unyielding seal or the so-called definitive haemostatic plug.

Blood coagulation

Blood remains in a fluid condition within the blood vessels throughout life. But, when the blood is shed from the blood vessels or collected in a container, it loses its fluidity within a few minutes and gets converted into a jelly-like mass, which is called a *clot*. This phenomenon is called

coagulation or clotting of blood. Both these properties of blood are essential for life:

- **Fluidity** is essential for circulation, and
- **Coagulation** provides an indispensable defence against excessive bleeding from the wounds. Thus, coagulation of the blood is one of the mechanisms involved in the process of haemostasis (prevention of blood loss).

The process of blood coagulation consists of a complex cascade of reactions. The final step in the process of coagulation is transformation of plasma protein *fibrinogen* into *fibrin* forming a sort of network within which the cellular elements of the blood are arrested. Before discussing the mechanism of blood coagulation in detail, it will be worthwhile to study the essential features of the various clotting factors involved in this process.

Clotting factors

The process of coagulation essentially involves a stepwise activation of certain substances, mostly proteins, present in the blood and/or tissue fluids. These substances are called clotting factors and have been given Roman numerals:

- Factor I (fibrinogen),
- Factor II (prothrombin),
- Factor III (thromboplastin),
- Factor IV (calcium),
- Factor V (labile factor or proaccelerin or accelerator globulin),
- Factor VI (nonexistent),
- Factor VII (stable factor or proconvertin),
- Factor VIII (antihaemophilic factor A (AHF) or antihaemophilic globulin (AHG)),

- Factor IX (Christmas factor or plasma thromboplastic component (PTC or antihæmophilic factor B))
- Factor X (Stuart–Prower factor),
- Factor XI (plasma thromboplastin antecedent, i.e. PTA or antihæmophilic factor C),
- Factor XII (Hageman factor or glass factor or contact factor),
- Factor XIII (fibrin-stabilizing factor or fibrinase or Laki–Lorand factor),
- HMW-K (high molecular weight kininogen or Fitzgerald factor),
- Pre-Ka (Prekallikrein or Fletcher factor),
- Ka-(kallikrein) and
- PL-(platelet phospholipid).

Factor I (fibrinogen).

It is a soluble plasma protein globulin in nature. Its molecular weight is 340,000 Da and is synthesized in the liver. It has 6 polypeptide chains, with its plasma concentration about 0.3 g/dL. It is converted into fibrin in the presence of the enzyme thrombin.

Factor II (prothrombin).

It is an inactive precursor of thrombin. Its features are described on page 212.

Factor III (thromboplastin).

It is also called tissue factor or tissue thromboplastins. It is released in the extrinsic pathway formation of prothrombin activator (see page 211).

Factor IV (calcium).

Ionic calcium is essential for blood coagulation. Its role in coagulation is described on page 213.

Factor V (labile factor).

It is also called proaccelerin. It is a protein and as the name indicates, it is the labile or unstable factor of the plasma. It is required for the formation

of the prothrombin activator and thus conversion of prothrombin to thrombin in both, extrinsic as well as intrinsic mechanisms of blood coagulation. Factor V is consumed during clotting and is therefore absent from serum. Its deficiency occasionally occurs as a congenital anomaly simulating haemophilia.

Factor VII (stable factor or autoprothrombin I).

It is a stable protein synthesized in liver in the presence of vitamin K. It is required for activation of factor X in the extrinsic pathway. It is not consumed during clotting and therefore is present in serum, as well as plasma. Deficiency of factor VII is a rare natural occurrence, but is frequently induced by oral anticoagulant drugs of the coumarin type, overdose of which may lead to bleeding.

Factor VIII (antihæmophilic globulin).

It is a protein of β_2 globulin type synthesized in the liver. It is required for the activation of factor X, and thus formation of the prothrombin activator in intrinsic pathway. It is consumed during clotting and is therefore absent from the serum. Its congenital deficiency causes classical haemophilia (haemophilia A), which is an inherited disease in which the clotting time is prolonged.

Factor IX (Christmas factor).

It is also called plasma thromboplastic component (PTC) or autoprothrombin II. It is a protein synthesized in the liver independent of vitamin K. It is activated by the active factor XI in the presence of Ca^{2+} , and is essential for the formation of prothrombin activator in the intrinsic pathway. Its absence or deficiency causes haemophilia B, which is an inherited disease and is similar to haemophilia A. This disease was first discovered in a patient named Christmas and hence the factor was termed as *Christmas factor*.

Factor X (Stuart–prower factor).

It is a protein present in plasma and is synthesized in the liver. It is activated by active factor IX in the presence of factor VIII, Ca^{2+} and phospholipids. Activated factor X, along with active factor V, Ca^{2+} and phospholipids forms a complex which is called *prothrombin activator*, both in extrinsic as well as intrinsic pathways.

Factor XI (plasma thromboplastin antecedent).

It is activated by active factor XII. It is required for the activation of factor IX in the presence of Ca^{2+} in intrinsic pathway. Its deficiency causes a haemorrhagic state.

Factor XII (Hageman factor).

Factor XII is activated to XIIa when it comes in contact with negatively charged surfaces, foreign substances or rough surfaces. Its activation in the blood initiates intrinsic pathway by activating factor XI (PTA) to XIa. Activated factor XII also activates prekallikrein to kallikrein, which in turn activates XII to XIIa (*feedback activations*). In deficiency of factor XII, blood clots very slowly in glass but there is no haemorrhagic state.

Factor XIII (fibrin-stabilizing factor).

This is a plasma protein which is required for stabilization of fibrin polymers in the presence of Ca^{2+} .

Hmw-k (high molecular weight kininogen).

It is responsible for attracting prekallikrein and factor XI to the site of reaction with factor XII. This is possible because HMW-K, like factor XII, is attracted towards the negatively charged surfaces which provide the site of reactions.

Prekallikrein and kallikrein.

Prekallikrein is activated to kallekrein by XIIa, which in turn activates XII to XIIa. This phenomenon is called feedback activation of XII and is shown as:

Platelet phospholipids (PPL).

Platelets contain phospholipids which are essential for clotting in the absence of tissue extract, i.e. in intrinsic pathway of coagulation. *Arabic* numerals are sometimes used for platelet activities affecting blood

coagulation. For example, the term:

- *Platelet factor 3 (PF-3)* is used for platelet phospholipid procoagulant activity.
- *Platelet factor 4 (PF-4)* is used for heparin neutralizing activity of platelets.

Mechanism of coagulation

Normally, blood circulates in the blood vessels and does not clot spontaneously. Factors responsible for this will be discussed later. Clot formation is initiated under the following situations:

- Trauma to the vascular wall and adjacent tissues,
- Trauma to blood,
- Contact of blood with damaged endothelial cells or collagen or other tissue elements outside the vessel.

The process of coagulation involves a *cascade* of reactions in which activation of one factor leads to activation of the next clotting factor (Fig 3.5-5). This enzyme cascade reaction is also called *waterfall sequence*. It is important to note that each factor activates (compared to its own amount) a huge quantity of the other factor, i.e. at each stage amplification of result is obtained. Thus, the process can be viewed as a *bioamplifier*. The process of coagulation can be divided into three main steps:

- A. Formation of prothrombin activator,
- B. Conversion of prothrombin to thrombin, and
- C. Conversion of fibrinogen into fibrin.

1. Formation of prothrombin activator

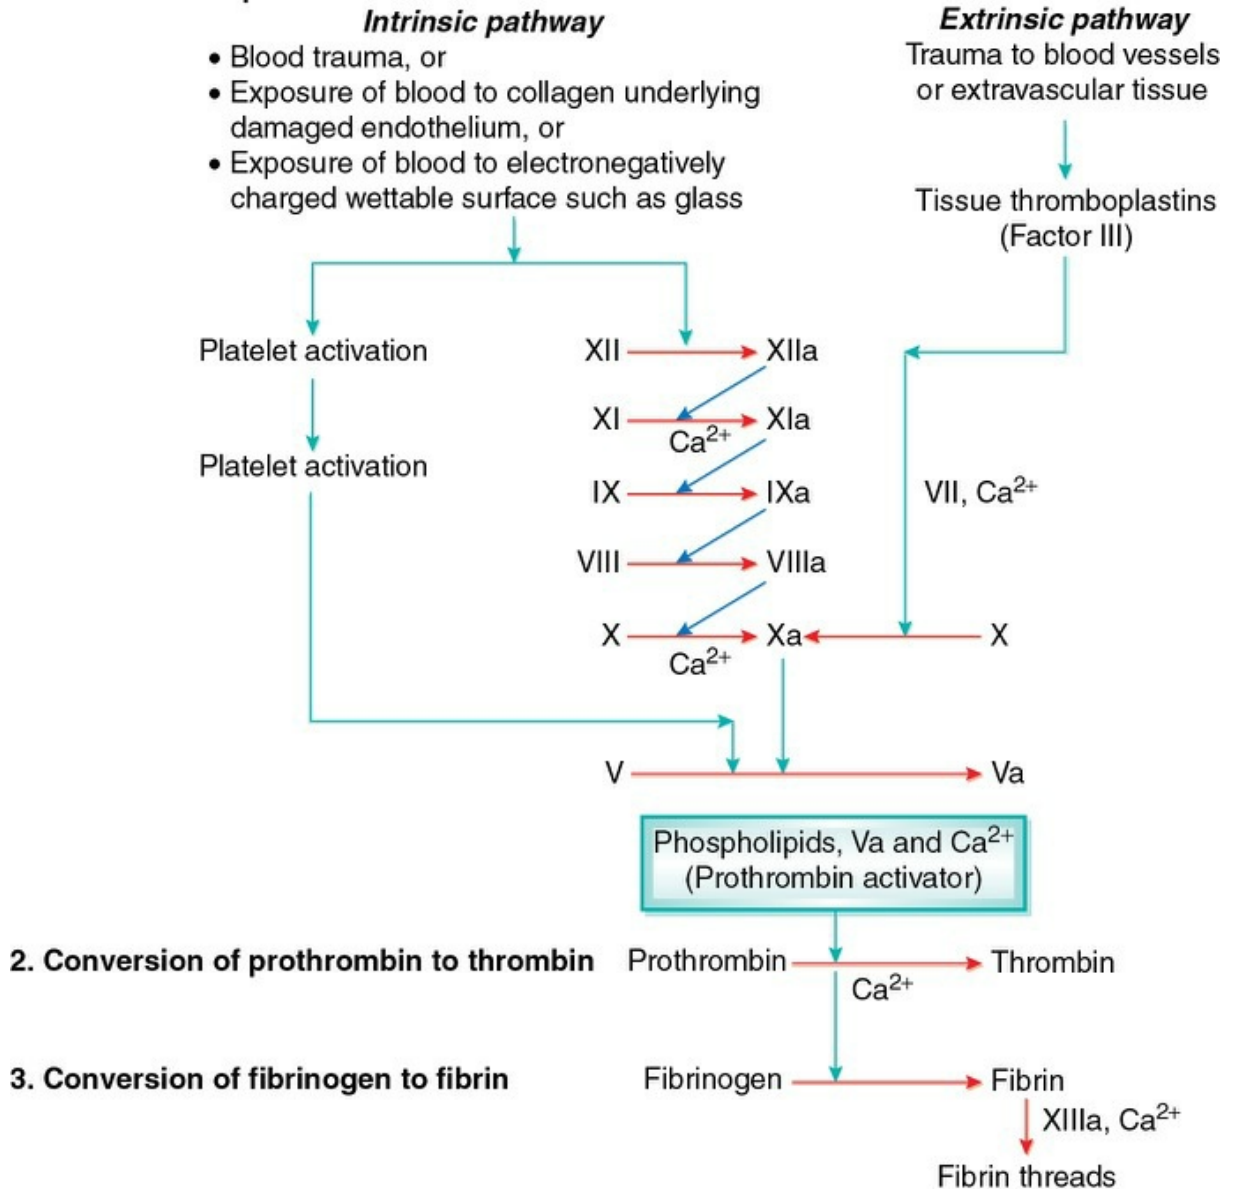

FIGURE 3.5-5 Mechanism of blood coagulation.

A. Formation of prothrombin activator

Process of coagulation is initiated by formation of a complex substance called prothrombin activator. Two different mechanisms involved in the formation of the prothrombin activator are:

1. Extrinsic pathway, and
2. Intrinsic pathway.

Extrinsic pathway

The extrinsic pathway of formation of prothrombin activator begins with trauma to the vascular wall or the tissues outside the blood vessel. It

includes the following three basic steps (Fig 3.5-5).

1. Release of tissue thromboplastins.

The traumatized tissues release several substances which are together known as *tissue thromboplastin (factor III)*. This includes phospholipids of cell membranes of the tissues and lipoprotein complex containing glycoprotein which acts as an enzyme.

2. Activation of factor X to form activated factor X.

Tissue thromboplastin combines with factor VII (stable factor) to form the tissue thromboplastin factor VII complex, which in the presence of Ca^{2+} activates factor X to form activated factor X (Xa).

3. Effect of activated factor X to form prothrombin activator.

The activated factor X, along with tissue phospholipids or phospholipids released from platelets, factor V (labile factor) and Ca^{2+} forms a complex which is called prothrombin activator.

Intrinsic pathway

The intrinsic pathway of formation of prothrombin activator begins in the blood itself following trauma to the blood or exposure of blood to collagen in a traumatized vascular wall. The steps of intrinsic pathway are summarized in Fig 3.5-5:

• Activation of factor XII.

Trauma to blood or exposure to collagen fibres underlying damaged vascular endothelium (or electronegatively charged wettable surface such as glass, in vitro) activates plasma factor XII to form XIIa and initiates the intrinsic pathway. Platelets are also activated.

• Activation of factor XI

to form XIa is caused by the activated factor XII. High molecular weight (HMW), kininogen and prekallikrin accelerate this reaction.

• Activation of factor IX

to form IXa is in turn caused by the activated factor XI in the presence of Ca^{2+} .

• Activation of factor X.

Factor IXa in the presence of activated factor VIII, Ca^{2+} and phospholipids

(released by activated platelets) activate factor X to form Xa. In thrombocytopenia and deficiency of factor VIII (classical haemophilia), this reaction is deficient.

- **Formation of prothrombin activator.**

The activated factor X, along with the phospholipids released by activated platelets, activated factor V and Ca^{2+} forms a complex which is called prothrombin activator.

Extrinsic versus intrinsic pathway

- Extrinsic pathway begins with trauma to the vascular wall or the tissue outside the vessel wall, while intrinsic pathway begins in the blood itself.
- Extrinsic pathway is explosive in nature, with severe tissue trauma clotting occurring in as little as 15 s, while intrinsic pathway is much slower to proceed, usually requiring 2–6 min to cause clotting.
- The extrinsic and intrinsic pathways are initiated by different factors, though, both converge at factor X and then follow the same common pathway (Fig 3.5-5).

B. Conversion of prothrombin to thrombin

Prothrombin

Prothrombin (factor II) is a plasma protein (an α_2 globulin) with following features:

- It is the inactive precursor of enzyme thrombin (which is not present normally in the circulating blood).
- Its molecular weight is about 69,000 Da.
- It is synthesized in liver in the presence of vitamin K (*Note*: Hepatic synthesis of factor VII, IX and X is also dependent on the presence of vitamin K).
- Its concentration in plasma of an adult is 40 mg/dL which falls in liver diseases: In a newborn baby, plasma concentration of prothrombin is lower.

Conversion of prothrombin to thrombin

is caused by the prothrombin activator in the presence of Ca^{2+} . This occurs on the surface of platelets which form the platelet plug at the site of injury. Thus, clot formation starts at the site of injury. The rate of formation of thrombin is directly proportional to the quantity of prothrombin activator available, which in turn is proportional to degree of trauma to the vessel wall or to the blood.

Thrombin

Thrombin so formed acts as proteolytic enzyme. Its molecular weight is 34,000 Da, exactly half of prothrombin. The amount of thrombin produced is in excess of the need. It has been estimated that the amount of thrombin produced during clotting of only 1 mL of blood is sufficient to coagulate 3 litres of blood. Thus, this presents a dangerous possibility of extensive intravascular clotting whenever the haemorrhage mechanism is in operation (even in a trivial cut). However, practically it does not occur so, since there exist adequate mechanisms in the body to prevent it (see page 214).

Roles played by thrombin

are:

- *Conversion of fibrinogen to fibrin* (discussed below).
- *Positive feedback role of thrombin*: It accelerates the rate of formation of prothrombin activator by activating factors VIII, V and XIII. The cascade mechanism of enzyme activation acts in such a way that small amounts of activated factor XII ultimately generate large amounts of prothrombin activator. In this way, thrombin itself can cause further conversion of prothrombin into thrombin (amplification effect).
- It also activates protein-C (which is an anticoagulant).

C. Conversion of fibrinogen to fibrin

Fibrinogen

Fibrinogen (Factor I) is a soluble plasma protein globulin in nature.

- Its molecular weight is 340,000.

- It is synthesized in the liver.
- It has 6 polypeptide chains each having 450 amino acids.
- Its plasma concentration is about 0.3 g/dL.

Conversion of fibrinogen into fibrin

Conversion of fibrinogen into fibrin involves three reactions (Fig 3.5-6):

FIGURE 3.5-6 Types of reactions involved in conversion of soluble fibrinogen into insoluble fibrin clot.

1. Proteolysis.

Thrombin acting as proteolytic enzyme removes four low molecular weight peptide chains from each molecule of fibrinogen to convert it into fibrin monomer.

2. Polymerization.

Fibrin monomer polymerizes with another monomer to form *long fibrin*

threads which form reticulum of the clot. Initially, the clot is weak because the fibrin threads are not cross-linked with each other.

3. Stabilization of fibrin polymers.

Fibrin stabilizing factor (factor XIII), which is normally present in the plasma and also released from the activated platelets is activated by the thrombin to form XIIIa, but XIIIa in the presence of Ca^{2+} causes formation of covalent cross-linkages between fibrin threads, thus adding tremendous strength to the fibrin meshwork. The fibrin meshwork traps the remaining components of plasma and blood cells to form a solid mass called clot.

Blood clot retraction

The blood clot formed at the end of the coagulation process is composed of a meshwork of fibrin threads running in all directions along with the entrapped blood cells, platelets and plasma. The fibrin threads adhere to the damaged surface of blood vessels.

At this juncture, it is important to note that *coagulation is the property of plasma alone*. The RBCs and WBCs do not take part in it. They only become caught up in the meshwork of the clot.

- Within a few minutes after a clot is formed, it begins to contract and usually squeezes out most of the fluid called *serum* (plasma without fibrinogen and other clotting factors) within 30–60 min.
- *Platelets are essential* for clot retraction. Platelets are attached to fibrin fibres of the clot in such a way that they actually bind different fibres together. The contractile proteins (platelet thrombosthenin, actin and myosin) present in the cytoplasm of platelets cause strong contraction of platelet spicules attached to fibrin fibres. This helps to compress the fibrin meshwork, i.e. cause clot contraction. This contraction is activated by thrombin and calcium ions. The process of contraction of blood clot and oozing of serum is called *clot retraction*.
- If a blood clot is kept for several hours, the clot retracts to about 40% of its original volume.
- Clot retraction is impaired if blood platelets have been removed.

Role of calcium in blood coagulation

From the study of mechanism of blood coagulation, it is quite clear that except for the first two steps in the intrinsic pathway, calcium ions are required for promotion of all the reactions. Therefore, in the absence of calcium ions, blood clotting will not occur. Thus, coagulation of blood can be prevented in vitro (e.g. for storage in the blood bank or for separation of plasma) by removal of calcium ions. The use of oxalates and citrates as in vitro anticoagulants is based on this principle. However, in vivo the degree of hypocalcaemia (e.g. due to deficiency of vitamin D or hypoparathyroidism) is compatible with life and does not cause bleeding disorder.

Role of vitamin K, liver and vascular wall in haemostasis and coagulation

Vitamin K

Chemical structure.

Vitamin K is a complex naphthoquinone derivative. There are at least two fractions present in natural vitamin K, of which it (1.4-naphthoquinone) is more active. It is soluble in fat solvents and insoluble in water. Therefore, it can only be administered orally or intramuscularly. However, for intravenous administration it has to be specially prepared by being very finely emulsified.

Sources.

Vitamin K is obtained from food, as well as synthesized by bacterial flora in the gut.

- *Food source.* Vitamin K is found in traces in green vegetables, cereals and animal tissues.
- *Synthesis by bacterial flora.* Vitamin K can be synthesized by many bacteria including those normally present in the human intestine (e.g. *E. coli*). In humans, the bacterial flora can provide an adequate supply of vitamin K and thus its deficiency from dietary abnormalities is very rare.

Dietary vitamin K and that synthesized by the bacterial flora is absorbed from the gut and reaches the liver. Its absorption from the small intestine only occurs in the presence of adequate amounts of bile salts. In the liver, synthesis of following factors is dependent upon

vitamin K:

- Coagulant like prothrombin,
- Factor VII, IX and X, and
- Circulatory anticoagulant protein.

Vitamin K deficiency.

Effects. In the deficiency of vitamin K prothrombin, time and blood clotting time is prolonged and serious haemorrhages may occur.

Causes. As mentioned above, vitamin K deficiency is unlikely to develop in dietary deficiency alone. Deficiency of vitamin K is seen in following clinical conditions:

1. *Obstructive jaundice.* In this condition, bile salts do not reach the gut and thus vitamin K cannot be absorbed.
2. *Newborn babies* are likely to develop vitamin K deficiency and thus haemorrhagic disorders because gut bacterial flora which synthesizes vitamin K is not developed satisfactorily in the early infancy. Therefore, it is recommended that the newborn babies should be routinely given injection of vitamin K to prevent its deficiency.
3. *Chronic diarrhoea.* The syndrome of vitamin K deficiency has been reported in chronic diarrhoea. The cause may be failure of absorption or an abnormal state of the intestinal bacteria leading to defective synthesis of vitamin K. This syndrome may also occur with defective fat absorption in sprue.
4. *Side effect of antibiotics.* Vitamin K deficiency has also been reported in morbid patients living on glucose–

saline transfusion and receiving heavy amounts of broad spectrum antibiotics particularly *cephalosporin*. Antibiotics kill the bacterial flora of the gut leading to deficient synthesis of vitamin K.

Role of liver.

Liver plays following significant role in the coagulation mechanism:

1. ***Synthesis of procoagulants.*** It is the site of synthesis of factor V, VII, IX, X, prothrombin and fibrinogen.
2. ***Removal of activated procoagulants.*** Liver also removes the activated procoagulants from the blood.
3. ***Synthesis of anticoagulants.*** Liver also synthesizes anticoagulants like heparin, antithrombin III and protein-C.

Liver failure can cause both:

- *Bleeding disorders* due to hypocoagulability of the blood; and
- *Uncontrolled extensive clotting* inside the blood vessels where clotting is not only unwanted, but dangerous as well.

Role of blood vessels.

Role played by endothelium, subendothelial tissue and smooth muscles of the media of the blood vessels in coagulation and haemostasis mechanisms is summarized.

Endothelium.

Endothelium plays both an anticoagulatory as well as a coagulatory role.

Anticoagulatory roles played by endothelium

- It acts as a barrier between the thrombogenic subendothelial tissue and the blood.
- It produces heparin and α_2 macroglobulin which are coagulation inhibitors.

- Smoothness of uninjured endothelial cells prevent platelet aggregation.
- Endothelial cells produce PGI₂ (a prostaglandin), which opposes platelet aggregation.

Roles in clotting mechanism

- *Endothelium secretes von Willebrand's factor (VWF)*. The plasma VWF acts as a connecting bridge between the platelets and the subendothelial tissue (exposed after injury) and thus initiates platelet aggregation and haemostasis.
- *Tissue factor (TF)* is released by endothelial cells following trauma. The TF initiates the process of extrinsic pathway of clotting mechanism.
- *Plasminogen activator* which activates plasminogen to plasmin is also released by endothelial cells.

Subendothelial tissue.

Subendothelial tissue, which chiefly consists of collagen fibres, plays the following roles in coagulation:

- *Platelet aggregation* is initiated when blood comes in contact with the subendothelial collagenous tissue; and
- *Intrinsic coagulation pathway* is initiated when factor XII is activated following contact of blood with subendothelial collagenous tissue.

Vascular smooth muscle.

Smooth muscles of the vascular wall play a role in haemostasis by causing vasoconstriction. Vasoconstriction is initiated by mechanical injury to muscles and is later facilitated by the vasoconstrictors such as serotonin, prostaglandins and noradrenaline released by the platelets which adhere at the site of injury.

Why circulating blood does not clot

We all know that blood circulating in the blood vessels does not clot and that fluidity of the blood is essential for life. By now we have discussed most of the factors responsible for fluidity of the blood. They are summarized below.

1. Velocity of circulation.

Blood is pumped into the vessels and circulated at a constant velocity which contributes to its fluidity. That is why, a decrease in circulation velocity in certain conditions is associated with intravascular clotting.

2. Surface effects of endothelium

- Smoothness of endothelial lining inhibits platelet adhesion and thus prevents initiation of intrinsic clotting mechanism.
- A layer of glycocalyx (mucopolysaccharide) adsorbed to the inner surface of endothelium being negatively charged repels clotting factors (anion proteins) and platelets and thereby prevents clotting.
- Intact endothelium acts as a barrier between the thrombogenic subendothelial collagenous tissue and the blood.
- Endothelial cells also produce thrombin-binding protein (thrombomodulin), which slows the process of clotting by removing thrombin (see page 216)

3. Circulatory anticoagulants

or the so-called natural anticoagulants present in the blood, which prevent clotting, are:

- Heparin,
- Antithrombin III,
- Alpha 2 macroglobulin and
- Protein-C (for details see page 216).

4. Fibrinolytic mechanism.

Protein-C is a naturally occurring anticoagulant which inactivates factor V and VIII, and also inactivates an inhibitor of tissue plasminogen activator increasing the formation of plasmin which acts fibrinolytic.

- Further, whenever there is trauma, along with activation of clotting mechanism, the fibrinolytic system is also activated, which prevents spread of intravascular clotting.

5. Removal of activated clotting factors.

Liver plays a role in preventing the intravascular clotting by removing activated clotting factors in the event of onset of spontaneous clot formation.

Thrombosis

We have studied that physiologically under normal conditions the circulating blood does not clot and that clotting of blood occurs only extravascularly when a vessel has been injured and bleeding has occurred. However, under certain pathological conditions, intravascular clotting may occur. The intravascular clotting is called *thrombosis*, and the clot so formed is called thrombus. Thus, *thrombus* may be defined as a solid mass formed in the living heart or blood vessels from the constituents of blood. Intravascular thrombosis can be distinguished from extravascular clotting or clotting in wounds, and also from clotting which occurs in blood vessels after death.

Predisposing factors.

Virchow described three primary events which predispose to thrombus formation (*Virchow's triad*). These are:

1. Endothelial injury.

We have studied how an intact endothelium prevents coagulation (page 214). Endothelial injury may occur in many conditions, of which a few important ones are: ulcerated plaques in advanced atherosclerosis, haemodynamic stress in hypertension, arterial disease, diabetes mellitus and hypercholesterolaemia.

2. Alterations in flow of blood.

Both, in turbulence as well as stasis of blood, normal axial flow of blood is disturbed and platelets come in contact with endothelium initiating thrombus formation. Stasis of blood is commonly associated with venous thrombosis especially in leg veins after major operations on the abdomen (postoperative thrombosis), or otherwise bedridden patients in which muscular contraction in legs and trunk (responsible for normal venous blood flow) is decreased.

3. Hypercoagulability of blood

which predisposes to thrombosis may occur due to:

- Increase in coagulation factors such as fibrinogen, prothrombin, factors VIa, VIIa and Xa.
- Increase in platelet count and their adhesiveness, and
- Decreased levels of coagulation inhibitors such as antithrombin III and fibrinogen degradation products.

Sequence of events in thrombogenesis.

Sequence of events which lead on the formation of a thrombus are:

- **Adherence of platelets**

to endothelium (in the individuals having any of the above listed predisposing factors) is the first step in thrombogenesis. The mass of platelets grows by adhesion of other platelets as they pass by. The laminae of platelets (which fuse together and lose their identity) stand out as layers running transversely to the blood stream. Passing leucocytes adhere to their borders (like flies on sheets of sticky flypaper).

- **Activation of coagulation system.**

The platelets liberate thromboplastin and activate coagulation system; thus filaments of fibrin spread out from them on all sides. Fibrin filaments from one lamellae meet with filaments from the next lamellae. The lamellae of platelets are thus braced together by fibrin filaments.

- **Entanglement of red blood cells and white blood cells**

then occurs in the fibrin network, and finally a solid mass of a peculiarly constructed clot called thrombus is formed. The red cells disintegrate and lose their haemoglobin; the initial red thrombus as it ages becomes yellowish-grey; but newly formed thrombi added to it will be red.

Types of thrombi.

Grossly, there are three types of thrombi:

- **Red thrombi.**

Venous thrombi are usually red and occlusive. Red thrombi are soft, red and gelatinous. Red thrombi closely resemble blood clots in vitro.

- **White thrombi.**

Arterial thrombi usually tend to be white and mural, whereas white

thrombi are pale and firm.

- **Mixed or laminated thrombi**

are also common and consist of alternate white and red layers called *lines of Zahn*.

Effects of thrombi.

Intravascular thrombi may cause variable effects (may be even life-threatening) depending upon their size and site. Thrombi cause harmful effects by one of the following mechanisms:

1. Ischaemia and infarction.

Thrombi may decrease or stop the blood supply to part of an organ and cause ischaemia, which may subsequently result in infarction. *Arterial thrombi* usually produce ischaemia and infarction. For example, thrombus formation in coronary arteries may cause myocardial ischaemia and infarction.

2. Thromboembolism.

The thrombus or its part may get dislodged and be carried along in the blood stream as *embolus* to lodge in a distant vessel. Cardiac and venous thrombi produce emboli more frequently than arterial thrombi. Examples of emboli formation are:

- *Pulmonary embolism*, i.e. blockage of pulmonary artery may be caused by an embolus arising from the calf veins.
- *Cerebral embolism*, i.e. blockage of cerebral artery may be caused by an embolus arising from the heart or carotid artery.

Prevention of thrombi.

Formation and/or extension of a thrombus can be prevented by administration of:

- *Drugs which decrease platelet adhesiveness* such as aspirin, dextran or dipyridamole, and
- *Anticoagulants* such as low doses of heparin and dicoumarol
- *Intermittent compression* or electrical stimulation of the calf muscles is necessary in addition to above drugs for preventing postoperative

venous thrombosis.

Antihaemostatic mechanisms

The factors which balance the tendency of the blood to clot in vivo constitute the *antithrombotic factors*. These can be grouped as:

- Factors preventing platelet aggregation,
- Factors preventing coagulation (circulatory anticoagulants) and
- Factors causing fibrinolysis (fibrinolytic mechanism).

A. Factors preventing platelet aggregation

Prostacyclin.

Prostacyclin is an endogenous factor which prevents platelet aggregation by inhibiting the thromboxane A₂ formation (which promotes platelet aggregation). Normally, there is a delicate balance between thromboxane A₂ and prostacyclin, which keeps the platelet plug localized, i.e. prevents intravascular spread of plug. For details see page 799

Note. The drug *aspirin* also inhibits the formation of thromboxane A₂ and thus can prevent platelet plug formation. This makes aspirin a valuable drug for the prevention of thrombosis in patients prone to myocardial infarction and stroke.

B. Circulatory anticoagulants

The natural anticoagulants circulating in the blood constitute the anticoagulant mechanism of the body. These include:

- Heparin,
- Antithrombin III or heparin cofactor II, and
- Protein-C.

1. Heparin.

Heparin is a powerful, naturally acting anticoagulant since it was first isolated from the liver, and so it is named heparin (hepar = liver). However, it is also present in many other organs. It is a polysaccharide

(glycosaminoglycan) containing many sulphate groups. Its molecular weight is 15,000–18,000 Da.

- **Secretion.**

Heparin is secreted by the basophils and mast *cells* (present in various tissues such as liver, lungs and tissues rich in connective tissue).

- **Destruction.**

Heparin is destroyed by the enzyme *heparinase* present in the liver.

- **Functions.**

Heparin is one of the factors, which maintains fluidity of the circulating blood and prevents spread of intravascular thrombosis postoperatively and after trauma to vessels.

- **Mechanism of action.**

Heparin is present on the luminal surface of vascular endothelium. Heparin by itself has little or no anticoagulant properties, but it acts as cofactor with antithrombin III (antithrombin–heparin cofactor) and increases the effectiveness of antithrombin III by hundredfold for removing thrombin. During clot formation, most of the thrombin formed from prothrombin gets adsorbed onto fibrin threads, heparins thus prevent further excessive spreading of the clot. The remaining thrombin that does not get adsorbed on fibrin, soon combines with antithrombin III and blocks the effect of thrombin on fibrinogen. Therefore, heparin acts as an anticoagulant by the following mechanisms:

- Prevents activation of prothrombin to thrombin.
- Inhibits the action of thrombin on fibrinogen.
- Facilitates the action of antithrombin III, i.e. acts as its cofactor and thereby inhibits the active forms of clotting factors IX, X, XI and XII.

2. Antithrombin III.

Antithrombin III is present in plasma as well as vascular endothelium. It is a protease inhibitor, which inactivates a number of coagulation factors (active forms of IX, X, XI and XII) including thrombin. Its action is greatly facilitated by heparin as mentioned above.

3. Protein C.

Protein C is a plasma protein synthesized in liver. It, along with *thrombomodulin* and protein-S constitute an important negative feedback pathway that keeps the coagulatory process under control. The steps of protein-C pathway are given in Fig 3.5-7.

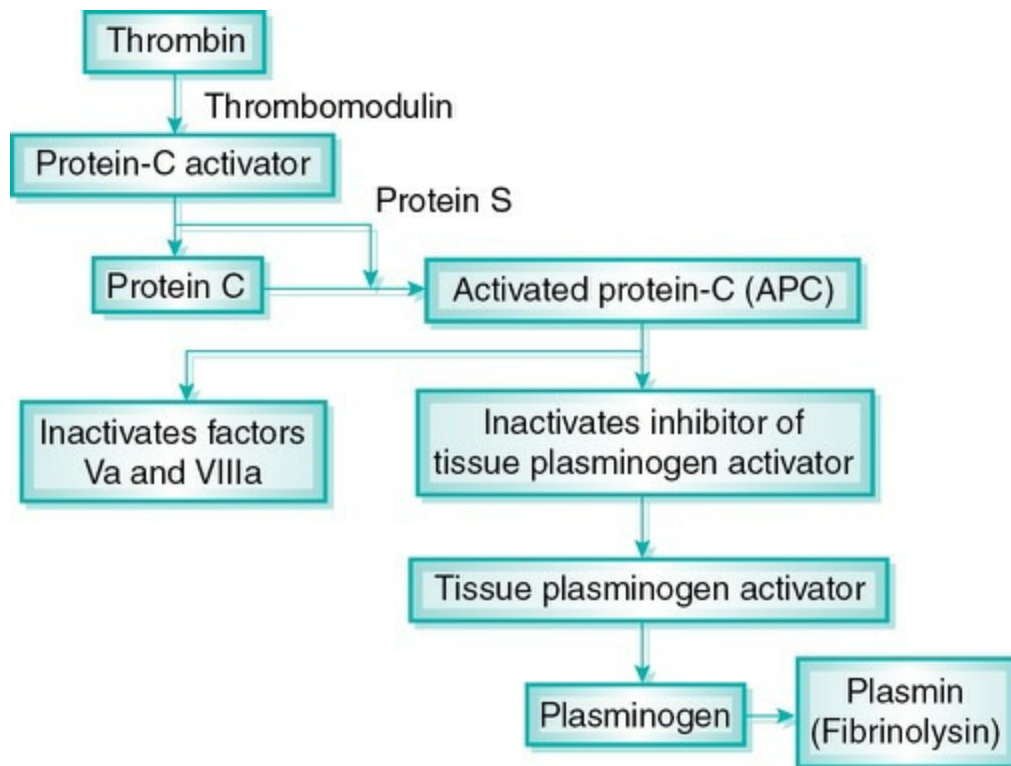

FIGURE 3.5-7 Steps of protein C pathway in inhibiting coagulation and promoting fibrinolysis.

- **Thrombomodulin**

is a thrombin-binding protein produced by all endothelial cells except those in the cerebral microcirculation. It converts thrombin into *protein C* activator.

- **Protein C**

is activated by the protein C activator. For the formation of activated protein C (APC), a cofactor protein-S is required.

- **Activated protein C (APC)**

inactivates factors VIIIa and Va and thus inhibits the clotting mechanism. It also increases fibrinolysis by promoting plasmin formation.

C. Fibrinolytic mechanism

Fibrinolysis refers to the process that brings about the dissolution of fibrin. The important component of the fibrinolytic system is *plasmin* or fibrinolysin, which is present in the blood in an inactive form called *plasminogen* or profibrinolysin. The fibrinolytic or the so-called plasmin system causes lysis of blood clot allowing slow cleaning of extraneous blood clots in the tissue. It also allows reopening of clotted blood vessels. Especially, it removes minute clots which are formed in many tiny peripheral vessels, which would eventually occlude if there was no plasmin system.

Plasminogen.

Plasminogen is a β -globulin produced by the liver. Structurally, human plasminogen consists of a heavy chain of 560 amino acids and a light chain of 241 amino acids. The heavy chain at its amino terminal is folded into five loops, which are held together by disulphide bonds. These loops are called *kringles*. The kringles are the binding sites by which the molecule attaches to fibrin and to other clotting proteins (clotting factors) and also to prothrombin. During clotting or purification of fibrinogen, it is associated closely with the fibrinogen molecule. It is extremely difficult to prepare fibrinogen free of plasminogen. A normal clot usually contains sufficient amounts of plasminogen to ensure clot dissolution if it is activated. Plasminogen is activated by plasminogen activator systems to produce plasmin.

The receptors of plasminogen are located mainly on the surface of endothelial cells and also on different types of cells. When plasminogen binds to its receptors it gets activated

Plasmin.

Plasmin is a powerful protease formed from its precursor, the plasminogen. It lyses fibrin and fibrinogen into fragments known as *fibrin degradation products (FDP)* that inhibit thrombin. Thus, there is a negative feedback which controls plasmin generation. There are two plasminogen activator systems in the body: intrinsic and extrinsic.

Extrinsic plasminogen activator system.

It seems to be the predominant mechanism of plasminogen activation since, in its absence, there is extensive spontaneous fibrin deposition. Wound healing is delayed and there are also defects in growth and fertility; since plasminogen system not only lyses clots but also plays a role in the cell movement and in ovulation.

The extrinsic activator system (Fig 3.5-8) operates through the following agents:

FIGURE 3.5-8 Fibrinolytic mechanism operating through extrinsic plasminogen activator system.

1. Tissue plasminogen activator (TPA)

also called as vascular plasminogen activator is released from the vascular endothelium. The release of TPA from the vessel wall depends upon the release of serotonin from platelets and also release of adrenaline. When there is physical/mental stress or exercise or liberation of adrenaline on sympathetic stimulation, the TPA is released vigorously and thus removes fibrin so that bleeding tends to prolong. In violent deaths (e.g. of a soldier in the battlefield), the blood is fluid and incoagulable due to fibrinolysis. This is due to a large amount of adrenaline released into the blood before death. The adrenaline causes rapid release of TPA from endothelial cells causing massive fibrinolysis. Another factor which regulates release of TPA is fibrin itself (autoinactivation).

Mechanism of action: Tissue plasminogen activator binds to fibrin via lysine-binding sites and activates plasminogen to plasmin.

Note. It is important to note that TPA is now produced by recombinant DNA techniques and is available for clinical use. It lyses clots in the coronary arteries if given to patients soon after the onset of myocardial infarction.

2. Urokinase-type plasminogen activator (UPA).

The UPA is found in a number of tissues including endothelial cells, renal cells and tumour cells. Urokinase is isolated from cultured human kidney cells and induces a systemic lytic state like TPA.

Note: *Streptokinase and staphylokinase* are bacterial enzymes known to produce activation of plasmin-like TPA and UPA. Streptokinase (Streptase) is a protein produced by β -haemolytic streptococci. It forms streptokinase–plasminogen complex which produces a conformational change that exposes active sites on plasminogen molecule and lyse to form plasmin. Therefore, they are used in the treatment of early myocardial infarction to lyse thrombi.

Intrinsic plasminogen activator system.

Contact factors (factor XIIa and kallikrein) that initiate clotting mechanism also stimulate the dissolution of clots by activating plasminogen and constitute the intrinsic plasminogen activator system (Fig 3.5-9).

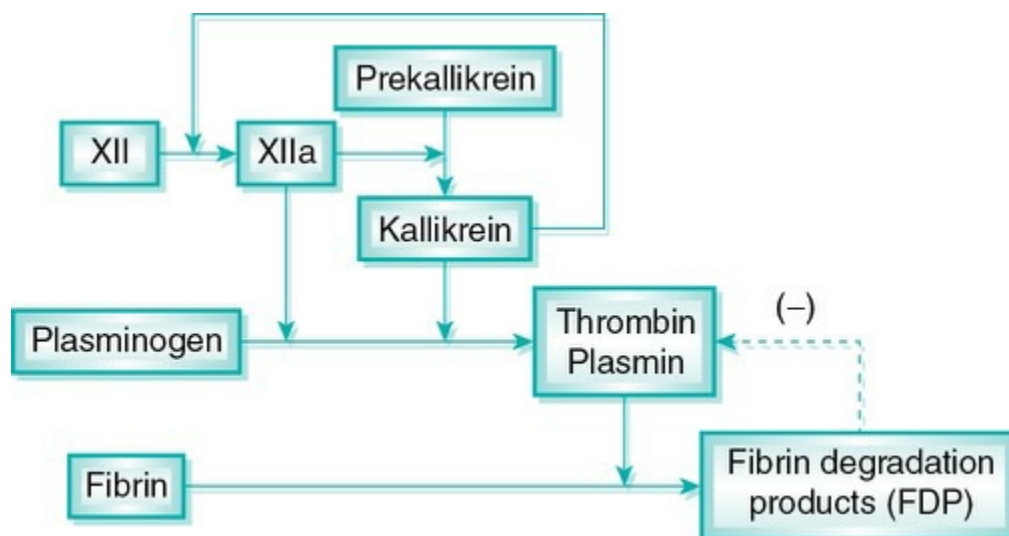

FIGURE 3.5-9 Fibrinolytic mechanism operating through intrinsic plasminogen activator system.

Fibrinolysis inhibitors.

The rate of fibrinolysis is influenced by the promoters (i.e. plasminogen activators) and inhibitors. Fibrinolysis inhibitors are present in plasma, blood cells, tissues and extracellular matrix. These can inhibit plasmin (antiplasmin) or prevent the activation of plasminogen. The various inhibitors are:

- *Antiplasmins* such as α_2 -antiplasmin,
- *Drugs* like aprotinin (a trypsin inhibitor) and epsilon-aminocaproic acid (EACA) inhibit fibrinolysis.

Physiological role of fibrinolysis system.

Plasmin of the fibrinolysis system plays the following physiological roles:

1. Cleaning the minute clots of tiny vessels.

It has been suggested that in physiological conditions the clotting system of the plasma is continually forming small amounts of fibrin, which are deposited to form a thin layer on vascular endothelium and that the fibrinolytic system is constantly in action to prevent excessive fibrin formation.

2. Promote normal healing process.

Lysis of clot formed as a result of tissue injury helps to promote normal healing process.

3. Liquefaction of menstrual clot

in the vagina is carried out by fibrinolytic system.

4. Liquefaction of sperms in the epididymis

when seminal ejaculation does not occur is caused by the fibrinolysin system.

5. Role in inflammatory response.

In addition to its fibrinolytic activity, plasmin can form plasma kinins (bradykinins and kallidin) and thus contribute to the vascular and sensory features (pain) of the inflammatory response to injury.

Anticoagulants

Anticoagulants refer to the substances which delay or prevent the

process of coagulation of blood. In vitro, blood clotting can be prevented by substances which sequester calcium, e.g. sodium citrate or oxalate, sodium edetate (EDTA).

In vivo, the tendency of thrombosis can be inhibited by:

- Antagonizing clotting factors (e.g. heparin),
- By destruction of the key substance fibrinogen or
- By inhibiting the synthesis of factors II, VII, IX and X (vitamin-K antagonists).

Types. Anticoagulants may be divided into endogenous and exogenous anticoagulants.

A. Endogenous anticoagulants.

Endogenous anticoagulants are those which are present inside the blood naturally:

- Heparin,
- Antithrombin III, and
- Protein-C.

For details see page 216.

B. Exogenous anticoagulants.

Exogenous anticoagulants are administered from outside or are used in vitro. These include:

- Heparin and its derivatives,
- Calcium sequesters,
- Vitamin K antagonist and
- Defibrination substances.

1. Heparin.

Heparin, a naturally acting anticoagulant can also be synthesized. It inhibits blood coagulation both in vivo and in vitro (see page 216). For

commercial use, heparin is extracted from certain animal tissue, and is prepared in pure form. Synthesized form has longer life; therefore, its action lasts for 4–5 h. It mainly inhibits activated factors of intrinsic and common pathway including thrombin, Xa and IXa. This effect results in prolongation of platelet thromboplastin time (PTT) and thrombin time (TT). See page 224.

Clinical use: Due to its rapid action heparin can be used:

- To treat thrombosis and pulmonary emboli.
- Initial management of patient with unstable angina, acute myocardial infarction (MI) and during cardiac bypass surgery.
- In selected patients with disseminated intravascular coagulation (DIC).

Note: Protamine. The basic protein is used as an antidote to neutralize the effect of heparin, because it forms an irreversible complex with heparin.

- *Danaparoid* is a mixture of nonheparin glycosamine glycan isolated from porcine intestinal mucosa cells (84% heparin, 12% dermatan sulphate and 4% chondroitin sulphate). It mainly causes inhibition of factor Xa by antithrombin, but does not prolong PTT.
- *Lepirudin* is a recombinant derivative of hirudin present in salivary gland secretion of medicinal leech. It is a direct inhibitor of thrombin.

2. Calcium sequesters or decalcifying agents.

In vitro, blood clotting can be prevented by substances which sequester (remove) calcium from the blood. These include two types of agents:

- Substances which form insoluble salts with calcium such as sodium citrate and sodium oxalate, and
- Calcium chelators which bind calcium such as ethylenediaminetetraacetic acid (EDTA).

3. Vitamin K antagonists.

These are used orally and thus can prevent coagulation in vivo effectively. These agents occupy vitamin K receptor sites in the liver and

prevent vitamin K from carrying out its normal physiological function, hence the name vitamin K antagonists. Thus, these substances inhibit synthesis of vitamin K-dependent factors, i.e. factors VII, IX and X. These include coumarin derivatives (e.g. dicoumarol), warfarin, phenindione and nicoumalone.

i. *Dicoumarol* is the first original oral anticoagulant isolated for clinical use, but because of its slow and erratic absorption, it is seldom used.

ii. *Warfarin*. For synthesis of vitamin K-dependent coagulation factors, vitamin K acts as cofactor for formation of γ carboxyglutamic acid residues on the coagulation factors. The enzyme γ -glutamyl carboxylase and epoxide reductase are responsible for formation and metabolism of vitamin K. Warfarin acts by inhibiting enzyme epoxide reductase complex-1 (VKOR-1). This enzyme converts inactive (oxidized) form of vitamin K into active (reduced) form (Fig 3.5-10). The anticoagulant function of warfarin begins after 24 h and lasts longer.

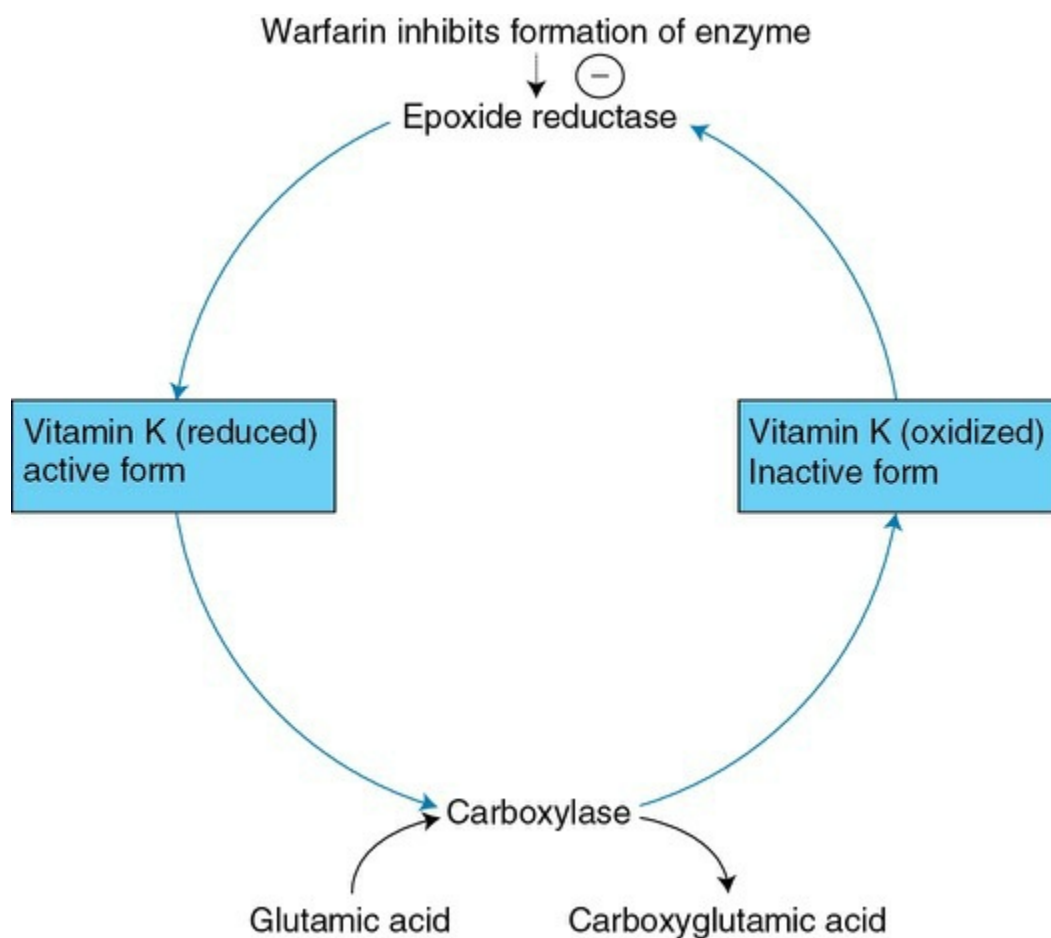

FIGURE 3.5-10 Vitamin K cycle.

4. Thrombolytic drugs

include tissue plasminogen activator (TPA), streptokinase and urokinase. For details see page 217.

5. Antiplatelet drugs

like aspirin prevent platelet plug formation (For details see page 209).

6. Defibrination substances.

Defibrination substances are those which cause destruction of fibrinogen. These include:

- *Malaysian pit viper venom*. It is a type of snake venom which in vivo acts as anticoagulant by causing defibrination and also by stimulating the fibrinolytic system. In vitro, it has a direct anticoagulant effect on fibrinogen by forming imperfect fibrin polymer.
- *Arvin or Ancord*. It is a purified preparation of snake venom. It is glycoprotein in nature and is administered by injection. It acts as an anticoagulant by causing defibrination and thus producing fibrinogenpenia.

7. Cold.

Keeping blood cold (at 5–10°C) can retard the process of coagulation but cannot absolutely prevent it. Because of this reason, blood is stored in blood banks at low temperature but some anticoagulant agent is always used. Further, it looks paradoxical that whenever bleeding occurs, ice is applied to arrest the haemorrhage (while cold delays coagulation); in fact, when ice is applied on the surface it prevents bleeding by inducing reflex vasoconstriction.

Bleeding disorders

Bleeding disorders are characterized by spontaneous escape of blood from blood vessels (in the tissues, inside the body cavities or on few surfaces like (skin and mucous membrane) or persistent and/or excessive bleeding following minor injuries like tooth extraction, etc.

Classification of bleeding disorders

I. Platelet disorders

A. *Deficiency of blood platelets. Thrombocytopenic purpura.*

1. Essential or idiopathic thrombocytopenic purpura and
2. Secondary thrombocytopenic purpura.

B. *Functional disorder of platelets*

II. Coagulation disorder or defective coagulation mechanism

1. Deficiency of clotting factors (see [Table 3.5-1](#)),
2. Vitamin K deficiency (see page 213),
3. Anticoagulant overdose and
4. Disseminated intravascular clotting (DIC).

TABLE 3.5-1
Deficiency of Clotting Factors

Deficiency of factor	Clinical syndrome	Cause
• Factor I	Fibrinogenopenia Afibrinogenaemia	Depletion during pregnancy with premature separation of placenta Congenital (rare)
• Factor II	Hypoprothrombinaemia (Haemorrhagic tendency in liver disease)	Decreased hepatic synthesis, usually secondary to vitamin K deficiency
• Factor V	Parahaemophilia	Congenital
• Factor VII	Hypoconvertinaemia	Congenital
• Factor VIII	Haemophilia A or classical haemophilia	Congenital defect due to abnormal gene on X chromosome
• Factor IX	Haemophilia B or Christmas disease	Congenital
• Factor X	Stuart–Prower factor deficiency	Congenital
• Factor XI	PTA deficiency	Congenital
• Factor XII	Hageman trait (does not produce bleeding)	Congenital
• Von Willebrand's factor	Von Willebrand's disease	Congenital

III. Vascular disorders. damage of capillary endothelium (nonthrombocytopenic purpura)

- Due to infection by bacteria and their toxins,
- Due to toxic effects of drugs and chemicals,
- Due to avitaminosis C,
- Allergic purpura and
- Connective tissue diseases.

Only a few important bleeding disorders are described briefly.

Purpura

Purpura is a group of bleeding disorder occurring due to various causes. The term purpura is derived from purple-coloured petechial haemorrhages and bruises in the skin. The blood that leaks out changes colour from red to blue to dark blue and green over a period of time.

Causes and types of purpura

I. Platelet disorders.

Platelets play an important role in haemostasis and coagulation (see functions of platelets page 206); therefore, platelet disorders are associated with bleeding disorders. Platelet disorders include:

1. Deficiency of platelets

(thrombocytopenic purpura). Normal platelet count ranges from 1.5 to 4.5 lakh/mm³ average, count of 2.5 lakh/ μ L. Decrease in the platelet count below 1.5 lakh/ μ L is called thrombocytopenia. Thrombocytopenic purpura may be:

- *Primary thrombocytopenic purpura* (idiopathic, cause not known). In many of the idiopathic cases, antibodies develop against platelets (immune thrombocytopenic purpura, ITP).
- *Secondary causes of platelet deficiency* (secondary thrombocytopenic purpura) are:

- Bone-marrow depression due to effects of various cytotoxic drugs. Whole-body irradiation and hypoplastic and aplastic anaemia.
- Leukaemia and secondary deposits of malignancies in the bone marrow,
- Acute septicaemia, toxemia, uraemia, and
- Hypersplenism.

<i>Relation between platelet count and bleeding is as follows:</i>	
• Above 100,000/ μ L	No clinical symptoms; bleeding is rare.
• From 50,000–100,000/ μ L	Bleeding may occur after major surgery.
• From 20,000–50,000/ μ L	Bleeding occurs with minor trauma in everyday life.
• Below 20,000/ μ L	Spontaneous haemorrhage in urinary tract, GI tract, nosebleeds, etc.
• At very low counts	Fatal haemorrhage may occur in the brain.

Treatment

- In thrombocytopenic purpura, bleeding can be effectively stopped for few days by transfusing either fresh blood or platelets only.
- Splenectomy is also helpful because the spleen removes large numbers of platelets from the blood.

2. Functional disorders of platelets

(thrombocytopenic purpura). Functional disorders of platelets (defects in platelet adhesion or aggregation) are characterized by prolonged bleeding time with normal platelet counts. Functional disorders of platelets include:

- ***Drug-induced defects*** occur with aspirin, large doses of penicillin and other drugs.
- ***Von Willebrand's disease***. It is inherited as an autosomal dominant trait. This condition is associated with a deficiency of factor VIII-related antigen (VIII R:Ag) also called as von Willebrand factor (VWF).

This factor acts as a carrier of factor VIII, so its deficiency results in diminished adherence of platelets to collagen fibres in a damaged vessel.

Treatment

Von Willebrand disease can be treated by injecting 1-deamino-8D arginine vasopressin (DDAVP) or desmopressin intravenously. DDAVP releases VWF and Factor VIII from endothelial stores.

Antifibrinolytic agents like epsilon-aminocaproic acid (EACA) or Tranexamic acid is an important therapy either alone or with DDAVP, particularly during dental procedures (e.g. tooth extraction).

- *Other diseases* in which platelet functions become defective are uraemia, cirrhosis and leukaemia.

II. Vascular disorders.

Bleeding tendencies seen in patients with vascular disorders (damage to capillary endothelium) are referred to as *nonthrombocytopenic purpura*. In all cases of purpura due to vessel wall defects, the platelet counts are normal, but bleeding time is prolonged and capillary fragility test is positive.

Causes of nonthrombocytopenic purpura

1. *Drug-induced damage to capillary wall* is seen in patients with prolonged treatment with corticosteroids, penicillin, sulpha drugs and aspirin.
2. *Deficiency of vitamin C (scurvy)* causes failure of collagen formation and associated with impaired hydroxyproline synthesis. Petechiae and bleeding from gums occur due to decreased intercellular substance and less stable capillary basement membrane.
3. *Allergic purpura* occurs due to damage to capillary walls by antibodies.

4. **Infections** such as typhus, bacterial endocarditis and haemolytic streptococcus may be associated with capillary wall damage.
5. **Senile purpura** refers to purpuric haemorrhagic spots seen on the back of hands and forearms due to prolonged pressure or mild trauma. Small vessels in old age rupture due to increased mobility of skin resulting from loss of elastic and connective tissues around the blood vessels.
6. **Connective tissue diseases** are also sometimes associated with damage to capillary walls and purpuric haemorrhages.

Haemophilia

Haemophilia is the name given to a group of disorders occurring due to *hereditary deficiency of coagulation* and characterized by bleeding tendencies hardly distinguishable from one another, associated with increased clotting time (CT). The haemophilia includes:

- Haemophilia A (83% cases),
- Haemophilia B (15% cases) and
- Haemophilia C (2% cases).

1. Haemophilia A

- Haemophilia A, also known as true or classical haemophilia occurs due to *deficiency of factor VIII, i.e. antihemophilic globulin (AHG)*.
- It is the most common hereditary coagulation disorder. Being a sex linked recessive disease, it affects males exclusively and females act as carriers (Fig 3.5-11). The carrier female shows no symptoms due to the presence of the X chromosome, which is dominant over recessive chromosome (X*) X. Only mating of a haemophilic male with a carrier female will produce a haemophilic female, which is a very rare occurrence.

The majority of patients with haemophilia A have blood levels of factor VIII below 5%, and so usually bleed severely on minor trauma.

Relationships of levels of factor VIII with status of haemostasis are as:

Factor VIII activity	Status of haemostasis
>50%	Normal haemostasis
25–50%	Excessive bleeding after

	Severe trauma
5-25%	Excessive bleeding after
	Minor trauma
1-5%	Severe bleeding on minor trauma
<1%	Spontaneous bleeding

- Clinical features (bleeding tendency) are not apparent since birth but generally start early in life (within first three years).
- The haemophilics have the tendency to bleed into soft tissues, muscles, joints, GI tract, urinary tract and from the nose.
- Joints of haemophilic patients become severely damaged due to repeated joint haemorrhage.
- Haemorrhage into the soft tissue around the floor of the mouth may cause respiratory obstruction and death by suffocation.
- Haemophilics have normal bleeding time, platelet count and prothrombin time. Coagulation time (CT) is increased and typically, the patients have prolonged PTT.
- Hemophilia A can be treated by transfusion of:
 - Repeated small fresh blood, within 30 min of collection from the donor (because factor VIII is lost rapidly on storage), or
 - Fresh plasma or
 - Factor VIII concentrate commercially available as cryoprecipitated antihemophilic factor for intravenous infusion.

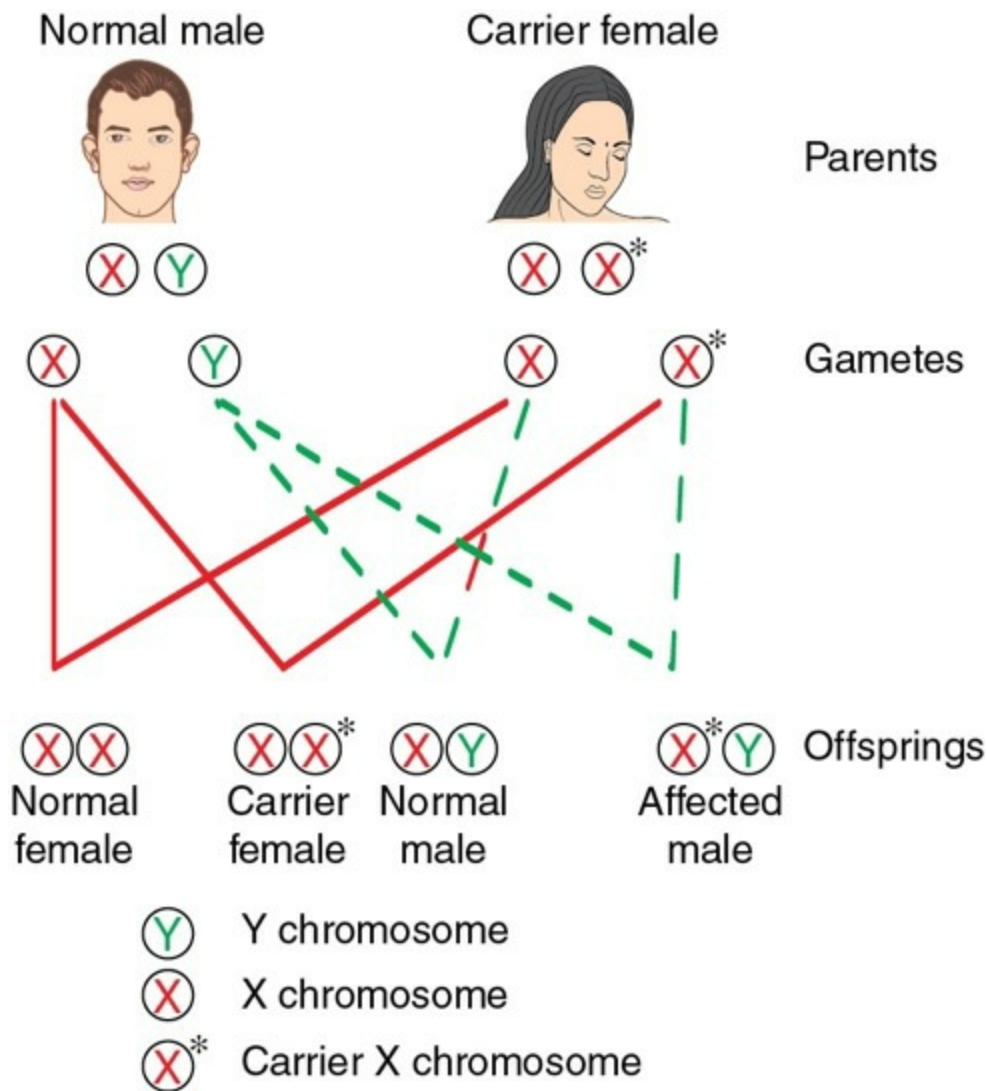

FIGURE 3.5.11 Sex-linked inheritance of haemophilia A.

2. Haemophilia B

- Haemophilia B, also known as *Christmas disease*, occurs due to deficiency of factor IX (Christmas factor or plasma thromboplastin component (PTC)). It was discovered in a family with the surname Christmas.
- Like haemophilia A, haemophilia B is also a recessive X-linked disease that occurs in males and is transmitted by females.
- Since factor IX is more stable on storage, it is not necessary to use fresh blood for treatment.

3. Haemophilia C

- Haemophilia C refers to a deficiency of PTA (factor XI).
- It is inherited as *Mendelian dominant* and affects both males and females.
- This condition may occur without bleeding tendency.
- Clotting time in this condition may be prolonged or may be within normal limits.

Disseminated intravascular coagulation

- Disseminated intravascular coagulation (DIC), as the name indicates, refers to the condition when clotting mechanism becomes activated in widespread areas of the circulation (Fig 3.5-12).
- Due to widespread intravascular coagulation, there occurs plugging of small vessels with clots resulting in decreased O₂ and nutrient supply to its tissues causing multiple organ damage.
- The widespread intravascular coagulation uses up most of the coagulation factors and platelets present in the blood resulting in failure of haemostatic mechanism. The patient thus develops bleeding tendencies and hence, the condition is also called *consumption coagulopathy*.
- The fibrin degradation products (FDP) that are formed as a result of fibrinolysis of the clot have antihemostatic effect and further aggravate the bleeding tendency.
- DIC, is thus a grave condition. It can result as a consequence of an adverse condition in which there occur large amounts of traumatized or dying tissue in the body, which release thromboplastin, or toxins accumulate in the body, which stimulate many coagulation factors. DIC is associated with conditions like septic shock, metastatic malignancies, prolonged postpartum haemorrhage, snake bite, etc.

Treatment: The main basis of DIC treatment is:

- To control or elimination of underlying primary cause.
- Management of hemorrhagic symptoms due to thrombocytopenia by

platelet concentrate (dose 1–2U/kg body weight)

- Drugs to control coagulation; such as heparin, antithrombin III or fibrinolytic agents (EACA or tranexamic acid in low doses)

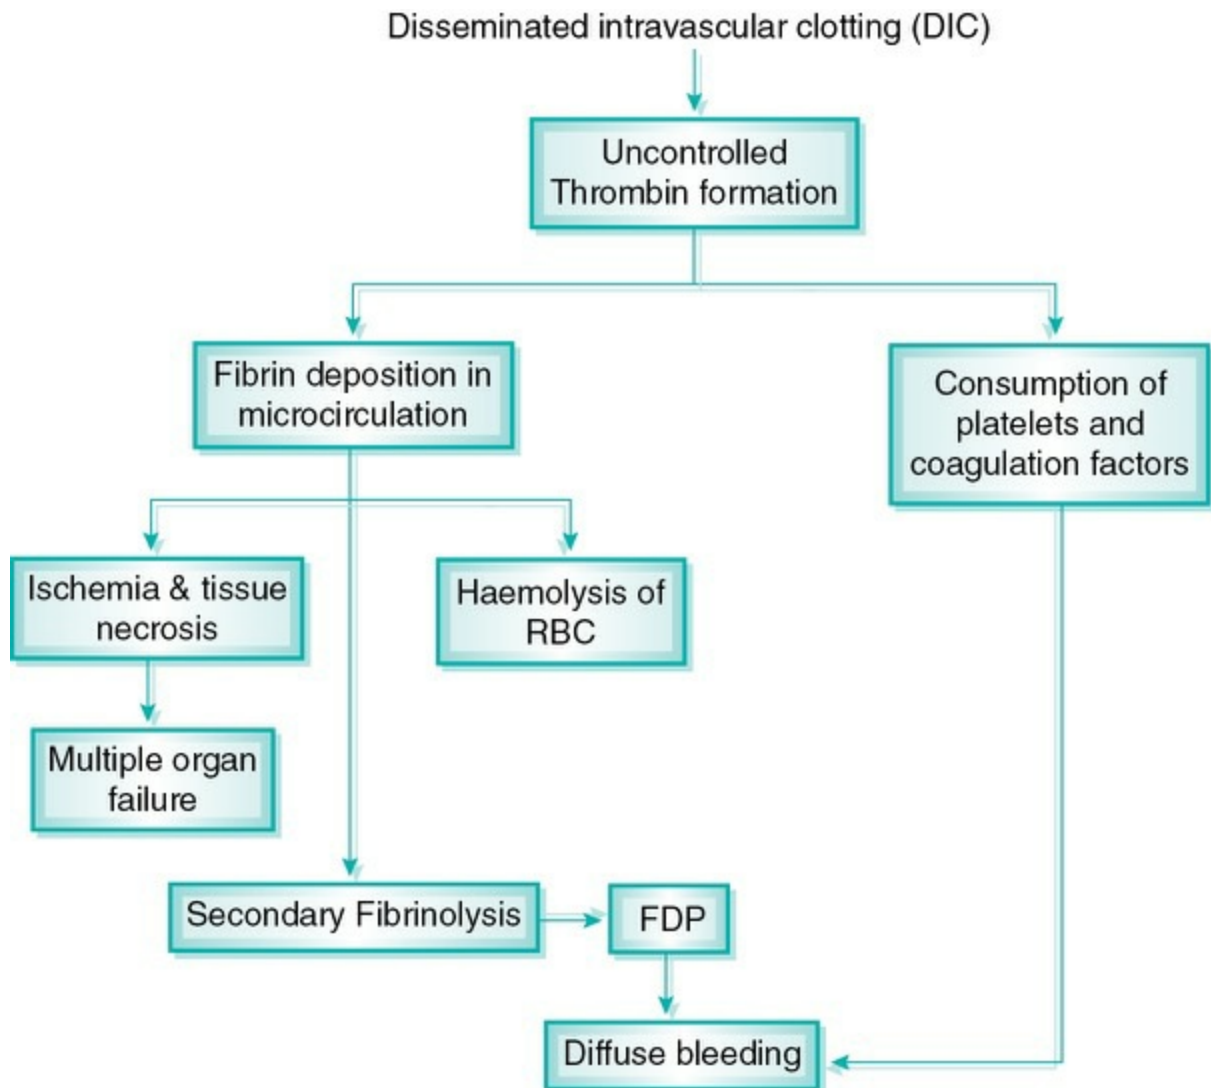

FIGURE 3.5-12 Interaction between coagulation and fibrinolytic pathway results in thrombosis and bleeding in disseminated intravascular coagulation.

Laboratory tests in bleeding disorders

Bleeding time (BT)

Definition.

Bleeding occurs from the skin when it is pricked with a needle, which normally stops of its own within a few minutes. The time lapse between

the skin prick and the arrest of bleeding is called *bleeding time* (BT).

Procedure.

(i) *Duke's method*. To estimate BT, the tip of a finger or ear lobe is pricked with a sharp needle. A stopwatch is run and blood is wiped away with a clean filter paper every 15 s till bleeding stops. The time taken for the arrest of bleeding is BT.

Normal BT

by Duke's method varies from 1 to 6 min. Normal BT indicates that platelets count and their function, as well as health of capillaries is normal.

(ii) *Ivy's method*. In this method, a pressure of 40 mmHg is applied to the upper arm with a blood pressure cuff and then a skin deep prick is made on the anterior surface of the forearm. Rest of procedure is same as above. *Normal BT by Ivy's method is 3–6 min at 37°C.*

Note: Bleeding time depends on the depth of the prick. Specified depth of prick in Duke's method for ear lobe is 4 mm and for IVY method for forearm is 2.5 mm.

Prolonged BT occurs in purpura, while it is normal in haemophilia.

Important Note

- A clean or straight cut with a blade or knife bleeds longer than an irregular injury. In an irregular cut, bleeding time is less because collagen gets exposed and a rough surface available for platelet aggregation and factor XII can get activated.

Capillary fragility test of hess or tourniquet test

Tourniquet test is performed to assess the mechanical fragility of the capillaries by raising pressure within them. It may demonstrate latent purpura.

Procedure.

A circle of 1-inch diameter is marked on the front of the forearm. Any purple spots present in the circle are marked with blue ink. Then a pressure midway between systolic and diastolic blood pressure is applied on the upper arm for 15 min using the blood pressure cuff.

Appearance of 10 or more new petechiae is a positive test. *Positive tourniquet test* occurs in various types of purpurae and vessel wall defects.

Platelet count

Normal platelet count

varies from 1.5–4.5 lakh/ μL with an average 2.5 lakh/ μL . Platelet count is decreased in primary and secondary thrombocytopenic purpura (pages 207 and 220).

Procedure

(i) *Direct method*. Fresh blood should be diluted in a RBC pipette with Reese-Ekar fluid and the stained platelets should then be counted in a haemocytometer. (ii) *Indirect method*. In this method, platelet count is calculated from the RBC count and platelet:RBC ratio. Normally there is 1 platelet to 16–18 red cells.

Coagulation time (CT)

Definition.

Coagulation time (CT) refers to the time taken by the fresh fluid blood to get coagulated (demonstrated by formation of fibrin threads). It is an insensitive measure in the assessment of coagulation defects and is abnormally prolonged when the coagulation factors are seriously deficient.

Procedure.

(i) *Capillary tube method*. In this method, a capillary tube is filled with fresh blood from the finger prick and 1 cm bits of the tube are broken from one end every 30 s. The end point is reached when fibrin threads span a gap of 5 mm between the broken ends (*rope formation*). Normal CT by capillary method is 3–6 min.

Comments. It is important to note that clotting of blood with this method involves both the intrinsic and extrinsic systems, as there is injury to the blood, as well as to the tissue.

(ii) *Modified Lee–White test tube method* (whole blood coagulation time). Presently, this method is considered the standard method to estimate CT. Principle of this method is to collect blood with a clean nontraumatic venipuncture and put it in an 8 mm diameter test tube at

37°C and see how long it requires to clot. The end point is reached when test tube can be tilted through an angle greater than 90° without spilling the blood. *Normal value of CT* by Lee–White method is 8–12 min for a glass tube and 20–60 min for a siliconized tube. Clotting time is more because siliconized tubes are smooth surfaced, and therefore, activation of factor XII becomes slow or difficult.

Comments. This method tests the intrinsic system of blood clotting as there is no admixture of blood with tissue fluid. Therefore, this method is considered more reliable than the capillary tube method.

Importance of clotting time.

The CT is prolonged in haemophilia and other clotting disorders, because thrombin cannot be normally generated; however, the bleeding time (BT), which reflects vasoconstriction and platelet plug formation independently of clot formation, is normal since CT can increase due to deficiency of any of the factors so it is a nonspecific test. More specific tests include *prothrombin time, partial thromboplastin time, thromboplastin generation test, thrombin time*, etc. Specific tests can pinpoint the particular deficient factor.

- *Physiologically*, clotting time is reduced during menstruation and before and during parturition.
- *Pathologically CT is prolonged in* haemophilia, liver diseases, afibrinogenaemia, Christmas disease, vitamin K deficiency and disseminated intravascular coagulation (DIC).

Prothrombin time (PT)

Procedure.

Quick's one-stage method now is the standard method to measure prothrombin time (PT). In this method, tissue thromboplastin (commercially available) and calcium chloride solution (to provide calcium ion) are added to the oxalated or citrated plasma of the patient; and the mixture is incubated at 37°C. The end point is conversion of fluid plasma into a gel (due to formation of fibrin). Normal PT is 11–16 s.

Plasma from a normal person is used as a control and the result is expressed as prothrombin ratio (PTR). Normal PTR varies from 0.9–1.2.

Note: International normalized ratio. Prothrombin time may vary even in the same individual depending on the difference in the tissue

factor activity and analytical system. International normalized ratio (INR) is devised for standardized measurement of prothrombin time. For each type and batch of tissue factor, the manufacturing company assigns an international sensitivity index (ISI), which indicates the tissue factor activity with the standardized sample. The INR is the ratio of prothrombin time of person to normal control sample raised to the power of ISI:

$$\text{INR} = [\text{PT}_{\text{test}}/\text{PT}_{\text{control}}]^{\text{ISI}}$$

The normal range of INR is 0.9–1.3.

Short prothrombin time or low INR (e.g. 0.5) is mainly determined by prothrombin concentration. The curve relating prothrombin time to prothrombin concentration is used to quantify the concentration of prothrombin in the blood (Fig 3.5-13).

FIGURE 3.5-13 Prothrombin concentration in blood in relation to prothrombin time.

Comments.

Intrinsic system is not involved in this test since plasma does not contain

platelets. Obviously it is extrinsic system which is tested. In this test, calcium nullifies the effect of oxalate or citrate and tissue thromboplastin acts as the prothrombin activator, i.e. it initiates extrinsic pathway. Though originally introduced as a test for prothrombin activity (hence its name), it is also sensitive to deficiency of factor I, V, VII and X.

Importance of PT.

PT is increased in patients on oral anticoagulants, liver failure, vitamin K deficiency, abnormally low fibrinogen concentration, deficiency of factors II, V, VII and X.

- *PT is normal* in haemophilia and Christmas disease.

It is used to monitor patients receiving anticoagulant therapy (e.g. warfarin) to adjust its dose.

Partial thromboplastin time (PTT)

Partial thromboplastin time (PTT), also known as kaolin cephalin clotting time (KCCT), detects coagulation defects too small to lead to prolongation of the whole blood clotting time.

Procedure.

To the oxalated or citrated plasma of the patient are added kaolin (to provide surface contact), cephalin (to provide phospholipids) and calcium chloride (to provide calcium ions), and the mixture is incubated at 37°C. The end point is formation of plasma gel. Normal PTT is about 40 s.

Comments.

Since the mixture so formed lacks tissue thromboplastins, so extrinsic pathway is not involved in this test. Thus, it measures the intrinsic pathway, i.e. factors XII, XI, X, IX, VIII, V, II and I.

Importance of PTT.

It is used to monitor the heparin therapy.

PTT is prolonged in haemophilia, von Willebrand's disease, liver failure, deficiency of contact factor XII, anticoagulant therapy and intravascular clotting.

Thromboplastin generation test (TGT)

This test measures generation of thromboplastin, i.e. the efficiency of a part of the intrinsic mechanism of coagulation. Normal value of TGT is 12 s or less. Prolonged TGT indicates deficiency of factors needed to form prothrombin activator by the intrinsic mechanism, i.e. factor VIII, IX, X and V.

Comments.

From values of prothrombin time (PT) and thromboplastin generation test (TGT), following inferences can be drawn:

- In haemophilia, PT is normal but TGT is prolonged.
- In pure factor VII deficiency, PT is prolonged, but TGT will remain normal.
- In factor X deficiency, both PT and TGT will be abnormal.

Thrombin time (TT)

This test measures the final step in coagulation, i.e. functional fibrinogen available. In this test, thrombin is added to plasma, which will convert fibrinogen present in the plasma to fibrin. Normally, a clot is formed in about 10 s, which is the end point. *TT is prolonged* in hypofibrinogenaemia, dysfibrinogenaemia, DIC and heparin treatment.

Clot retraction test

Clot retraction test measures time needed for contraction of an undisturbed clot. It indicates the function and number of platelets. Normally, clot retraction begins within 2 h and is completed within 24 h.

- *Clot retraction is retarded* in thrombocytopenia.
- Clot is small and soft in thromboasthenia, i.e. functional disturbance of platelets.

3.6

Blood groups and blood transfusion

BLOOD GROUPS

- Introduction
- Classical ABO blood grouping system
 - Agglutinogens
 - Agglutinins
 - Types of ABO blood groups
 - Population distribution
 - Inheritance
 - Determination
- Rh blood grouping system
 - Rh antigen
 - Rh antibodies
 - Inheritance
 - Haemolytic disease of newborn
- Clinical applications of blood groups
- Other Blood Groups

BLOOD TRANSFUSION

- Indications

- Donor and recipient
- Precautions during blood transfusion
- Hazards of blood transfusion
- Autologous blood transfusion
- Storage of blood for transfusion
- Blood components

Blood groups

Introduction

Agglutinogens and agglutinins

- *Agglutinogens* refer to the antigens present on the cell membranes of RBCs. A variety of antigens are present on the cell membrane, but only a few of them are of practical significance.
- *Agglutinins* refer to the antibodies against the agglutinogens. These are present in the plasma.
- *Agglutination* of RBCs can be caused by the antigens present on their cell membrane in the presence of suitable agglutinins (antibodies). That is why, these antigens are called agglutinogens.

Blood grouping systems.

Depending upon the type of agglutinogen present or absent on the red cell membranes, various blood grouping systems are known, which can be classified as:

- *Major blood group systems* are based on the presence of agglutinogens which are widely prevalent in the population and are known to cause the worst transfusion reactions. These include:
 - The classical ABO blood grouping system and
 - Rh (CDE) blood grouping system.

- *Minor blood group systems* are based on the presence of agglutinogens which are found only in a small proportion of the population and occasionally produce mild transfusion reactions. These include:
 - MNS blood group system and
 - P blood group system.
- *Familial blood group systems* are based on the presence of agglutinogens which are found only in a few families. Examples of familial blood group systems are Kell, Duffy, Lutheran, Lewis, Deigo, Kidd and many others.

Note:

From a clinical point of view, only major blood group systems, i.e. classical ABO and Rh (CDE) blood grouping systems are important and so will be discussed in detail.

Landsteiner law.

Karl Landsteiner, in 1900, framed a law in relation to agglutinogens and agglutinins, which states that:

1. *If an agglutinogen is present* on the red cell membrane of an individual, the corresponding agglutinin must be absent in the plasma; and
2. *If an agglutinogen is absent* from the cell membrane of RBCs of an individual, the corresponding agglutinin must be present in the plasma.

It is important to note that:

- The Landsteiner law is applicable to ABO blood group system only and
- The law is not applicable to other blood group systems, because there are no naturally occurring agglutinins in these systems.

Classical ABO blood grouping system

A and B agglutinogens

- The classical ABO blood grouping system is based on the presence of antigens called A and B agglutinogens on the cell membrane of RBCs.
- A and B agglutinogens are complex oligosaccharides differing in their terminal sugars. In antigen A, the terminal sugar is N-acetylgalactosamine while in B antigen, the terminal sugar is galactose. Basically, these antigens are carbohydrates present on the backbone of the cell membrane of RBCs, either as glycosphingolipids or glycoproteins, and are secreted into plasma and body fluids as glycoproteins. H substance is the precursor on which A and B antigens are added, and H substance is formed by addition of fructose to glycoprotein or glycolipid backbone. Then, addition of N-acetyl galactosamine produces A antigen and galactose the B antigen.
- The A and B antigens present on the membranes of RBCs are also present in many other tissues, like salivary glands, pancreas, kidney, liver, lungs and testis, and also in body fluids like saliva, semen and amniotic fluid. The antigens on RBC membrane are glycolipids, while in the tissues and body fluids they are soluble glycoproteins.
- In addition to A and B antigens, H antigen is also present usually in all individuals. H antigen is not antigenic, so there is no corresponding antibody.

Anti-A and anti-B agglutinins

All individuals produce antibodies to ABH carbohydrate antigen that they lack; thus, A blood group individual produces anti-B, 'B' blood group anti-A, 'AB' blood group-neither A nor B and O blood group produces both anti A and B.

- The individuals with rare *Bombay blood group* produce antibodies to H substance as well as to A and B antigens.
- The naturally occurring antibodies are termed as isoagglutinins and demonstrable agglutinins are present in 50% of newborns only that have been filtered across the placenta.

- The specific agglutinins start appearing at 10 days; reach a peak at 10 years and then decline.
- Anti-A (or α) agglutinin and anti-B (or β) agglutinin refer to the antibody, i.e. which reacts with or acts on antigen A, and antigen B, respectively.
- The α and β agglutinins are globulins of the IgM type and *cannot cross the placenta*.
- There are two types of α agglutinins: the α_1 and α proper.
- Presence or absence of a and b agglutinins is determined by Landsteiner law as described above.
- The α and β agglutinins act best at low temperature (5–20°C) and are therefore also called cold antibodies.

However, the production of anti-A and anti-B has been explained by the fact that the blood group substance (antigen) has similarity with substances present in food and bacterial antigens. They enter the body along with food, bacteria and other ways. The bacterial antigens that belong to intestinal flora get absorbed and induce antibody production, because they are recognized as nonself antigens.

Types of ABO blood groups

Depending upon the presence or absence of A and B agglutinogens and α and β agglutinins, there are four types of blood groups.

Blood group A

is characterized by:

- Presence of A agglutinogen and absence of B agglutinogen on the cell membrane of RBCs.
- Presence of anti-B (or β) agglutinin and absence of anti-A (or α) agglutinin from the plasma.
- Group A has two subgroups: A_1 and A_2 . The α_1 -agglutinin agglutinates with subgroup A_1 only, while α -proper agglutinin agglutinates with both A_1 and A_2 subgroups.

Blood group B

is characterized by:

- Presence of B agglutinogen and absence of A agglutinogen on the membrane of RBCs, and
- Presence of anti-A (or α) agglutinin and absence of anti-B (or β) agglutinin from the plasma.

Blood group AB

is characterized by:

- Presence of both A and B agglutinogens on the cell membrane of RBCs, and
- Absence of both anti-A (or α) and anti-B or (β) agglutinins from the plasma.
- Blood group AB has two subgroups, namely A_1B and A_2B .

Blood group O

is characterized by:

- Absence of both A and B agglutinogens on the red cell membrane, and
- Presence of both anti-A and anti-B agglutinins in the plasma.

Population distribution of ABO blood groups (table 3.6-1)

TABLE 3.6-1

Population Distribution of ABO Blood Groups in India vis-à-vis in Britain

Blood group	India (%)	Britain (%)
A	20	42
B	40	09
AB	08	03
O	32	46

Inheritance of ABO blood groups

Agglutinogens A and B

or the nonantigenic substances which determine the blood groups are genetically inherited as Mendelian dominant in the classical Mendelian pattern.

The genes that determine A and B phenotypes are located on chromosome 9P. The enzymes glycosyltransferases are the gene products which confer enzymatic ability for addition of specific antigenic carbohydrates. Therefore, individuals who lack 'A' and 'B' transferases are 'O' type, while those who inherit both 'A' and 'B' are 'AB' type, and

Individuals who lack the H gene (responsible for coding fructose transferase) cannot produce H substance. Such individuals are homozygous for silent h allele (hh) and are known as Bombay phenotype, i.e. (Oh), but are rare. The ABO phenotype and possible genotype have been listed in [Table 3.6-2](#). *If the blood group of the father is B and that of the mother is A, then the blood group of the offspring will be as shown in [Table 3.6-3](#):*

TABLE 3.6-2

The ABO Phenotypes and Possible Genotypes

Phenotype	Genotypes
Blood group A	AA, AO
Blood group B	BB, BO
Blood group AB	AB
Blood group O	OO

TABLE 3.6-3

The Possible Blood Groups (Genotype and Phenotype) of Offspring when the Blood Group of Father is B and That of Mother is A

	Father				Mother				
Phenotype	B				A				
Genotype	BB		BO		AA		AO		
Inherited gene	B	B	B	O	A	A	A	O	
	I	II	III	IV	1	2	3	4	
Offspring	1	2	3	4					
I	AB	AB	AB	BO					Genotype
	AB	AB	AB	B					Phenotype
II	AB	AB	AB	BO					Genotype
	AB	AB	AB	B					Phenotype
III	AB	AB	AB	BO					Genotype
	AB	AB	AB	B					Phenotype
IV	AO	AO	AO	OO					Genotype
	A	A	A	O					Phenotype

The various possibilities of inheritance of antigen A, B or nonantigenic substance O from the mother and father will determine the blood group of the offspring as shown in Table 3.6-4:

TABLE 3.6-4

Possible Blood Groups of Offspring Depending upon the Blood Group of Father and Mother

Mother		Father					
Phenotype →		A	B	AB	O		
↓	Genotype → ↓	AA	AO	BB	BO	AB	OO
A	AA	A, O	AB, B, A, O			B, AB O	B, O
	AO						
B	BB	A, B, AB, O		B, O		A, B, AB	B, O
	BO						
AB	AB	A, B, AB		A, B, AB		A, B, AB	A, B
O	OO	A, O		B, O		A, B	O

• **Agglutinogens A and B first appear in the sixth week of fetal life.**

Their concentration at birth is 1/5th of adult level and it progressively rises during puberty and adolescence.

• **Anti-A (or α) and anti-B (or β) agglutinins**

(specific blood group antibodies) are absent at birth, but they appear 10–

15 days after birth and reach a maximum concentration by the age of 10 years.

- **Origin of agglutinins.**

Agglutinins A and B are of gamma globulins (mainly IgM and IgG types) produced by the bone marrow and lymph nodes. As we know, the antibodies are produced in response to an antigen. In case of ABO blood groups, the antibodies (i.e. agglutinins A or B are produced in persons who do not possess the corresponding antigen A or B on the surface of RBCs. The probable mechanism of appearance of α and β agglutinins is described. Antigens very similar to A and B antigens are commonly present in the intestinal bacteria and foods. When the newborn is exposed to these antigens, these are absorbed into the blood and stimulate the formation of antibodies against the antigens recognized as nonself (i.e. not present in their own body) by the immune system.

Note: The gut of an infant is relatively permeable to larger protein molecules compared with adults; therefore, the bacterial antigens get absorbed intact from the gut and induce antibody production.

- **Agglutinin titre.**

The quantity of agglutinin is practically nil immediately after birth. The titre of agglutinin starts rising after 2 months as the infant begins to produce agglutinins and maximum titre is attained by the age of 8–10 years and then starts declining throughout the life (Fig. 3.6-1). The relative concentration of agglutinins in saliva and semen is 600, amniotic fluid 175, tears 5, urine 3, cerebrospinal fluid 0 and red blood cells 8.32.

FIGURE 3.6-1 Titre of agglutinins with age. The figure indicates the dilution factor before losing its agglutinating potency.

Note. The figures indicate the dilution factor before losing the agglutinating potency.

Determination of ABO blood groups

The ABO blood group of an individual can be determined by mixing one drop of suspension of his/her red cells (in isotonic saline) with a drop each of antiserum A (containing α agglutinins) and antiserum B (containing β agglutinins) separately on a glass slide. The antiserum A will cause agglutination (clumping of RBCs having A antigens and antiserum B will cause agglutination of RBCs having B antigens). The blood group of the individual will be shown by the presence of agglutination with one, both or none of the sera (Table 3.6-5 and Fig. 3.6-2).

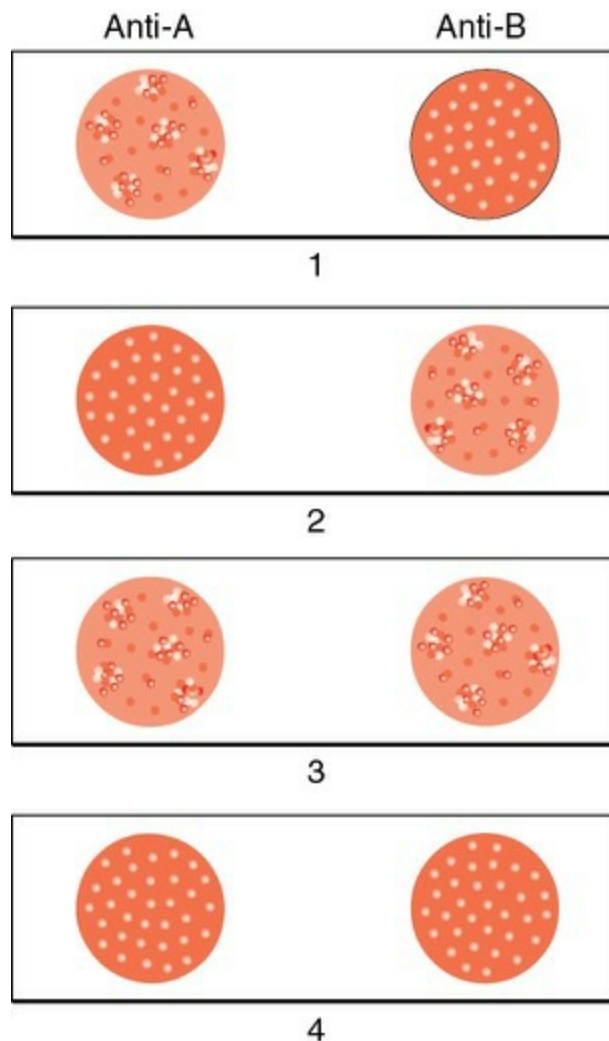

FIGURE 3.6-2 Determination of blood groups—the RBCs showing agglutination with antisera are: **1**, of blood group ‘A’ with antisera A; **2**, of blood group B with antisera B; **3**, of blood group ‘AB’ with antisera A and B (both); and **4**, of blood group ‘O’ with none.

TABLE 3.6-5

Determination of Blood Group of an Individual

Blood group of RBCs suspension	Agglutination with	
	<i>Antiserum A (containing α agglutinins)</i>	<i>Antiserum B (containing β agglutinins)</i>
A	+	–
B	–	+
AB	+	+
O	–	–

Note: The antisera A and B are available commercially. For a quick identification, the anti-A serum is tinted blue and anti-B serum is tinted yellow.

Rh (rhesus) blood grouping system

Rh antigens

- The antigens responsible for this blood grouping system are called Rh antigens or Rh agglutinogens or Rh factor because these were first discovered in the RBCs of rhesus monkeys. Based on the presence of Rh antigen, two types of blood groups are described:
- Rh positive blood group and
- Rh negative blood group.
- The Rh antigens were discovered by Landsteiner and Weiner in 1940. They noticed that when RBCs of the rhesus monkey (monkey with red ischial callosity) were injected into a rabbit, antibodies were formed against these RBCs. When this rabbit's serum was tested against human red cells, agglutination occurred in 85% of the cases, i.e. this person's RBCs contained antigens which reacted with antibodies formed against the rhesus monkey's RBCs. They labelled this antigen as Rh antigen and such persons as Rh +ve. The remaining 15% were labelled as Rh -ve.
- Three types of Rh antigens, viz. C, D and E have been recognized. However, D antigen is the commonest and produces the worst transfusion reactions. Therefore, for all practical purposes, the term Rh antigen refers to D antigen. Consequently, the Rh +ve and Rh -ve individuals are also sometimes called D +ve and D -ve individuals, respectively.
- Rh antigens are integral membrane proteins. These are *not found* in tissues other than RBCs (e.g. ABO antigens, which are also found in some other tissues).

Rh antibodies

- There are no natural antibodies of Rh antigens, while in the ABO system of blood grouping α or β antibodies are always present naturally if the appropriate antigen is absent.

- Rh antibodies (also called anti-D) are produced only when an Rh –ve individual is transfused with Rh +blood or when an Rh –ve mother gives birth to an Rh +ve baby (Rh +ve RBCs of fetus enter into the maternal circulation), Rh antibodies of IgG type and can cross the placenta. Since these react best at body temperature, they are also called warm antibodies.
- Once produced, the Rh antibodies persist in the blood for years and can produce serious reactions during the second transfusion. Because of the same reason during second pregnancy in an Rh –ve mother with Rh +ve fetus, severe incompatibility reactions occur causing the so-called haemolytic disease of newborns (because Rh antibodies present in the mother can cross the placenta).

Inheritance of Rh antigens

- The Rh antigen (D antigen) is inherited as the dominant gene D. When gene D is absent from a chromosome, its place is occupied by the alternate form (allelomorph) called 'd' Rh gene, which is inherited from both the father and the mother.
- An Rh +ve individual may have two genotypes, DD (homozygous) or Dd (heterozygous). Out of 85% Rh +ve individuals, about 35% have DD genotype and 50% have Dd genotype.
- The genotype of Rh –ve individuals is dd.
- Therefore, the genotype (gene composition) of the offspring will be:
- DD when gene D is carried by both sperm and ovum,
- Dd, when one gamete carries D and the other d and
- dd, when both the gametes carry gene d.

Inheritance of Rh antigen is summarized in [Fig. 3.6-3](#).

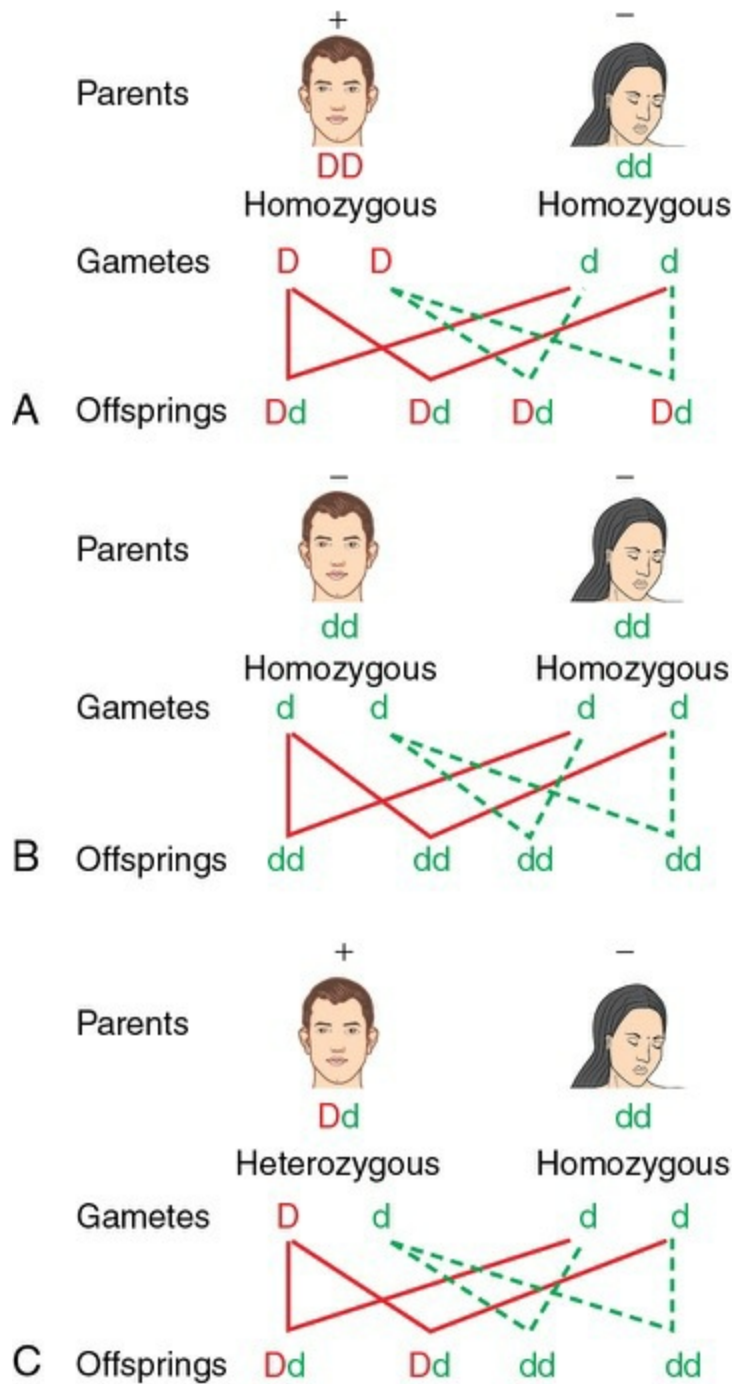

FIGURE 3.6-3 Inheritance of Rh antigen: **A**, when father is homozygous Rh +ve and mother is homozygous Rh -ve; then all the offspring are heterozygous Rh +ve; **B**, when father and mother both are homozygous Rh -ve, then all the offspring are homozygous Rh -ve; and **C**, when father is heterozygous Rh +ve and mother is homozygous Rh -ve, then 50% of offspring are Rh +ve (heterozygous) and other 50% are Rh -ve (homozygous).

Haemolytic disease of newborn

Haemolytic disease of newborn (HDN) occurs as a result of

incompatibility of Rh blood groups between the mother and fetus. The mechanism is described below. It is important to note that incompatibility of ABO blood groups between the mother and fetus is very common, but there is seldom any complication because the α and β agglutinins, i.e. antibodies against antigen A and B are of IgM type, which cannot cross the placental barrier.

Mechanism of haemolytic disease of newborn in Rh incompatibility.

Mechanism of development of haemolytic disease of the newborn can be described under the following steps:

1. Entrance of Rh +ve fetal RBCs into Rh -ve mother's circulation during first pregnancy.

When an Rh -ve mother (genotype dd) bears an Rh +ve child (genotype Dd) with father being Rh +ve (genotype DD or Dd), at the time of delivery the fetal RBCs enter maternal circulation because of severance of umbilical cord. Before delivery, usually the fetal and maternal circulation do not mix. Since the Rh +ve RBCs enter maternal circulation during delivery, so the first child is usually normal.

2. Production of Rh antibodies (anti-D) in mother.

During postpartum period, i.e. within a month after delivery, the mother develops Rh antibodies in her blood. As mentioned earlier, the Rh antibodies are of IgG type and are able to cross the placental barrier. Once formed, the Rh antibodies persist for a long period in the mother's blood.

3. Rh incompatibility reaction during second pregnancy.

When the Rh -ve mother in the second pregnancy also bears an Rh +ve child, the Rh antibodies present in the mother's blood enter the fetal circulation by crossing the placental barrier and cause agglutination of fetal RBCs leading to haemolytic disease of newborn.

Manifestations of haemolytic disease of newborn.

Depending upon the severity the haemolytic disease of newborn may manifest as:

- Erythroblastosis fetalis,

- Icterus gravis neonatorum,
- Kernicterus and
- Hydrops fetalis.

1. *Erythroblastosis fetalis* is characterized by:

- *Erythroblastosis*, i.e. appearance of a large number of erythroblasts in peripheral blood occurs as the haemopoietic tissue of the baby attempts to rapidly replace the haemolysed RBCs.
- *Anaemia* occurs due to excessive haemolysis of RBCs by Rh antibodies. Infant may even die of severe anaemia.

2. *Icterus gravis neonatorum*

- *Jaundice* may occur within 24 h of birth due to excessive formation of bilirubin as a result of excessive haemolysis of RBCs.
- *Liver and spleen* are enlarged.

3. *Kernicterus*. It is a neurological syndrome occurring in newborns with severe haemolysis. The excessive bilirubin formed may enter the brain tissue as the blood–brain barrier is not well developed in infants and cause damage. The bilirubin mostly affects the basal ganglia, producing disturbance of motor activities. It usually develops when the serum bilirubin level exceeds 18 mg/dL.

4. *Hydrops fetalis*, i.e. the fetus is grossly oedematous. It occurs when haemolysis is very severe. Usually there occurs intrauterine death of fetus or if born prematurely or even at term, the infant dies within a few hours.

Prevention and treatment

- **Screening for HDN in pregnancy:**

At 12–16 weeks, every pregnant woman should be tested for ABO and Rh group and testing for red cell alloantibodies that maybe directed against paternal blood group antigens.

- **Anti-D immunoglobulins prophylaxis**

in a mother who is Rh negative

- **Prevention for haemolytic disease of newborn**

during second pregnancy can be prevented by injecting a single dose of Rh antibodies (anti-D) in the form of Rh-immunoglobulin to the mother soon after the first childbirth within 72 h of delivery. These antibodies will destroy the Rh +ve RBCs of the fetus which have gained access to maternal circulation. In this way, active antibodies will not be formed by the mother.

Note: Maternal blood sample is checked for remaining fetal RBCs and extra anti-D should be given if indicated.

Treatment of haemolytic disease of newborn.

Treatment of haemolytic disease of the newborn is replacement of baby's Rh +ve blood with Rh -ve blood. The baby's own blood is removed slowly with the help of a polyethylene catheter into the inferior vena cava along the umbilical vein, and is replaced by an equal amount of Rh -ve blood. This is called exchange transfusion.

About 400 ml of Rh -ve blood is infused in 1.5–2 h. The procedure may be repeated many times during the few weeks of neonatal period to maintain low-levels of bilirubin to prevent Kernicterus.

By this time (6–18 weeks), the infant's own Rh +ve RBCs replace the Rh -ve infused RBCs, the time required for formation of RBCs (erythropoiesis)

Clinical applications of blood grouping

1. In blood transfusion.

Though before blood transfusion cross-matching is always done (for details see page 231); blood grouping, however does help in narrowing down the choice of compatible blood.

2. In preventing haemolytic disease

in newborns due to Rh incompatibility (as discussed above).

3. In paternity disputes.

The ABO, Rh and MNS blood grouping is helpful in settling cases of disputed paternity. Antigens A and B are dominant, whereas O is recessive. It is possible to prove that a person could not have been the father, but not that he was or is father, e.g.

- If the child's blood group is O, whatever the blood group of the mother, a person with blood group AB cannot be the father,
- If the child's blood group is AB, whatever the blood group of the mother, a person with blood group O cannot be the father (Table 3.6-6). The predictive value of such a test is strengthened further if several blood group systems are considered. DNA fingerprinting can prove or disprove fatherhood with 100% certainty.

TABLE 3.6-6

Predictive Blood Groups of Parents in Paternity Disputes

Blood group of child	Parents must have given blood group	Mother's blood group	Father not have been of blood group
O	O+O	No matter which	AB
AB	A+B	No matter which	O
A	A+O or A+A	B or O	B or O
B	B+O or B+B	A or O	A or O

Note. The child's true ABO typing may not be set until 1 year of age.

4. In medicolegal cases.

Any red stain on a clothing may be claimed to be blood by a supposed victim. Therefore, it is first confirmed that it really is blood by preparing hemin crystals from the stain extract. Blood grouping of the extracted sample can then prove or disprove the claims of victim.

5. In knowing susceptibility to diseases.

The incidence of certain diseases is related to blood groups, e.g.

- Individuals with blood group O (nonsecretors) are said to be more susceptible to duodenal ulcer (peptic ulcer) than the individuals with

blood group A and B (secretors).

- Individuals with blood group A are more susceptible to carcinoma of stomach, pancreas and salivary glands.
- To some extent, incidence of diabetes mellitus is more in individuals with blood group A.

Other blood group system

More than 100 blood group systems are recognized, which are composed of more than 500 antigens. These include:

- **Lewis system (Le):** In this system, carbohydrate antigen is not the integral part of the red cell membrane but is adsorbed on RBC membrane from the plasma. The antibodies to Lewis are IgM type and cannot cross the placenta.
- **I system:** In this system, the antigens are oligosaccharides related to H, A, B and Le, but differ in their branching system. The antibodies produced are cold agglutinins, and their binding is low at body temperature.
- **P system** is another blood group in which the carbohydrate antigen is controlled by specific glycotransferases, and its clinical significance is in rare cases.
- **MNSsU system** is regulated by genes located on chromosome 4. M and N are determinants of an RBC membrane protein (i.e., glycoporphin A₁) and Ss are of glycoporphin B.

Blood transfusion

Indications

Blood transfusion is a life-saving measure and should be carried out when it is absolutely essential. Common situations in which blood transfusion is indicated are:

1. Blood loss.

Severe blood loss is the most important indication for blood transfusion.

It may occur in:

- Accidents,
- Major operations,
- Ruptured peptic ulcer,
- Ruptured aortic aneurysm and
- Ruptured ectopic pregnancy.

2. For quick restoration of haemoglobin

in patients with severe anaemia it is required in situations like pregnancy and emergency surgery.

3. Exchange transfusion

is required in haemolytic disease of newborn.

4. Blood diseases

like aplastic anaemia, agranulocytosis, leukaemias, haemophilia, purpurae and clotting defects may require blood transfusion.

5. Acute poisoning,

e.g. carbon monoxide poisoning.

Donor and recipient

Donor

refers to a person who donates the blood and the person who receives blood is a recipient.

Precautions to be taken while selecting a donor are:

- Donor should be healthy, and aged between 18 and 60 years.
- Pregnant and lactating mothers preferably should not donate blood.
- Donor should be screened to exclude the diseases which are spread through blood such as AIDS, viral hepatitis, malaria and syphilis.
- Haemoglobin and PCV of the donor should be within normal range. Its approximate concentration is tested using the Tallquist method or the

specific gravity method.

Universal donor.

Blood of the individuals with blood group O does not contain any agglutinogen. So, when this blood is transfused to a person with any blood group (A, B, AB or O), theoretically its RBCs will not be agglutinated. Because of this fact, an individual with blood group O is called universal donor. However, practically this term is no longer valid, as it ignores the complications produced by existence of the Rh factor and other blood group systems.

Universal recipient.

Blood of an individual with blood group AB does not contain any agglutinins. So, theoretically when such an individual receives blood from an individual with any blood group (A, B, AB or O), there should be no transfusion reaction. Because of this fact, an individual with AB blood group is called universal recipient. However, practically this term is also no more valid because it ignores the complications produced by the existence of Rh factor and other blood group systems.

Precautions to be observed during blood transfusion

1. Absolute indication

should always be there for the transfusion of blood.

2. Cross-matching

should always be done before the blood transfusion. For it blood is collected from donor as well as recipient. Plasma and RBCs are separated in each. The cross-matching involves two steps: major and minor cross-matching.

- **Major cross-matching (direct cross-matching)** will reveal the presence of anti-ABO agglutinin in the serum of recipient and also complete anti-D. Major cross-matching involves mixing of donor's cells with recipient's plasma. This is called major cross-matching because of the fact that when mismatched blood is transfused in a recipient, the donor cells get agglutinated as against their agglutinogen there is sufficiently high concentration of agglutinins in the recipient's plasma.
- **Minor cross-matching.** Involves mixing of recipient's cells with donor's

plasma. This is called a minor cross-match due to the fact that reaction of donor's plasma and recipient's cells usually does not occur or is very mild on giving mismatched blood transfusion because:

- Firstly, the donor's plasma in the transfusion (about 250 ml) is usually so diluted by the much larger volume of recipient's blood (about 5 L) that it rarely causes agglutination even when the titre of agglutinins against the recipient's cell is high and
- Secondly, donor's agglutinins are also neutralized by soluble agglutinogens which are found free in the recipient's body fluid.

Coomb's test detects incomplete anti-D. It is carried out in two stages:

- Direct Coomb's test: Suspension of donor is when red cells in 20% albumin are tested against the recipient's plasma. Direct Coomb's test reveals presence of incomplete antibodies present on the RBCs.
- Indirect Coomb's test: This test is supplemented on washed red blood cells and recipient plasma to detect incomplete anti-D, which are not present on the RBCs.

Important Notes

- *For all practical purposes*, if there is no agglutination in either of the cases (major as well as minor cross-matching) described above, only then the recipient can safely receive donor's blood.
- *In extreme emergencies* like war casualties and massive train accidents, where time does not permit the grouping and cross-matching, O-Rh negative blood (universal donor) may be used.

3. Rh +ve blood should never be transfused to Rh -ve person.

It is particularly a must for females at any age before menopause, because once she is sensitized by the Rh antigen, the anti-D antibodies are formed and she will not be able to bear an Rh +ve fetus. In other

words, Rh + transfusion may make a woman permanently childless.

4. Donor's blood should always be screened

for diseases which are spread through blood such as AIDS, hepatitis B, malaria and syphilis.

5. Blood bag/bottle should be checked

for the name of recipient and blood group on the label before starting the blood transfusion.

6. Blood transfusion should be given at slow rate

(not more than 20 drops/min). If rapid transfusion is given, citrate present in stored blood may cause chelation of calcium ions leading to decreased serum calcium level and tetany.

7. Proper aseptic measures

must be taken during transfusion of blood.

8. Careful watch on recipient's condition

is a must for the first 10–15 min of starting the transfusion, and from time to time, later. The transfusion must be stopped if there is a rapid rise of temperature ($>40^{\circ}\text{C}$), or any other reaction.

Hazards of blood transfusion

1. Mismatched transfusion reactions.

Mismatched transfusion reaction is the most serious and potentially fatal hazard of blood transfusion. It is characterized by:

- *Agglutination* of donor's red blood cells in the recipient's circulation.
- *Tissue ischaemia* occurs due to blockage of certain vessels by agglutinated cells. Soon, the patient complains of violent pain in the back or elsewhere and tightness of chest.
- *Haemolysis* of agglutinated red cells occurs rapidly releasing large amounts of haemoglobin in circulation (haemoglobinaemia)
- *Haemolytic jaundice* may occur due to excessive formation of bilirubin from haemoglobin released by haemolyzed RBCs.

- *Renal vasoconstriction* is caused by toxic substances released from the haemolyzed RBCs.
- *Circulatory shock* occurs due to loss of circulating red cells and release of toxic substances leading to fall in arterial blood pressure and decreased renal blood flow.
- *Haemoglobinuria* occurs when total free haemoglobin becomes more than that can bind with haptoglobin (plasma protein binding haemoglobin). The extra free haemoglobin leaks through glomerular membrane and is passed in urine producing haemoglobinuria.
- *Renal tubular damage*. If urine is acidic and glomerular filtration is slow, the free haemoglobin passing through glomeruli is precipitated in the tubules as acid haematin. This obstructs the lumen of tubules producing renal tubular damage.
- *Acute renal shutdown (anuria)* sets in ultimately due to the combined effects of renal vasoconstriction, circulatory shock, hypotension and renal tubular damage. Acute renal shutdown usually occurs within a few minutes to few hours after transfusion of mismatched blood and continues.
- *Uraemia* (increased nitrogenous substances and potassium in the body) results due to acute renal failure, soon producing coma and death.

2. Circulatory overload

due to hypervolaemia may occur following blood transfusion when the transfusion is rapid, especially in patients with cardiac diseases, chronic anaemia and kidney diseases. The rate of transfusion therefore, should not exceed 1 ml/kg body weight 1 h.

3. Transmission of blood-borne infections

such as AIDS, viral hepatitis, malaria, syphilis, etc. maybe transmitted to recipient from the infected donor.

4. Pyrogenic reaction

characterized by fever and chills may occur probably due to destruction of leucocytes and platelets by antibodies against them.

5. Allergic reactions

such as skin rashes and asthma may occur if donor blood contains substances to which patient is allergic.

6. Hyperkalaemia

may occur after excessive transfusion because K^+ concentration in stored blood is high. Owing to leakage of K^+ from the RBCs into the plasma.

7. Hypocalcaemia

producing tetany may occur following massive transfusion of citrated blood. Following rapid and massive transfusion, the citrate cannot be metabolized fully. The extra citrate chelates calcium ions leading to decreased serum calcium levels and tetany. That is why, intravenous calcium gluconate is given with citrated blood transfusion.

8. Reduced tissue oxygenation

may occur in patients receiving large amounts of transfusion. Red cells in stored blood have very low amounts of 2,3-BPG in them and thus have high affinity for O_2 and consequently tend to give off less O_2 to the tissues. The reduced release of O_2 to tissues can cause serious problems.

9. Haemosiderosis

due to iron overload may occur following repeated transfusions, as in thalassaemic patients. The excessive iron is deposited in liver, heart and endocrine organs and produces damage.

10. Thrombophlebitis

at the venepuncture site may develop if the needle remains in the same site for many hours.

11. Air embolism,

i.e. entry of air into the blood is much less likely to occur because of the use of plastic bags which collapse down as they empty out of blood.

Autologous blood transfusion

Autologous blood transfusion refers to transfusion of an individual's own blood which has been withdrawn and stored. Autologous transfusion is done under following situations:

- For elective surgery,

a self-predonation is a common practice in some hospitals. After starting a course of iron tablets, two units of blood are collected, one 16 days and another 8 days before surgery. This practice avoids the hazards of transfusion of blood donated by some other individual.

- **During surgery,**

the cell-saver machine when used sucks up blood from the wound, recycles it, and returns it to the patient's body.

- **Some sportspersons**

are also known to use autologous transfusion a few days before an important event to enhance their performance.

Storage of blood for transfusion

Some facts about the storage of donated blood are:

- *One unit of blood* (420 ml) can be collected from a donor at a time under all aseptic measures. An individual can safely donate one unit of blood every 6 months. ACD mixture (120 ml) is added to the blood and stored in a sterile container.
- *Contents of ACD mixture* are:
 - Acid citrate (monohydrous), 0.48 g,
 - Trisodium citrate, 1.32 g and
 - Dextrose 1.47 g
 - Distilled water 100 ml.
- *Dextrose (glucose) present in ACD mixture provides* energy for maintenance of sodium–potassium pump activity. The pump activity is essential for maintaining the size of cells. Therefore, if the glucose is not added to stored blood, the RBCs swell up and haemolyze rapidly. Further, glucose liberates lactic acid, which by decreasing the pH helps in survival of RBCs, both in vitro and in vivo.
- *Anticoagulant activity* is provided by the citrates present in the ACD

mixture, which also decreases the pH of blood.

- *Up to 21 days* the blood can be stored under above conditions.
- *The RBCs in the stored blood* swell up due to following changes as a result of decreased cell metabolism in cold storage.
- *Loss of intracellular K^+* , which increases plasma K^+ concentration from 4–5 to 20–30 mEq/L,
- *Increase in intracellular Na^+* from 12 to 30–40 mEq/L
- *Increase in intracellular water content.* Because of the above changes, the RBCs become more spherocytic and their haemoglobin in hypotonic solution increases. Such cells may rupture in vitro even in 0.8% NaCl solution. With reference to Na^+ and K^+ content, volume, shape and saline fragility, the RBCs become normal within 48 h of transfusion.
- *WBCs and platelets in stored blood* are virtually absent after 24 h of storage. Therefore, stored blood is not a suitable medium for transferring WBCs and platelets to a recipient.
- *After transfusion of stored blood*, 80% RBCs survive for 24 h, and thereafter, surviving cells are destroyed at a rate of 1% per day.

Blood components

The whole blood is routinely collected for transfusion. The most donated blood is processed into its various components:

- Packed Red blood Cells (PRBCs)
- Platelets
- Fresh frozen plasma (FFP)

- Cryoprecipitates
- Plasma derivatives
- WBC concentrates

Whole blood: The whole blood provides oxygen-carrying capacity and volume expansion. Therefore, it is an ideal for patients of acute haemorrhage (> 25% of total volume loss). The whole blood is separated into RBCs and platelet-rich plasma by slow centrifugation. The platelet-rich plasma is then centrifuged at high speed to yield one unit platelets and one unit of fresh frozen plasma (FFP). The cryoprecipitate is produced by thawing FFP to precipitate the plasma proteins and then separated by centrifugation.

Apheresis is technology which is used for collection of multiple units of platelets from single donor and for preparation of various plasma derivatives such as albumin, immunoglobulin, antithrombin and coagulation factor concentrates from pooled plasma from many donors.

1. **Packed red blood cells (PRBC)** increase oxygen-carrying capacity. Therefore, used in severely anaemic patients to maintain adequate oxygenation (especially hypoplastic and haemolytic anaemia). The advantage of PRBC over whole blood is:

- a) Circulatory overloading is prevented.
- b) Extra burden of sodium, potassium and other electrolytes on the body system can be prevented.
- c) Plasma can be used for other patients (example: burns).

2. **Platelets** are collected either as pools prepared from five to eight random donors (RDs) or as single donor apheresis (SDAPs). These are transfused in patients with thrombocytopenia to reduce the incidence of bleeding. The threshold for prophylactic platelet concentrate transfusion is 5000/ μ L. Other indications for platelet concentrate transfusion are:

- Prolonged surgical procedure in which patients'

platelets are consumed to stop bleeding.

- Massive blood transfusions of stored blood (platelets and leucocytes have short life).
- Leukaemia and lymphoma, because of less production of platelets.
- Patients receiving chemotherapy/radiotherapy as a treatment for malignancy because anticancer drugs suppress the bone marrow activity.

Note: Grouping and cross-matching should be done because platelet concentrate is not absolutely free from RBCs.

3. *Fresh frozen plasma (FFP)* contains plasma proteins (fibrinogen, albumin, protein C, protein S and antithrombin) and stable factors. Therefore, indications for fresh frozen plasma may be used as plasma for replacement therapy to expand blood volume in conditions where fluid lost from the body (e.g. burns) is massive. The indications for FFP are:

- For correction of coagulation disorders,
- In cases of deficient plasma proteins (hypoalbuminemia),
- Reversal of warfarin effects and
- Treatment for thrombotic–thrombocytopenic purpura.

4. *Cryoprecipitate:* Cryoprecipitate is an ideal source of fibrinogen, factor VIII, and von Willebrand factor (VWF).

5. *Plasma derivatives:* Pooled plasma from multiple donors provide specific protein derivatives:

- Albumin solution is used as a plasma substitute for

replacing fluid volume. Also, it acts as volume expander because it stays longer in the circulation due to its high molecular weight.

- Immunoglobulin preparations are used in:
 - Immunodeficient patients to prevent infections,
 - Anti-D immunoglobulins to prevent the development of endogenous response to Rh antigen (see page 230) and
 - Antisera containing immunoglobulins against Hepatitis B, C, etc.

6. **WBC concentrates:** WBC concentrate is prepared from fresh whole blood by leukapheresis. WBC concentrate is used in patients with granulocytopenia and immunodeficiency (occurs due to chemo and radiotherapy) or any other cause where infection becomes unresponsive to antibiotic therapy.

SECTION 4

Cardiovascular System

OUTLINE

Introduction

4.1. Functional anatomy of heart and physiology of cardiac muscle

4.2. Origin and spread of cardiac impulse and electrocardiography

4.3. Heart as a pump: Cardiac cycle, cardiac output, and venous return

4.4. Dynamics of circulation: Pressure and flow of blood and lymph

4.5. Cardiovascular regulation

4.6. Regional circulation

4.7. Cardiovascular homeostasis in health and disease

Introduction

The cardiovascular system (CVS) consists of the heart and the blood vessels. The *heart* acts as a system of two pumps working in series and forms the driving force for blood flow. The blood vessels that take blood from the heart to various tissues are called *arteries*. The smallest arteries are called *arterioles*. Arterioles open into a network of *capillaries*, which

constitute the microcirculation. The most important function of blood vessels, i.e. the rapid exchange of materials between the blood and extracellular fluid, bathing the tissue cells is served by the capillaries. In other words, capillaries serve as the *exchange region*. In some situations, capillaries are replaced by slightly different vessels called *sinusoids*. Blood from capillaries (or from sinusoids) is collected by small *venules* which join to form *veins*. Veins serve as the blood reservoir and return the collected blood to the heart.

Functions of CVS

Primary functions of the CVS as a transport system are carried out by *convection* (i.e. the mass movement of fluid caused by a difference in pressure between two points). These functions are:

- Distribution of nutrients and oxygen (O₂) to all body cells and
- Collection of waste products and CO₂ from different body cells and to carry them to excretory organs for excretion.

Secondary functions that are subserved by the CVS are:

1. Thermoregulation by control of blood flow to the skin and extremities to enhance or retard heat loss,
2. Distribution of hormones to the target tissues and
3. Delivery of antibodies, platelets and leucocytes to aid body defence mechanism.

Physiology of CVS

Physiology of CVS includes various aspects of physiology of heart as a pump and physiology of two main divisions of blood circulation – the pulmonary and systemic circulation.

- The heart consists of two pumps in series (right and left halves) that are connected by pulmonary and systemic circulation.
- In systemic circulation, the various systemic organs receive blood through parallel distribution channels. The parallel arrangement of

vessels supply the body organs with blood of the same arterial composition (i.e. same O₂ and CO₂ tension, pH, glucose level) and essentially the same arterial pressure.

- Since the pulmonary and systemic circulation divisions are arranged in series, both ventricles must pump the same amount of blood over any significant time period. Such a balanced output is achieved by an intrinsic property of the cardiac muscle known as *Frank–Starling mechanism*.

CHAPTER

4.1

Functional anatomy of heart and physiology of cardiac muscle

FUNCTIONAL ANATOMY OF HEART

- Chambers of heart
- Valves of heart
- Structure of the walls of heart

PHYSIOLOGY OF CARDIAC MUSCLE

- Functional anatomy
 - Structural organization of cardiac muscle
 - Structure of cardiac muscle fibre
 - Sarcotubular system
- Process of excitability and contractility
 - Electrical potentials in cardiac muscle
 - Excitation-contraction coupling phenomenon
 - Process of cardiac muscle contraction
- Properties of cardiac muscle
 - Excitability
 - Contractility

Functional anatomy of heart

The heart is a muscular pump designed to ensure the circulation of blood through the tissues of the body. The human heart weighs approximately 300 g and it consists of two halves, right and left, both structurally and functionally. The right half circulates blood through the lungs for the purpose of oxygenation (i.e. through pulmonary circulation). The left heart circulates blood to tissues of the entire body (i.e. through the systemic circulation).

Chambers of heart

Each half of the heart consists of an inflow chamber called the *atrium* and an outflow chamber called the *ventricle* (Fig. 4.1-1). Thus, there are four chambers in the heart.

FIGURE 4.1-1 Schematic diagram of the heart to show its chambers.

Atria

- *Interatrial septum* separates the right and left atria which are thin-walled chambers.

- **Right atrium** receives deoxygenated blood from tissues of the entire body through the *superior and inferior venae cavae*. This blood passes into the right ventricle through the *right atrioventricular orifice* which is guarded by *tricuspid valve*. The right atrium has got the pacemaker known as *sinoatrial node* that produces cardiac impulses and *atrioventricular (AV) node* that conducts these impulses to the ventricles.
- **Left atrium** receives oxygenated blood from the lungs through the four *pulmonary veins* (two rights and two lefts). This blood passes into left ventricle through the *left AV orifice* which is guarded by the mitral valve.

Ventricles

- **Interventricular septum** separates the right ventricle from left ventricle.
- **Interior of each ventricle** has an inflow part and an outflow part. The inflow part of each ventricle is a rough inner surface because of the presence of numerous bundles of cardiac muscles called *trabeculae carneae*. *Papillary muscles* are finger-like processes attached to the ventricular wall at one end, but free at the other. They are functionally related to the AV valves.
- **Right ventricle** receives blood from the right atrium and pumps through the pulmonary trunk (which divides into right and left pulmonary arteries) into the lungs. The *pulmonary valve* is present at the junction of right ventricle and pulmonary trunk.
- **Left ventricle** receives blood from the left atrium and pumps out into systemic circulation through the aorta. *Aortic valve* is present at the junction of left ventricle and the *ascending aorta*.

Valves of heart

There are four valves in human heart, two AV valves and two semilunar valves. Valves allow unidirectional flow of blood.

AV valves

The AV valves open towards the ventricles and close towards the atria. They allow blood to flow from atria to ventricles. But when ventricles contract, they are closed, and thus prevent backflow of blood from

ventricles to atria.

- **Right AV valve** is known as *tricuspid valve* and is made of 3 cusps: anterior, posterior and septal (Fig. 4.1-2).
- **The left AV valve** is called *mitral valve* or *bicuspid valve* and is made of 2 cusps: anterior and posterior (Figs. 4.1-2, 4.1-3).
- At the periphery, the cusps (flaps) of the AV valves are attached to the *AV ring*, which is a fibrous connection between the atria and ventricles. The free edges of the cusps are attached to *papillary muscles* through the cord-like structures called the *chordae tendineae* (Fig. 4.1-3).
- **Papillary muscles** arise from the inner surface of ventricles and contract when the ventricular walls contract. They do not help the valves to close but prevent the bulging of the valves into the atria when ventricles contract. Therefore, in the event of paralysis of papillary muscles or rupture of chordae tendineae the AV valve bulges (into the atria), and there occurs regurgitation of blood into the atria during systole when ventricles contract.

FIGURE 4.1-2 Valves of the heart.

FIGURE 4.1-3 Bicuspid valve attached with papillary muscles and chordae tendineae.

Semilunar valves

- ***Aortic valve*** is the semilunar valve present at the opening of aorta in left ventricle. It is made of three semilunar cusps: one anterior and two posterior (Figs. 4.1-4, 4.1-5).
- ***Pulmonary valve*** is the semilunar valve present at the opening of pulmonary trunk into the right ventricle. It is also made of three semilunar cusps: one posterior and two anterior (Fig. 4.1-4).
- ***Semilunar valves open*** away from ventricles and close towards the ventricles. These valves open when ventricles contract allowing the blood to flow from left ventricle to aorta and from right ventricle to pulmonary trunk.
- ***Semilunar valves close*** when ventricles relax, thus preventing backflow of blood from aorta or pulmonary trunk into the ventricles.

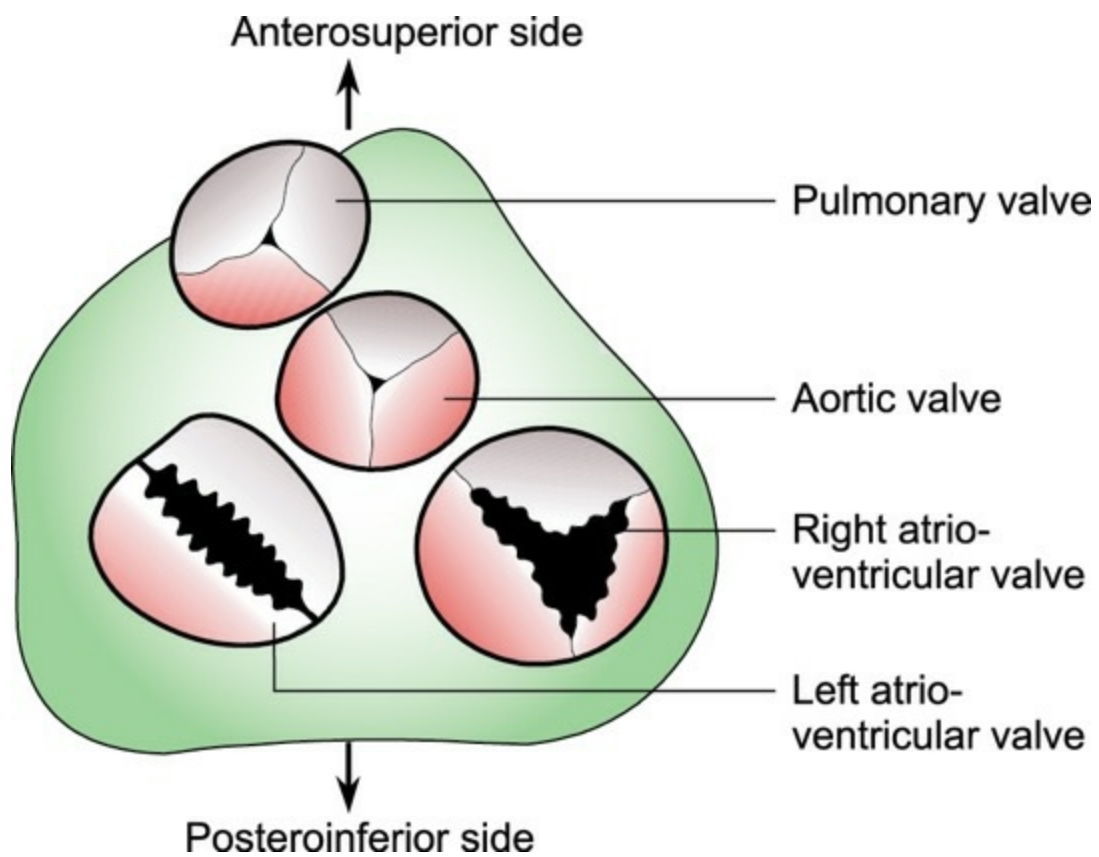

FIGURE 4.1-4 Semilunar valves and atrioventricular valves viewed from the posterosuperior aspect after removing the atria.

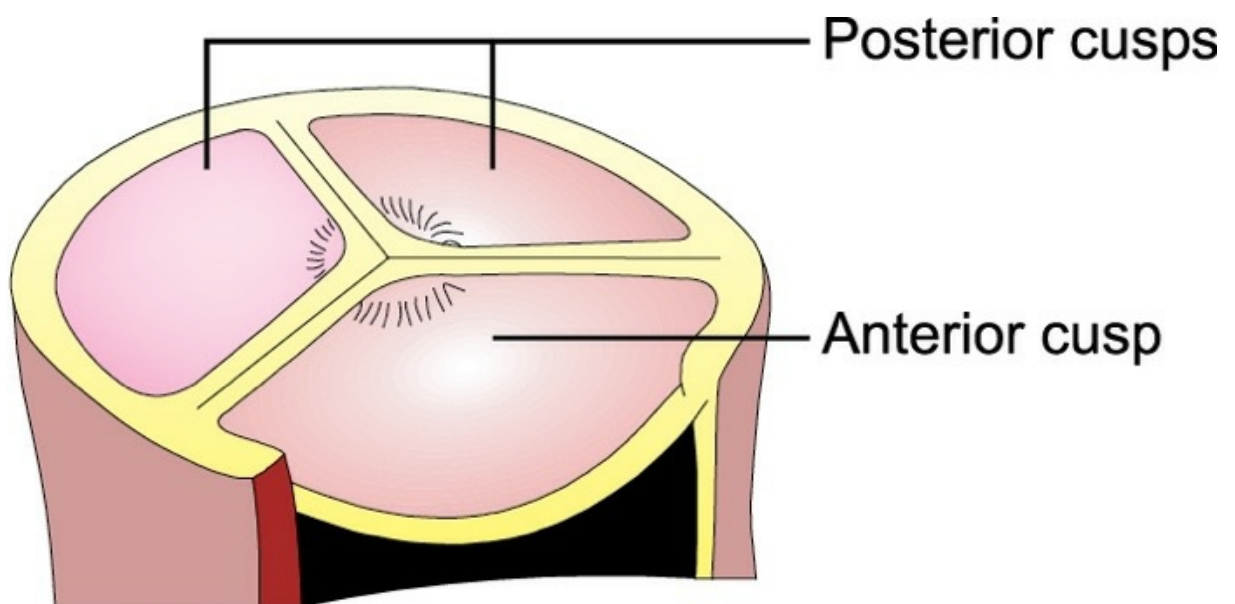

FIGURE 4.1-5 Aortic valve.

Structure of the walls of heart

Walls of the heart are composed of a thick layer of cardiac muscles, the *myocardium* (see page 240), covered externally by the *epicardium* and lined internally by the *endocardium*.

- Walls of the atrial portion of the heart are thin.
- Walls of the ventricular portion of the heart are thick.

Skeleton of the heart (Fig. 4.1-6) consists of fibrous rings that surround the AV, pulmonary and aortic orifices and are continuous with the membranous part of the ventricular septum. The fibrous rings around the AV orifices separate the muscular walls of the atria from those of the ventricles but provide attachment for the muscle fibres. The fibrous rings support the bases of the valve cusps and prevent the valves from stretching and becoming incompetent.

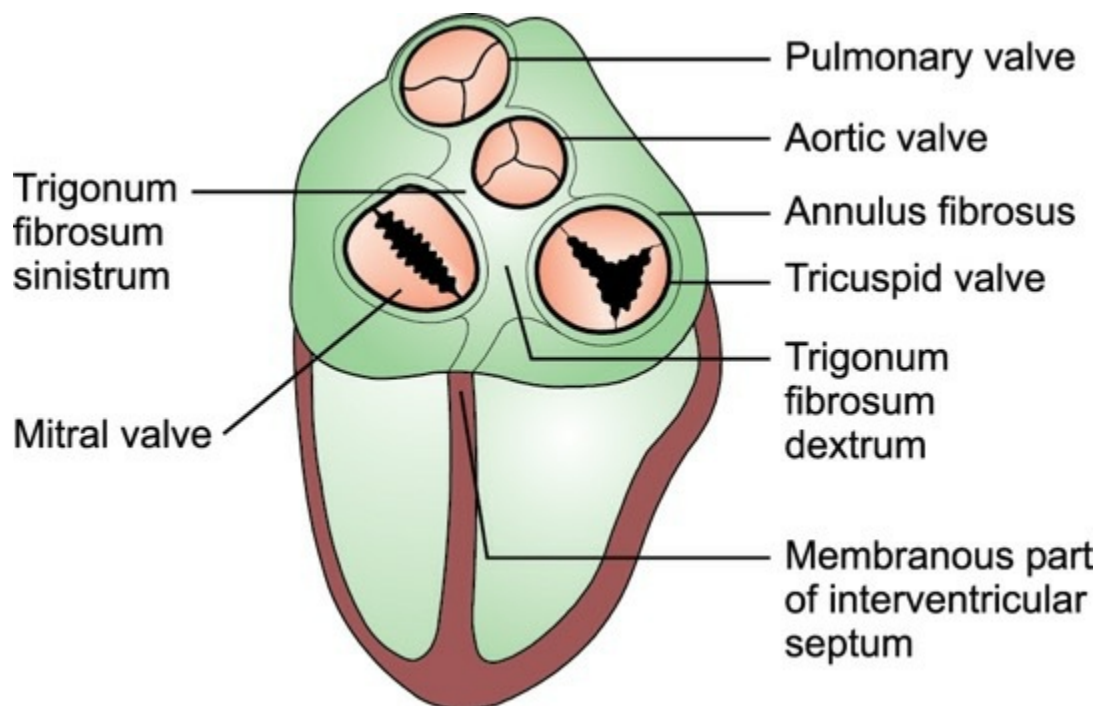

FIGURE 4.1-6 Skeleton of the heart.

Pericardium.

The heart and roots of the great vessels are enclosed by a fibroserous sac called pericardium. Its function is to restrict excessive movements of the heart as a whole and to serve as a lubricated container in which different parts of the heart can contract. Pericardium consists of two layers: outer fibrous and inner serous (Fig. 4.1-7A and B).

- **Fibrous pericardium** surrounds the heart like a bag and is attached with the surrounding structures.
- **Serous pericardium** has parietal and visceral layers. The *parietal layer* of serous pericardium lines the fibrous pericardium and is reflected around the roots of the great vessels to become continuous with the *visceral layer of serous pericardium* that closely cover the heart and is often called the *epicardium*. The slit-like space between the parietal and visceral layers of the serous pericardium is called *pericardial cavity* which contains small amount of *pericardial fluid* that acts as a lubricant to facilitate the movement of the heart.

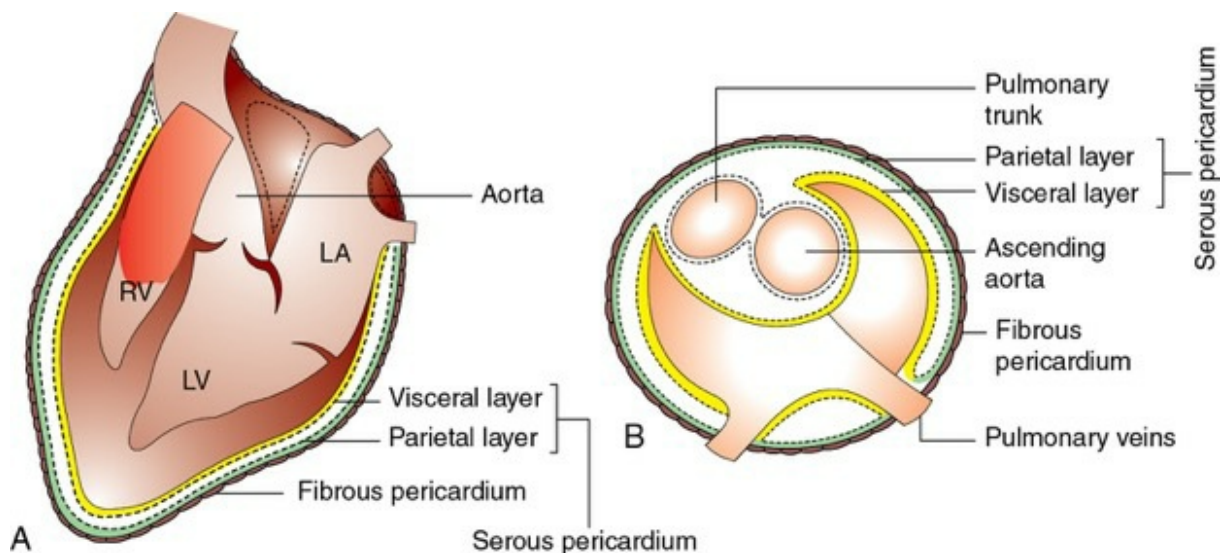

FIGURE 4.1-7 Schematic sagittal section of the heart showing fibrous and serous pericardium **(A)** and transverse section through upper part of the heart and pericardium **(B)**.

Myocardium

The myocardium (muscular tissue of the heart) is the main tissue constituting the walls of the heart. It consists of three types of muscle fibres:

- *Cardiac muscles* forming the walls of the atria and ventricles – contractile unit of the heart (see page 240),
- Muscle fibres forming the *pacemaker* which is the site of origin of cardiac impulse (see page 252) and
- Muscle fibres forming the conducting system which transmits the

impulse to the various parts of the heart (see page 253).

Endocardium

Endocardium is a thin, smooth and glistening membrane lining the myocardium internally. It consists of a single layer of endothelial cells. The endocardium continues as the endothelium of great vessels opening in the heart.

Physiology of cardiac muscle

Functional anatomy

The myocardium consists of three types of muscle fibres:

- *Cardiac muscles* forming the walls of atria and ventricles (contractile unit of the heart),
- Muscle fibres forming the *pacemaker* which is the site of origin of cardiac impulse and
- Muscle fibres forming the *conductive system* which transmits the impulse to the various parts of the heart.

This chapter is mainly devoted to physiology of cardiac muscles forming the walls of atria and ventricles.

Structural organization of cardiac muscle

- The cardiac muscle fibres are *striated* and resemble quite a lot to skeletal muscle fibres in structure. However, unlike the skeletal muscles, the cardiac muscles are *involuntary* (like smooth muscles). Thus cardiac muscles share some characteristics with skeletal muscles and some with smooth muscles.
- The cardiac muscle fibres are *ribbon like* rather than cylindrical. These are *branched* and interdigitate freely with each other, but each fibre is a complete separate unit. The branches from the neighbouring fibres join together. At the point of contact of two muscle fibres, the membranes of both muscle fibres are fused together and thrown into extensive infolding forming the so-called *intercalated disc* (Fig. 4.1-8). These discs

form tight junctions between the muscle fibres and do not allow the ions to pass through. However, the intercalated discs provide a strong union between fibres and thus play an important role during contraction of muscle fibres by transmitting the pull of one contractile unit along its axis to the next, thereby increasing the force of contraction.

- Along the sides near the outer border of intercalated disc, the two adjacent muscle fibres are connected with each other through the *gap junctions*. Though there is no anatomical connection between different cardiac muscle fibres, from functional point of view, the action potential passes from one cardiac muscle cell to the other through gap junctions which provide *low-resistance bridges* and thus the cardiac muscle acts as a *functional syncytium* of many cardiac cells. In this way, the cardiac impulse spreads throughout the muscle mass quickly resulting in a coordinated contraction of the whole tissue. In the heart, the cardiac muscle forms two separate syncytia, the *atrial syncytium* (walls of the two atria) and the *ventricular syncytium* (walls of the two ventricles). Action potential is conducted from the atrial syncytium to ventricular syncytium by way of specialized conducting system. Each syncytium obeys all or none of the law. Because atrial and ventricular syncytia are two separate syncytia, therefore, atria contract a short time ahead of ventricular contraction.
- The cardiac muscle fibres are supplied richly by the capillaries (one capillary/fibre).

FIGURE 4.1-8 Structure of cardiac muscle.

Structure of a cardiac muscle fibre

Each muscle fibre is about 80- μm long and about 15- μm broad. Its cell membrane is called *sarcolemma* and the cytoplasm is called *sarcoplasm*. The sarcoplasm is in abundance and contains all the cell organelles, a well-developed sarcoplasmic reticulum and a centrally placed nucleus. Each muscle fibre is made up of a number of *myofibrils* which lie parallel to each other. Each myofibril is 2 μm in diameter.

Myofibril. Each myofibril consists of thick and thin filaments. Essentially the structure and striations seen under a light microscope and a detailed electron microscope is similar to that of a skeletal muscle (see page 85).

Sarcotubular system

The sarcotubular system in cardiac muscles is well developed like that of skeletal muscles (page 88). However, the tubules of the T-system penetrate the sarcomere at Z-line (Fig. 4.1-9) and not at the junction of A and I bands (as in skeletal muscles). Therefore, in cardiac muscles, there is only one triad per sarcomere as compared to two in skeletal muscles (page 88). Further, the tubules are much wider than in skeletal muscles and typical triads are not always present. They are often replaced by dyads having one T-tubule and one cistern of the sarcoplasmic reticulum (L-tubule).

FIGURE 4.1-9 Sarcotubular system in the cardiac muscle.

Process of excitability and contractility: An electromechanical phenomenon

The cardiac muscle being an excitable tissue produces an action potential (*electrical phenomenon*) when stimulated and responds by contracting (*mechanical phenomenon*). The events which link the electrical phenomenon with mechanical phenomenon constitute the *excitation–contraction coupling phenomenon*. These three phenomena are discussed separately. As discussed earlier, the cardiac muscles comprise working myocardial cells or the contractile myocardial cells (CMC), pacemaker and conducting tissue. The present discussion is limited to activities in the CMC.

Electrical potentials in cardiac muscle

Resting membrane potential

The resting membrane potential (RMP) of a normal cardiac muscle fibre is -85 to -95 mV (negative interior with reference to exterior).

Action potential

When stimulated, each cardiac muscle fibre shows an electrical activity known as propagated action potential. It is different from the electrocardiogram, which refers to extracellular recording of the summed electrical events of all the cardiac muscle fibres generated with each heart beat (see page 253).

The action potential recorded from a single cardiac muscle fibre is unusually long and can be divided into five distinct phases (Fig. 4.1-10) as follows:

FIGURE 4.1-10 Various phases of action potential and ion conductance: Phase 0 = depolarization; Phase 1 = rapid repolarization; Phase 2 = plateau phase; Phase 3 = late rapid repolarization and Phase 4 = resting potential.

- **Phase 0: Rapid depolarization.**

The phase 0 (upstroke) is characterized by the depolarization which proceeds rapidly, an overshoot is present, as in skeletal muscle and nerve. In mammalian heart, depolarization lasts about 2 ms. In this phase, amplitude of potential reaches up to +20 to +30 mV (positive interior with reference to exterior).

Ionic basis. The initial rapid depolarization and the overshoot are due to the rapid opening of voltage-gated Na⁺ channels and rapid influx of Na⁺ ions similar to that occurring in nerve and skeletal muscle.

At -30- to -40-mV membrane potential, the calcium channels also open up and influx of Ca²⁺ ions also contributes in this phase.

Note: Tetrodotoxin (TT_x) is a specific blocker of sodium channels, acts as a very potent poison, because it blocks the influx of sodium ions, hence no excitation of cardiac muscle fibres and therefore, no contraction.

• Phase 1: Initial rapid repolarization.

Rapid depolarization is followed by a very short-lived slight rapid repolarization. The membrane potential reaches from +30 mV to -10 mV during this phase.

Ionic basis. The initial rapid repolarization is due to closure of Na⁺ channels and opening of K⁺ channels resulting in transient outward current.

• Phase 2: Plateau.

During plateau phase, the cardiac muscle fibre remains in the depolarized state. The membrane potential falls very slowly only to -40 mV during this phase. The plateau lasts for about 100–200 ms. This plateau in action potential explains the 5–15 times longer contraction time of the cardiac muscle as compared to the skeletal muscle.

Ionic basis. Very slow repolarization during the plateau phase is due to:

- Slow influx of Ca²⁺ ions resulting from opening of sarcolemmal *L-type* Ca²⁺ channels, and
- Closure of a distinct set of K⁺ channels called the inward-rectifying K⁺ channels.

• Phase 3: Repolarization.

During this phase, complete repolarization occurs and the membrane potential falls to the approximate resting value of -80 mV. This phase lasts for about 50 ms.

Ionic basis. The slow repolarization results from closing of Ca^{2+} channels and opening of following two types of K^{+} channels.

- *Delayed outward rectifying K^{+} channels*, which are voltage-gated and are activated slowly and
- Ca^{2+} -activated channels which are activated by the elevated sarcoplasmic Ca^{2+} levels.

• Phase 4: Resting potential.

In this phase of RMP (also called as polarized state), the potential is maintained at -90 mV.

Ionic basis. The RMP is maintained by a resting K^{+} current, the largest contributor to which is the inward rectifying K^{+} current.

Duration of action potential.

The duration of action potential (primarily repolarization is about 250 ms) at a heart rate of 75 beats/min. The duration of action potential decreases with increased heart rate (150 ms at a heart rate of 200 beats/min). It is shorter in the atrial muscle. This type of action potential found in CMCs of the ventricles is referred to as *fast response*.

Spread of action potential through cardiac muscles.

As discussed in functional anatomy, the cardiac muscle acts as a physiological syncytium due to the presence of gap junctions amongst the cardiac muscle fibres. Because of this, the action potential spreads through the cardiac muscles very rapidly. Further, as there are two syncytia (the atrial and the ventricular) in the heart, the action potential is transmitted from atria to ventricles only through the fibres of specialized conductive system.

Excitation–contraction coupling phenomenon in cardiac muscles

Excitation–contraction coupling refers to the sequence of events by which

an excited plasma membrane of a muscle fibre leads to cross-bridge activity by increasing sarcoplasmic calcium concentration.

The sequence of events during excitation–contraction coupling in the cardiac muscles is similar to those observed in a skeletal muscle (see page 89), with the following exception:

In cardiac muscles (as against that in skeletal muscles), extra calcium ions diffuse into the sarcoplasm from T-tubules without which the contraction strength would be considerably reduced. The T-tubules of cardiac muscle contain mucopolysaccharides which are negatively charged and bind an abundant store of calcium ions. T-tubules open directly to the exterior and therefore, Ca^{2+} ions in them directly come from extracellular fluid. These Ca^{2+} ions diffuse into the sarcoplasm when action potential propagates along the T-tubules (Fig. 4.1-11A and B). Because of this, strength of cardiac muscle contraction depends to a great extent on Ca^{2+} concentration in ECF. Whereas, skeletal muscle contraction is hardly affected by the calcium concentration in ECF.

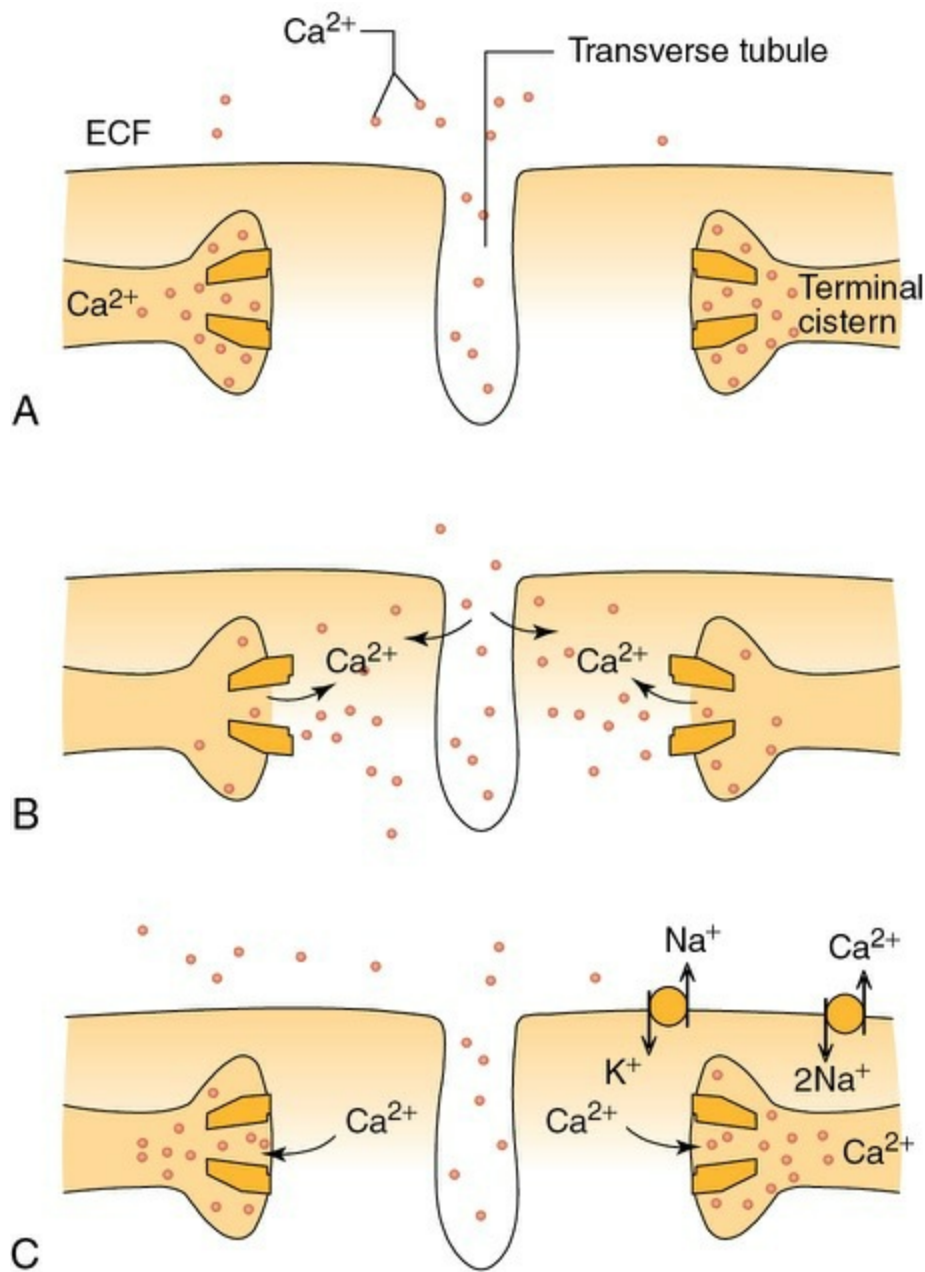

FIGURE 4.1-11 Dynamics of Ca^{2+} during excitation–contraction coupling phenomenon and relaxation in cardiac muscle. **A**, in resting state; **B**, calcium-induced calcium release during excitation and contraction state; **C**, during relaxation state.

Process of cardiac muscle contraction

The molecular mechanism of cardiac muscle contraction by cross-bridge cycling and sliding of filaments is primarily similar to that of skeletal muscles (page 89) and smooth muscles (page 117). However, its regulation shows features of both the skeletal and smooth muscles.

- Troponin–tropomyosin complex controls the onset and offset of cross-bridge cycling, similar to that in the skeletal muscles and
- Like smooth muscles, the contractility of cardiac muscle is sensitive to *phosphorylation*.

Relaxation of cardiac muscle

Relaxation of cardiac muscle (diastole) occurs when levels of Ca^{2+} ions fall in the cardiac muscle fibres. During diastole, the Ca^{2+} ions are extruded out of the cardiac muscle fibre by a carrier system operating at the sarcolemma in which two Na^+ ions are exchanged for each Ca^{2+} ion extruded (Fig. 4.1-11C). Thus, the rate of Ca^{2+} ion extrusion depends on the gradient of Na^+ created by Na^+ - K^+ ATPase.

Inhibition of this secondary active transport of Ca^{2+} ions, e.g. by digitalis or other cardiac glycosides raises the intracellular Ca^{2+} concentration and thereby increases myocardial contractility. This effect is utilized in patients with congestive heart failure.

Properties of cardiac muscle

The basic properties of cardiac muscle include:

- Automaticity,
- Rhythmicity (chronotropism),
- Conductivity (dromotropism),
- Excitability (bathmotropism) and
- Contractility (inotropism).

Some of the properties of cardiac muscle, viz automaticity, rhythmicity and conductivity are discussed in [Chapter 4.2](#) (see page 248).

The characteristics of excitability and contractility are described here.

Excitability

Excitability (bathmotropism) is the property by which tissues respond to stimuli. The cardiac muscle responds by depolarization (development of action potential). The essential features of the RMP and action potential of cardiac muscle have been discussed on page 241.

One of the characteristics of cardiac muscle excitability which needs a special emphasis is its refractory period.

Refractory period

Refractory period refers to the period following action potential during which the cardiac muscle does not respond to a stimulus. Cardiac muscle has a long refractory period (250–300 ms in ventricles and about 150 ms in atria). It is of two types as follows.

1. Absolute refractory period (ARP).

During this period the cardiac muscle does not show any response at all. It extends from phase 0 to half of phase 3 of action potential, i.e. until the membrane potential reaches approximately 50 mV during repolarization (Fig. 4.1-12). Normal duration of ARP in ventricles is about 180–200 ms.

FIGURE 4.1-12 Record of action potential (**A**) and mechanical response (**B**) from the cardiac muscle fibre shown on same time scale depicting the significance of long refractory period.

ARP, absolute refractory period; RRP, relative refractory period.

2. Relative refractory period (RRP).

During this period the muscle shows response if the strength of stimulus is increased to maximum. It extends from second half of the phase 3 to phase 4 of the action potential. Normal duration of RRP in ventricles is about 50 ms.

Significance of long refractory period in cardiac muscle.

As shown in Fig. 4.1-12, the cardiac muscle is refractory to any stimulus during the contraction phase (systole), therefore, the complete summation of contractions and thus tetanus cannot be produced in the cardiac muscle. This property is very useful. Since the heart has to function as a pump, it must relax, get filled up with blood and then contract to pump out the blood. A tetanized heart would be useless as a pump.

Experimental demonstration of refractory period in heart.

Experimental demonstration of refractory period in heart can be done both in a beating heart as well as in a quiescent heart.

Refractory period in a beating heart

of a pithed frog can be demonstrated during recording of a cardiogram. As shown in Fig. 4.1-13, when the electrical stimulus is applied to the base of ventricle during systole, no response is seen, depicting thereby that the heart is in ARP during systole.

- When the stimulus is applied during diastole, the heart responds by premature contraction producing *extra systole* followed by a *compensatory pause*. The total duration of the extra systole and the compensatory pause is equivalent to the duration of two cardiac cycles. These events can be explained as:
- When the stimulus is applied during diastole, the premature contraction occurs since the heart is in the phase of RRP.

- The natural impulse from the sinus venosus arrives at the time of premature contraction (ARP) and cannot produce contraction and thus the heart has to wait for the arrival of the next natural impulse. The heart stops during this period in relaxation producing the so-called *compensatory pause*.

FIGURE 4.1-13 Demonstration of refractory period in beating heart of a frog. VS, ventricular systole; VD: ventricular diastole.

Refractory period in a quiescent heart

can be demonstrated as:

- The heart is made quiescent by applying the first *Stannius ligature* between the sinus venosus and the right auricle.
- An electrical stimulus is applied at the base of the ventricle to stimulate the heart which starts contracting. When another stimulus is applied immediately after the first (i.e. during systole phase), the heart does not show any response, indicating that during contraction (systole), heart is in ARP (Fig. 4.1-14).
- When the second stimulus is applied during diastole the heart responds producing extra systole and the compensatory pause (Fig. 4.1-14), indicating that heart is in the state of *RRP* during diastole.

FIGURE 4.1-14 Refractory period in quiescent heart of a frog.

Contractility

Contractility is the ability of the cardiac muscle to actively generate force to shorten and thicken to do work when sufficient stimulus is applied.

Process of myocardial contractility is discussed on page 246.

Mechanical response in cardiac muscle fibre begins just after the start of depolarization and lasts about 1.5 times as long as the action potential (Fig. 4.1-15B). Thus the mechanical response (300 ms) overlaps the

electrical response (200 ms) for the whole period. This is in contrast to skeletal muscle, where the mechanical response begins a few milliseconds after the end of repolarization and lasts for 30–50 ms in mammalian skeletal muscle and 100 ms in amphibian skeletal muscle (Fig. 4.1-15A).

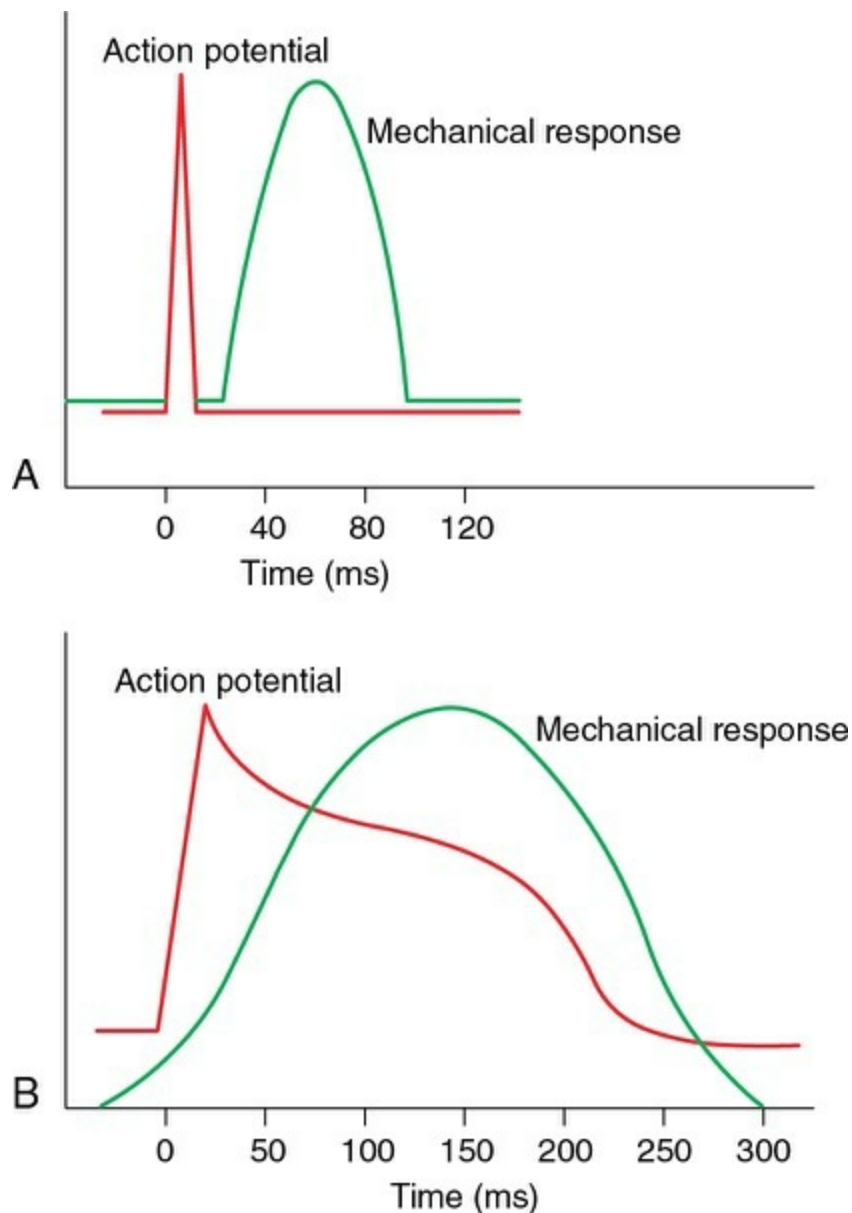

FIGURE 4.1-15 Relationship of action potential and mechanical response **(A)** in skeletal muscle and **(B)** in cardiac muscle.

Characteristic features of myocardial contractility and factors affecting are:

- All or none law,

- Staircase phenomenon,
- Summation of subminimal stimuli,
- Effect of preload,
- Effect of afterload,
- Effect of ions (see page 271) and
- Effect of temperature (see page 104).

1. All or none law

The response of the cardiac muscle to a stimulus is all or none in character, i.e. when a stimulus is applied, either the heart does not contract at all (none response) or contracts to its maximum ability (all response). This is because of the syncytial arrangement of the cardiac muscle fibres. Therefore, the 'all or none' law in heart is applicable to the whole functional syncytial unit, i.e. the entire atria or entire ventricle. While in skeletal muscles, it is applicable only to a single muscle fibre.

Demonstration of 'all and none' law

can be done in the quiescent heart of frog as:

- *Quiescent heart* is made by applying the first Stannius ligature between sinus venosus and atrium.
- When *subthreshold stimulus* is applied to the ventricle, no response is obtained.
- When *threshold stimulus* is applied to the ventricle, a contraction is recorded.
- *Maximal and supramaximal* strength of stimuli produce contractions of amplitude similar to that produced by the threshold stimulus (Fig. 4.1-16), proving 'all or none law' property of the cardiac muscle.

FIGURE 4.1-16 Demonstration of all or none law in quiescent heart of a frog.

2. Staircase phenomenon (treppe)

Staircase phenomenon or effect refers to the successive increase in the force of cardiac contractions in the first few (4–5) contractions after the quiescent heart starts beating, e.g. as seen after vagal stimulation (Fig. 4.1-17). This is because of the beneficial effect.

FIGURE 4.1-17 Staircase phenomenon (treppe) in cardiac muscle after vagal stimulation in frog.

Cause of beneficial effect.

When the heart stops, there occurs an increase in Na^+ and a decrease in K^+ concentration inside the cell, which increases Ca^{2+} influx. Thus, there occurs a progressive increase in the Ca^{2+} concentration in sarcoplasm due to the increase in Ca^{2+} influx with each action potential. This produces a progressive increase in the strength of the few (4–5) cardiac muscle contractions.

Demonstration of staircase phenomenon

can be done in the quiescent heart of frog as:

- *Quiescent heart* is made by applying the first Stannius ligature between sinus venosus and atria.
- *Ventricle is stimulated* repeatedly at intervals of 2 s without changing the strength of the stimulus.
- *Graph obtained* (Fig. 4.1-18) will show that in the first few contractions, the force of contraction is increased and then it remains constant. This is called staircase phenomenon or treppe (German word for staircase).

FIGURE 4.1-18 Demonstration of staircase phenomenon in quiescent heart of a frog.

3. Summation of subminimal stimuli

When a subthreshold stimulus is applied to the quiescent heart, there occurs no response. However, when subthreshold stimuli are applied repeatedly at an interval of one half to one second, there occurs a contraction of the heart after about 10 to 20 stimuli. This phenomenon is called *temporal summation* of subminimal stimuli (Fig. 4.1-19).

FIGURE 4.1-19 Temporal summation of subminimal stimuli in quiescent heart of a frog.

4. Effect of preload

A load which starts acting on a muscle before it starts to contract is called *preload*. The preload increases the initial length of the muscle. According to Starling's law, the force of contraction is the function of the initial length of the muscle fibres; and up to physiological limits the greater the initial length, greater is the force of contraction. In the case of heart muscles, the end diastolic volume forms the preload. The effect of changing end diastolic volume on force of cardiac contraction has been studied by Frank and Starling in 1910. *The Frank–Starling law of heart* states that within physiological limits the force of cardiac contraction is proportional to its end diastolic volume.

Length–tension relationship.

Length–tension relationship, i.e. the relation between initial fibre length and total tension in cardiac muscle is basically similar to that in skeletal muscle (see page 101). In cardiac muscles, the length–tension relationship graph is plotted with the end diastolic volume in ml (representing initial length) along the horizontal axis and the pressure developed in the ventricle in mmHg (representing tension) along the vertical axis (Fig. 4.1-20). The following inferences can be drawn from this graph (Starling's curve).

FIGURE 4.1-20 Length–tension relationship in cardiac muscle.

Diastolic intraventricular pressure represents the passive tension and it increases with the increase in end diastolic volume (i.e. with the passively increased muscle length). It is important to note that the pressure–volume curve for ventricles in diastole is initially quite flat, indicating that large increase in volume can be accommodated with only small increase in pressure.

Systolic ventricular pressure represents the active tension developed (isometric tension) which is proportionate to the degree of diastolic filling of the heart (initial length of muscle fibres). The graph (Fig. 4.1-20) shows that the developed tension increases as the diastolic volume increases until it reaches a maximum (ascending limb of Starling curve), then tends to decrease (descending limb of Starling’s curve). However, unlike skeletal muscle, the decrease in developed tension at high degrees of stretch is not due to decreased number of cross-bridges between actin and myosin, because even severely dilated hearts are not stretched to this degree. The descending limb is instead due to beginning of disruption of

the myocardial fibres.

Clinical significance of Frank–Starling law of heart

and its role in control of cardiac output is discussed in [Chapter 4.3](#) (see page 290).

5. Effect of afterload

Afterload refers to the load which acts on the muscle after the beginning of muscular contraction. The afterload affecting the force of contraction of the cardiac muscle is represented by the resistance against which the ventricles pump the blood. The afterload (resistance) for right ventricle is low in pulmonary artery due to its intrathoracic location. The afterload (resistance) for left ventricle is high in the aorta due to the resistance to blood flow through the aortic valves and systemic blood vessels, called *peripheral resistance*.

Cardiac muscle contraction with afterload.

[Figure 4.1-21A](#) is the model for contraction of afterloaded cardiac muscle. It shows two phases as given below.

- ***Isometric contraction phase.*** In this phase, the muscle contracts but there occurs no shortening of the muscle. The contraction of contractile component (CC) of the muscle stretches the series elastic component (SEC) and there occurs a rise in tension ([Fig. 4.1-21B](#)). The rise in tension continues till it equals the load. This is the end point of isometric contraction.

Isotonic contraction phase starts when the muscle tension exceeds the load starts moving. There occurs shortening of the muscle without further stretching of SEC ([Fig. 4.1-21C](#)). The performance of CC is given by the force–velocity relationship.

FIGURE 4.1-21 Model of contraction of cardiac muscle in afterloaded condition. **A**, resting phase; **B**, isometric contraction, phase; **C**, in isotonic contraction phase.

• **Force–velocity relationship.**

The force–velocity curve is plotted by noting the velocity of muscle contraction with progressively increasing the load on the muscle. In the heart, the load is represented by the resistance against which the ventricles pump the blood and velocity of muscle contraction is represented by the stroke output. Following inferences can be drawn from the force–velocity curve (Fig. 4.1-22A).

- When the load is zero, the muscle contracts rapidly and the velocity of muscle shortening is maximum (V_{max}).
- As the load increases progressively, the velocity of shortening decreases till it reaches zero. At this point, the force developed is called

maximum isometric force and is represented by P_o . Therefore, during muscle contraction, the velocity of shortening and force developed are inversely related. The force–velocity relationship curve is influenced by change in initial length of the muscle and the effect of catecholamines.

FIGURE 4.1-22 Force–velocity curve in cardiac muscle (A), and effect of change of initial length (B) and effect of catecholamines or increased Ca^{2+} concentration in ECF(C) on it.

- **Effects of change in initial length on force–velocity relationship curve.**

An increase in change in the initial length (within physiological limits) increases the force of contraction (P_o) without changing the velocity (V_{max}), i.e. the relationship shifts to the right (Fig. 4.1-22B).

- **Effect of catecholamines or increased calcium concentration in**

ECF.

The catecholamines or increased Ca^{2+} concentration in ECF, both cause an increase in P_o as well as V_{\max} (Fig. 4.1-22C).

Clinical implication of force–velocity relationship.

The cardiac muscle can alter its work and power (rate of working) at any given load and muscle length by nature of its changing force–velocity relationship in different chemical environment as:

- When the pressure against which the heart is pumping the blood is raised, the heart strokes out less blood than it receives for several beats. Consequently, blood accumulates in the ventricle increasing the end-diastolic volume which increases the initial length of muscle fibres (i.e. size of the heart). The distended heart beats more forcefully and output returns to its previous level, i.e. by an increase in the initial length of cardiac muscle the P_o is increased and the V_{\max} is achieved.
- Conversely, when the pressure against which the heart is pumping the blood is reduced, the stroke output rises transiently but the size of heart decreases and the stroke output falls to the previous constant level.

CHAPTER

4.2

Origin and spread of cardiac impulse and electrocardiography

ORIGIN AND SPREAD OF CARDIAC IMPULSE

- Introduction
- Anatomic consideration
 - Conducting system of the heart
 - Innervational characteristics of the heart
- Mechanism of origin of rhythmic cardiac impulse
 - Pacemaker
 - Electrical potential in pacemaker tissue
 - Role of autonomic nervous system in controlling heart rhythm
- Spread of cardiac impulse
 - Conduction from SA node and atria
 - Conduction through AV node
 - Conduction through ventricles

ELECTROCARDIOGRAPHY

- Introduction

- Recording of ECG
 - ECG leads
 - Electrocardiograph
- Normal electrocardiogram
 - Waves of ECG
 - Intervals and segments of ECG
- Vectorial analysis of electrocardiogram and vector cardiography
 - Concept of cardiac vectors

Origin and spread of cardiac impulse

Introduction

The cardiac muscle possesses special properties which include autorhythmicity, conductivity, excitability and contractility. The heart is able to perform its action as a unique pump because of these properties interacting in the same sequence as enumerated above.

Autorhythmicity, refers to the property of cardiac muscle which enables the heart to initiate its own impulse at constant rhythmical intervals. Because of this property, the heart continues to beat even after all nerves to it are sectioned or even if the heart is cut into pieces, the pieces

continue to beat. This is one of the earliest properties manifested during development even before the muscle fibres acquire the typical histological features. This is because of the presence of the specialized *pacemaker tissue* in the heart that can initiate repetitive action potentials. The pacemaker tissue makes a *conduction system* that normally spreads impulses through the heart.

Anatomic consideration

Conducting system of the heart

The conducting system of the heart consists of specialized fibres of the heart muscle present as the sinoatrial node, interatrial tract, internodal tracts, the atrioventricular (AV) node, the AV bundle of His and its right and left terminal branches, and the subendocardial plexuses of Purkinje fibres (Fig. 4.2-1).

FIGURE 4.2-1 Specialized conducting tissues of the heart.

1. Sinoatrial node.

Sinoatrial (SA) node is located in the wall of right atrium, just to the right of the opening of superior vena cava. Spontaneous rhythmical electrical impulses arise from the SA node and spread in all directions to

- Cardiac muscles of atria,

- Interatrial tract to left atrium and
- Internodal tracts to AV node.

2. Interatrial tract (Bachman's bundle).

It is a band of specialized muscle fibres that run from SA node to left atrium. It causes simultaneous depolarization of the atria, since the velocity of conduction of impulse in this tract is faster than the rest of the atrial muscles.

3. Internodal conduction pathway.

Impulses from the SA node have been shown to travel to the AV node more rapidly than they can travel by passing along the ordinary myocardium. This phenomenon has been explained by the description of special pathways in the atrial wall (Fig. 4.2-2), having a structure consisting of a mixture of Purkinje fibres and ordinary cardiac muscle cells. Three internodal conduction paths have been described:

- *Anterior internodal pathway of Bachman* leaves the anterior end of SA node and passes anterior to the superior vena cava opening. It then descends on the atrial septum and ends in the AV node.
- *Middle internodal pathway of Wenckebach* leaves the posterior end of SA node and passes posterior to superior vena cava opening. It then descends on the atrial septum to end in the AV node.
- *Posterior internodal pathway of Thorel* leaves the posterior part of the SA node and descends through the crista terminalis and the valve of inferior vena cava to the AV node.

FIGURE 4.2-2 Internodal conduction pathways.

4. AV node.

The AV node is strategically located just beneath the endocardium on the right side of lower part of atrial septum, near the tricuspid valve. It is stimulated by the excitation wave that travels through internodal tracts and atrial myocardium. From it, the cardiac impulse is conducted to ventricles by the AV bundle.

5. AV bundle of his.

The AV bundle arises from the AV node, descends through the fibrous skeleton of the heart and divides into right bundle branch (RBB) for right ventricle and left bundle branch (LBB) for the left ventricle. The branches break up and become continuous with the plexus of Purkinje fibres.

6. Purkinje fibres.

These are spread out deep to the endocardium and reach all parts of the ventricles, including the bases of papillary muscles.

Characteristic histological features of conducting system

- The conduction system of the heart is composed of modified cardiac muscle that has *fewer striations* and *indistinct boundaries*.
- The SA node and, to a lesser extent the AV node, also contains *small round cells* with few organelles, which are connected by *gap junctions*. These are probably the actual pacemaker cells, and therefore they are called *P cells*.
- The atrial muscle fibres are separated from those of the ventricles by a fibrous ring. Normally, the AV bundle is the only pathway of cardiac muscle that connects the myocardium of the atria and myocardium of ventricles and is thus the only route along which the cardiac impulse can travel from the atria to the ventricles.

Innervational characteristics of heart

- Both SA node and AV node are richly supplied by the sympathetic as well as parasympathetic nerves. Parasympathetic fibres come from the vagus nerve and most sympathetic fibres come from the stellate ganglion.
- SA node develops from the structures on the right side of the embryo and that is why it is supplied by right vagus nerve and right-sided sympathetics.
- AV node develops from the structures on the left side of the embryo and that is why it is supplied by left vagus and left-sided sympathetic nerves.
- Noradrenergic fibres are epicardial, whereas the vagal fibres are endocardial.
- Connections exist for reciprocal inhibitory effects of sympathetic and parasympathetic innervation of the heart on each. Thus, acetylcholine acts presynaptically to reduce norepinephrine release from the sympathetic nerves, and conversely, neuropeptide Y released from the noradrenergic endings may inhibit the release of acetylcholine.

Mechanism of origin of rhythmic cardiac impulse

Pacemaker

The part of the heart from which rhythmic impulses for heart beat are produced is called *pacemaker*. In mammalian heart, though the other parts of the heart like AV node, atria and ventricle can also produce the impulse, but *SA node acts as a pacemaker* because the rate of impulse generation by SA node is the highest. However, when there occurs blockage of transmission of impulse from SA node to AV node, the pacemaker activity may shift from SA node to other sites, e.g. AV node. When pacemaker is other than SA node, it is called as *ectopic pacemaker*. Ectopic pacemaker causes abnormal sequence of contraction of different parts of the heart.

Rate of production of rhythmic impulses by different parts of the heart is:

- SA node: 70–80/min,
- AV node: 40–60/min,
- Atrial muscle: 40–60/min and
- Ventricular muscles: 20–40/min.

Experimental evidences to prove that SA node acts as a pacemaker in mammalian heart are

- SA node becomes electrically negative before any other part of the atria thereby indicating that it is the first region to become active.
- Stimulation of SA node accelerates the heart rate.
- Local cooling of SA node reduces and warming increases the heart rate.
- When SA node is destroyed artificially, there occurs immediate stoppage of heart followed by an altered rhythm of heart beats (due to ectopic pacemaker taking over the function).

Pacemaker in amphibian heart

In amphibian heart, *sinus venosus* acts as pacemaker, however, other parts of the heart can also produce rhythmic impulses. These facts can be

proved by blocking the conduction mechanically by applying *Stannius ligatures*.

First Stannius ligature when tied between the *sinus venosus* and *atria*:

- The heart stops beating while the sinus continues to beat, indicating blockage of impulse from sinus to atria (Fig. 4.2-3A).
- After sometime, the atria start generating their own impulse which is also transmitted to ventricles and the atrial and ventricular segment starts beating independent of the sinus rhythm but at a slower rate (Fig. 4.2-3B).

FIGURE 4.2-3 Effect of Stannius ligature I and II on frog's heart: **A**, blockage of impulse from sinus venosus to atria; **B**, atrial rhythm; **C**, blockage of impulse from atria to ventricle; and **D**, idioventricular rhythm.

Second Stannius ligature is then tied between the atria and ventricle around the AV groove. After this ligature:

- The atria continue to beat with its own rhythm while the ventricle stops beating indicating blockage of the impulse from the atria to the ventricle (Fig. 4.2-3C).
- After sometime, the ventricle generates its own impulse and starts beating independent of atria at much slower rate than the atrial rate. This is referred to as idioventricular rhythm (Fig. 4.2-3D).

Electrical potential in pacemaker tissue

The electrical potential in cardiac muscle (contractile myocardial cells (CMC)) has been described on page 241. As shown in [Figure 4.1-10](#) in phase 4 of action potential of cardiac muscle (CMC), there exists a constant resting membrane potential of -85 to -90 mV. In pacemaker (SA node) fibres, however, the resting membrane potential is only of -55 to -60 mV; and that this is not steady, i.e. it shows a slow rise in resting membrane potential due to slow depolarization ([Fig. 4.2-4](#)). Due to this slow depolarization, the threshold level -40 mV is reached very slowly. Once the threshold level of -40 mV is reached, there occurs a rapid depolarization up to $+5$ mV followed by rapid repolarization, i.e. there occurs action potential and generation of an impulse. After rapid repolarization (phase 3 of action potential), once again the resting membrane potential (phase 4 of action potential) is reached which is not stable and starts rising slowly to again reach at threshold level to produce the second impulse. This slow rising resting membrane potential in between the action potentials is called *prepotential* or *pacemaker potential* ([Fig. 4.2-4](#)). Ionic basis of pacemaker potential is explained below. Presence of this unique feature in the cells of pacemaker tissue is the underlying mechanism responsible for self-generation of rhythmic impulses (autorhythmicity).

FIGURE 4.2-4 Phases of action potential in cardiac muscle fibre (0, 1, 2, 3, 4) and SA node showing pacemaker potential. AP = Action potential.

Ionic basis of pacemaker potential and action potential in SA node

The myocardial cells present in the SA node and AV node are called *slow fibres* and the other myocardial cells are called *fast fibres* depending on the membrane potential and the shape and conduction velocity of the action potential (Fig. 4.2-5).

- The slow fibres of the pacemaker tissue have a unique feature, i.e. leakage of resting membrane for sodium (while the resting membrane of fast fibres is relatively impermeable to Na^+). This causes *slow diffusion of Na^+ into the SA nodal fibres under resting condition. This slow entry of Na^+ in the cells slowly raises the potential to -55 mV (i.e. causes slow depolarization) due to the presence of non selective channels. This slow depolarization forms the initial part of pacemaker potential (Fig. 4.2-5). Nodal tissues also possess certain funny (f) channels because of their unusual activation following hyperpolarization, associated with increased permeability to both sodium and potassium but dominant effect is that of sodium conductance. These channels are*

also called 'h' channels, because of their activation during hyperpolarization of the membrane (-40 to -60 mV)

- Then the 'T' (transient) calcium channels open up and there is slow influx of Ca^{2+} causing further depolarization in the same at slower rate till a threshold level of -40 mV is reached. Thus calcium current (I_{Ca}) due to the opening of 'T calcium channels' forms the later part of pacemaker potential.
- At the threshold level (-40 mV) the 'long lasting calcium channels' open up and the action potential starts with rapid depolarization due to influx of Ca^{2+} . Thus, it is important to note that the depolarization in SA node is mainly due to influx of Ca^{2+} rather than Na^+ . Consequently, the depolarization is not as sharp as in the other myocardial fibres.
- At the end of depolarization, potassium channels open up and calcium channels close. This causes K^+ to diffuse out of the fibres resulting in rapid repolarization to -55 to -60 mV.
- Again, due to the unique feature of slow fibres of the SA node (i.e. *leakage of resting membrane to Na^+) the resting potential does not become stable but slow depolarization starts due to slow influx of Na^+ making initial part of prepotential.* And ultimately due to repetition of the above described steps another action potential is initiated. In this way, impulses are generated at regular intervals of time (*autorhythmicity*).

FIGURE 4.2-5 Pacemaker potential and its ionic basis. I_{CaT} : Ca^{2+} conductance through transient calcium channels; I_{CaL} : Ca^{2+} conductance through long lasting channels; I_k : potassium conductance.

Role of autonomic nervous system in controlling heart rhythm

Vagal tone.

SA node is richly innervated by parasympathetic fibres from the right vagus. Normal activity of vagus liberates acetylcholine from its nerve endings which increases the permeability of SA nodal fibres for potassium producing hyperpolarization (due to rapid efflux of K^+). This hyperpolarization slows the firing rate of SA node from its automatic rate of 90–120 impulses/min to the actual heart rate of about 72 beats/min. The normal vagal activity is called vagal tone.

Effect of parasympathetic stimulation.

Parasympathetic stimulation causes release of acetylcholine at vagal nerve endings and by the above described mechanism causes (Fig. 4.2-6A):

- Decrease in heart rate by decrease in the rate of sinus rhythm. The

acetylcholine released at the cholinergic nerve endings to nodal tissue causes hyperpolarization of the membrane by increasing permeability to K^+ . The increase in conductance (efflux) of K^+ , decreases the slope of prepotential.

Mechanism of action: This action of Ach is mediated by M_2 receptors via $\beta\gamma$ subunit of G protein, which opens the special set of K^+ channels and slows the depolarizing effect of Na^+ channels (I_h).

Activation of M_2 receptors also decreases cyclic adenosine 3'5' monophosphate in the pacemaker cells and slows the Ca^{2+} channels opening, thus decreasing the firing rate.

- Decrease in the rate of transmission of impulses to ventricles due to decreased excitation of the conducting system. Strong parasympathetic stimulation may even completely block the transmission and ventricles may stop beating for 4–10 s. If it happens, Purkinje system initiates the rhythm causing ventricular contraction at a rate of 15–40/min. This phenomenon is called *vagal escape*.

FIGURE 4.2-6 Effect of parasympathetic (A) and sympathetic (B) stimulations on pacemaker potential.

Effect of sympathetic stimulation.

Stimulation of sympathetic nerves causes release of norepinephrine at the nerve endings. Probably this increases permeability of cardiac muscle fibres to calcium by opening up 'L calcium channels'. This increases the rate of sinus rhythm, and rate of conduction of impulse as well as excitability in all the portions of the heart. Force of contraction of atria and ventricles also increases greatly (Fig. 4.2-6B).

Mechanism of action: Norepinephrine released acts by binding to β_1 receptors on the nodal tissue and increases intracellular cAMP, which facilitates the opening of long-lasting Ca^{2+} channels.

Spread of cardiac impulse

The cardiac impulse which originates in the SA node in the form of action potential spreads throughout the heart through the conduction system (properties of which are summarized in Table 4.2-1) in the sequence given below.

- **SA Node and atria.** The impulse travels over the muscle fibres of atria with which the ends of SA nodal fibres are fused, and through the interatrial tract to the left atrium. Conduction through these fibres causes simultaneous depolarization of both the atria. Atrial depolarization is completed in about 0.1 s. Through the internodal tracts (anterior, middle and posterior) the impulse reaches to AV node from SA node within 0.03 s after its origin.
- **AV Node.** Conduction through AV node is slow; there is a delay of about 0.1 sec. The causes of AV nodal delay are:
- Transitional fibres connecting internodal tracts and AV node are very small and conduct the impulse at a very slow rate, i.e. 0.02–0.05 m/s. AV nodal fibres also conduct the impulse at a very slow rate (0.02–0.05 m/s).
- Resting membrane potential of transitional fibres and AV nodal fibres (– 50 mV) is much less negative than rest of the cardiac muscle fibres (–90 mV). At this level

of -50 to -55mV potential, the fast Na^+ channels get closed due to inactivation gates. Therefore, opening of slow sodium–calcium channels thereby causes action potential. As a result, AV nodal action potential is slower to develop.

- There are very few gap junctions connecting successive fibres in the pathway.

TABLE 4.2-1
Properties of the Conduction System

Tissue	Fibres diameter (μm)	Resting membrane potential (mV)	Conduction velocity (m/s)
SA node	–	-40 to -50	0.05
Atrial muscle	8–10	-70 to -80	0.3–0.5
Interatrial and internodal tract	15–20	-80 to -90	1.0
AV node	Variable	-50	0.02–0.05
Purkinje fibres	70–80	-70	2.0–4.0
Ventricular muscle	10–16	-80	<1.0

The ability of the AV node to slow and to block the rapid impulse is called *detrimental contraction*. This *AV nodal delay is useful*, for it provides time for completion of atrial contraction and their emptying, (i.e. ventricular filling) before the ventricles contract. This delay is shortened by stimulation of the sympathetic nerves to the heart and lengthened by stimulation of the vagii.

- **Ventricular conduction.** The impulses conducted through the AV node are distributed to ventricles through bundle of His, its branches, and Purkinje fibres in 0.08–0.15 s. In humans, depolarization of the ventricular muscle proceeds as follows (Fig. 4.2-7):
- Starts at the left side of interventricular septum,
- Moves first to the right across the mid portion of the septum,

- The wave of depolarization then spreads down the septum to apex of heart.
- It, then, returns along the ventricular walls to the AV groove, proceeding from the endocardial to the epicardial surface.
- The last parts of the heart to be depolarized are the posterobasal portion of the left ventricles, the pulmonary conus, and the upper most portion of the septum.

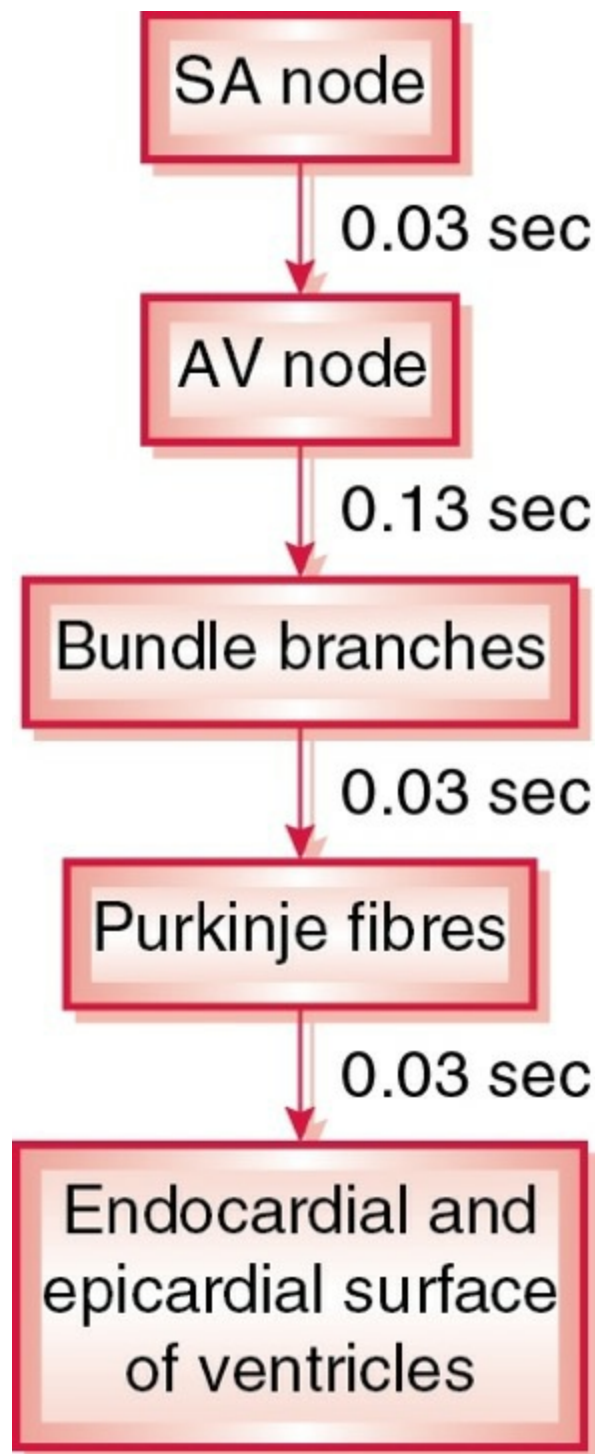

FIGURE 4.2-7 Spread of cardiac impulse.

Time taken for impulse to travel through different tissue is depicted below:

Thus, total time required for conduction from SA node to endocardial surface is 0.22 s.

Important Note

The AV bundle is the only connecting tissue between atria and ventricles. Therefore, if there is destruction of the AV node, then atria and ventricles beat independent of one another, i.e. atria at the rate of 72 beats/min and ventricles at a slower rate (30–40 beats/min). There is a complete dissociation of atrial and ventricular beating and is called

Electrocardiography

Introduction

William Einthoven, a Dutch physiologist, originally developed the technique of electrocardiography. He was awarded the Nobel prize in 1924 for his contribution and is called the father of modern electrocardiography.

Electrocardiography (ECG) refers to extracellular recording of the summed-up electrical events of all the cardiac muscle fibres generated with each heart beat. Electrically, heart behaves as a *dipole*, i.e. a two-terminal battery in which the excited part (depolarized segment) forms a negative pole and the nonexcited part forms the positive pole (Fig. 4.2-8). Thus, ECG is nothing but the surface recording of the potential difference between the two poles of the heart dipole at a given time. The record of the potential fluctuations during the cardiac cycle is called the *electrocardiography*. The machine used to record these potential fluctuations is called *electrocardiograph*, which is essentially a sensitive galvanometer.

FIGURE 4.2-8 The heart as a dipole.

Recording of ECG

ECG leads

ECG leads refer to the two electrodes which are placed on the body surface and connected to ECG machine for measuring the potential fluctuations between only two points. ECG is recorded using two types of leads, the bipolar and unipolar leads.

Bipolar leads

In bipolar recording, *both the electrodes are active* and one of the active electrodes is connected to the negative terminal of the ECG machine and the other to the positive terminal. Three standard limb leads used in bipolar recording are based on Einthoven's assumption that the body is like an electrically homogeneous plate in which the right and left shoulders and the pubic region form the corners of an equilateral triangle with heart in its centre (Einthoven's triangle) and that two active electrodes need to be placed at the two corners of this triangle (Fig. 4.2-9). However, for convenience, the electrodes are connected to the left arm

(LA), right arm (RA) and left foot (LF) instead of the shoulders and the pubic region (Fig. 4.2-9). Practically, it does not make any difference whether the electrodes are placed in proximal or distal part of the extremities, because the current flows in the body fluids and so the records obtained are similar.

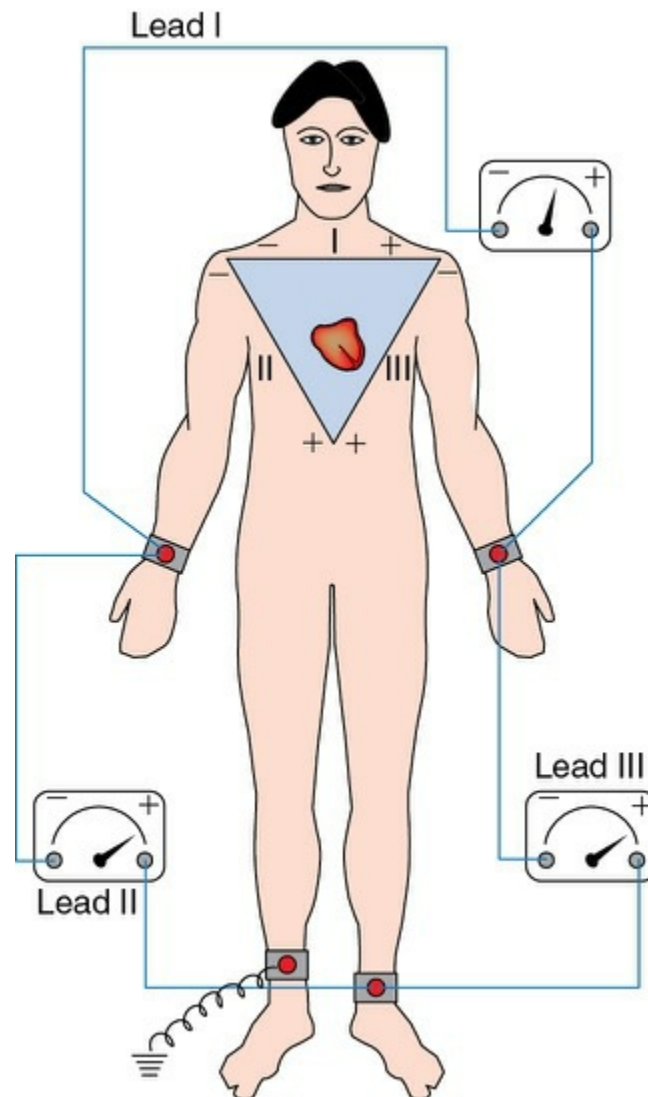

FIGURE 4.2-9 Einthoven's triangle and position of electrodes for standard limb leads (I, II and III).

In three standard limb leads, the two active electrodes are connected as:

- **Lead I (LI).**

In LI, the two active electrodes are connected to LA and RA.

- LA electrode is connected to the positive terminal and

- RA electrode is connected to the negative terminal of the ECG machine.

- **Lead II (II).**

In II, the electrodes are connected to RA and LF.

- LF electrode is connected to the *positive* terminal and
- RA electrode is connected to *negative* terminal of the ECG machine.

- **Lead III (LIII).**

In LIII, the electrodes are connected to LA and LF.

- LF electrode is connected to the positive terminal and
- LA electrode is connected to negative terminal of the ECG machine.

The position of electrodes in bipolar standard limb leads has been shown in [Fig. 4.2-9](#). The direction in which positive electrode points is called the axis of the lead. The direction of the lead axis is same in which the current flows in the heart and recorded deflection is upwards (positive). The electrodes are arranged in such a way that most of the deflection recorded in ECG is positive.

Unipolar leads

In unipolar recording, one electrode is *active* or the *exploring* electrode and the other is an *indifferent electrode* at zero potential. The potential at the indifferent electrode remains zero, so in unipolar recording, the records obtained represent the potential fluctuations occurring at the site of exploring electrode.

In a volume conductor, the sum of potentials at the points of an equilateral triangle with a current source at the centre is zero at all times. Therefore, if the three electrodes (placed on LA, RA and LF) are connected to a common terminal, through a resistance, an indifferent electrode that stays near zero potential is obtained. In clinical electrocardiography, two types of unipolar leads are used.

Unipolar chest leads.

There are six unipolar chest leads (precordial leads) designated V_1 to V_6 . The indifferent electrode is obtained as described above and the active electrode is placed on six points on the chest as given below ([Fig. 4.2-10](#)).

- *Lead V₁*: In the right fourth intercostal space, just near the sternum.
- *Lead V₂*: In the left fourth intercostal space, just near the sternum.
- *Lead V₃*: Halfway between V₂ and V₄.
- *Lead V₄*: In the left fifth intercostal space at midclavicular line.
- *Lead V₅*: In the left fifth intercostal space at anterior axillary line.
- *Lead V₆*: In the left fifth intercostal space at mid axillary line.

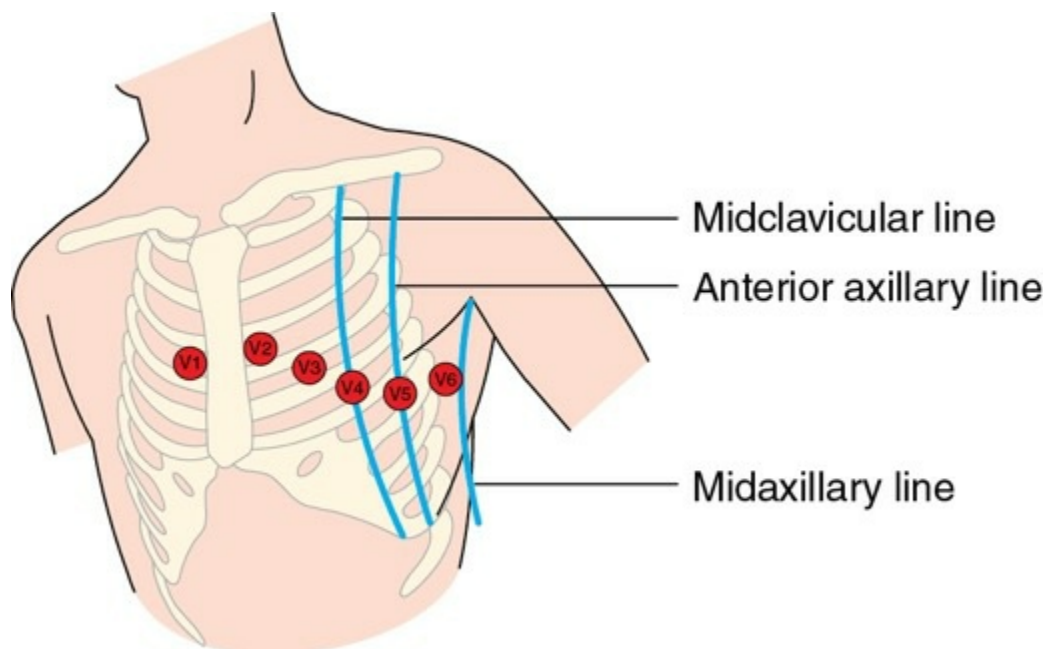

FIGURE 4.2-10 Position of electrodes for chest leads (V₁–V₆).

Unipolar limb leads.

These include lead VL, VF and VR. In unipolar limb leads, one *exploring* (active) *electrode* is placed over a limb (In lead VL over the left arm, in VF over the left foot and in lead VR over the right arm), and is connected to the positive terminal of the electrocardiograph. The *indifferent electrode* is obtained as described above and is connected to the negative terminal of the electrocardiograph. These leads are not used and have been replaced by augmented limb leads.

Augmented unipolar limb leads.

Generally augmented unipolar limb leads designated as aVR, aVL and aVF are used. In augmented leads, the size of potential is increased by 50% without any change in the configuration from the nonaugmented record. The *active electrode* is from one of the limbs, and the indifferent electrode is obtained by connecting the other two limbs through 5000 ohms resistance as:

- Lead aVR: Active electrode is from right arm (RA) and indifferent electrode is from left arm (LA) + left leg (LF).
- Lead aVL: Active electrode is from LA and indifferent electrode is from RA + LF.
- Lead aVF: Active electrode is from LF and indifferent electrode is from RA + LA.

Why these leads are called augmented leads is explained below.

Suppose in non augmented unipolar limb leads, the potential at left arm (VL) = right arm (VR) = left foot (VF)

Then,

$$aVF = VL - (VR + VF)/2$$

Or

$$2aVF = 2VL - (VR + VF) \quad \dots\dots \text{equation I}$$

In Einthoven triangle, if electrodes are connected to three limbs through a high resistance, then

$$VL + VR + VF = 0$$

Or

$$VL = -(VR + VF) \quad \dots\dots \text{equation II}$$

Substituting value of $-(VR + VF)$ in equation I, then

$$2aVL = 2VL + VL$$

Or

$$aVL = 3/2VL$$

Thus potential recorded in aVL is one and half times as that of recorded in VL.

Electrocardiograph

The electrocardiograph (ECG machine) is essentially a sophisticated string galvanometer. A modern electro-cardiograph amplifies and records the potential fluctuations on a moving strip of paper. Following recording mechanisms are used:

- Some machines have a writing ink pen that records directly on the moving sheet of paper.
- In other machines instead of ink pen, special paper is used which turns black on exposure to heat. The stylus (recording pen) is made hot by electrical current flowing through its tip.

Calibration of time and voltage on ECG paper

- The special ECG paper having 1 mm and 5 mm squares ([Fig. 4.2-11](#)) is used. The tracing is usually made at a standard recording speed of 25 mm/s.
- On horizontal axis, therefore, each millimetre represents 0.04 s (1/25).
- The sensitivity of electrocardiograph is adjusted in such a way that a potential fluctuation of 1 mV causes a vertical deflection of 1 cm. Thus, on vertical axis each millimetre represents 0.1 mV magnitude of potential.

FIGURE 4.2-11 Calibration of time and voltage (amplitude) on special ECG paper.

Normal electrocardiogram

Electrocardiogram (ECG) refers to the record of the potential fluctuations during the cardiac cycle. As a result of sequential spread of the excitation in the atria, the interventricular septum and the ventricular walls (Fig. 4.2-7) and finally repolarization of the myocardium, a series of positive and negative waves designated as P, Q, R, S and T are recorded during each cardiac cycle. Depolarization moving towards an active electrode in a volume conductor produces a positive deflection, whereas depolarization moving in the opposite direction produces a negative deflection.

Therefore, the shape and polarity of P, Q, R, S and T waves will vary in different leads due to differences in the orientation of each lead with respect to the heart (Fig. 4.2-12). Configuration of a typical electrocardiogram from a bipolar limb lead II (LII) is described below (Fig. 4.2-11).

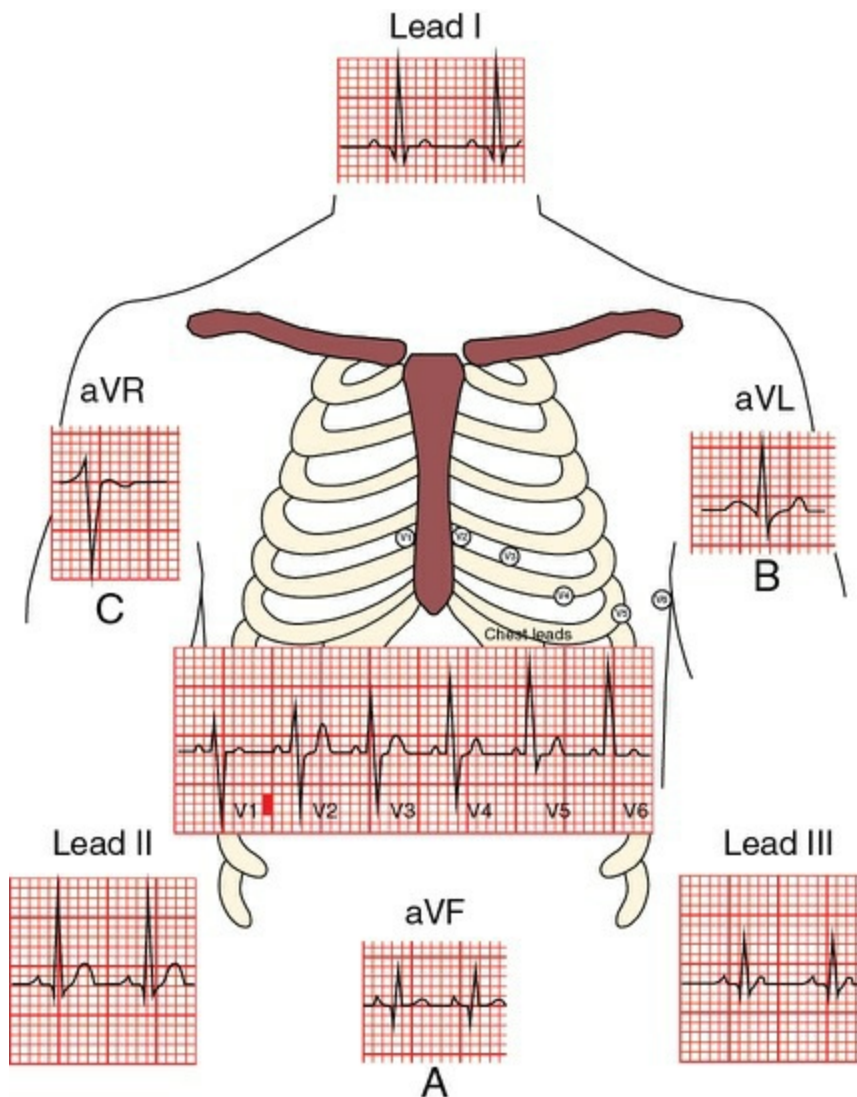

FIGURE 4.2-12 The electrocardiographic complexes recorded from different leads.

Waves of ECG

P wave

- **Configuration.**

P wave is the positive (upright rounded deflection).

- **Cause.**

It is produced by the depolarization of atrial musculature so also called atrial complex.

- **Duration**

of P wave is not more than 0.1 s.

- **Amplitude**

of P wave is from 0.1 to 0.12 mV.

- **Clinical significance.**

Magnitude of P wave is a guide to the functional activity of atria.

- In mitral stenosis the left atrium is hypertrophied and P wave becomes larger and prolonged.
- In tricuspid stenosis right atrium is hypertrophied and P wave becomes tall (0.5 mV) and peaked with normal duration.
- In atrial fibrillation P wave disappears and replaced by fine irregular oscillations.
- When the cardiac impulse arises from an ectopic pacemaker, the P wave is altered or even inverted.

QRS complex

- **Configuration.**

QRS complex consists of three consecutive waves. Q wave is a small negative wave which may be absent normally quite often. It is continued as a tall positive R wave which is followed by a small negative S wave.

- **Cause.**

The QRS complex is caused by ventricular depolarization.

- **Duration**

of QRS Complex is Normally less than 0.08 s. It is a Measure of Intraventricular Conduction Time.

- **Amplitude**

of Q Wave is 0.1–0.2 mV, R wave is 1.0 mV, and S wave is 0.4 mV (total 1.5–1.6 mV).

- **Clinical significance.**

QRS complex from precordial leads are more important than limb leads.

- Deep Q wave (more than 0.2m V) along with other changes is an important sign of myocardial infarction (MI).

- Tall R wave (more than 1.3 mV) is seen in ventricular hypertrophy.
- Low-voltage QRS complex (total sum less than 1.5 mV) is seen in hypothyroidism and pericardial effusion.
- QRS complex is prolonged in bundle branch block. Prolonged QRS complex is seen when one or both the ventricles are hypertrophied or dilated.

In blockage of Purkinje system, the QRS complex is abnormally prolonged (>0.12 s) due to decrease in impulse conduction.

Bizarre pattern of QRS complex is caused by destruction of cardiac muscle in ventricular region, and local blockages in the Purkinje system resulting in irregular impulse conduction, rapid shifts in voltages and axis deviations.

T wave

• Configuration.

T wave is the last, positive, dome-shaped deflection. Normally it is in the same direction as QRS complex, because ventricular repolarization follows a path opposite to depolarization.

• Cause.

T wave represents ventricular repolarization.

• Duration

of T wave is approximately 0.27 s.

• Amplitude

of T wave is about 0.3 mV.

• Clinical significance

- In old age, T wave is flattened.
- Exercise increases its amplitude in healthy hearts.
- Inverted T wave is an important sign of myocardial ischaemia or infarction.
- Tall and peaked T wave occurs in hyperkalaemia.

Important Note

Digitalis toxicity – Digitalis is a drug used for increasing the strength of cardiac muscle (glycoside). Nonspecific changes in T wave (inversion of T wave, biphasic T wave) may occur, biphasic T wave is the earliest sign of digitalis toxicity.

U wave

- **Configuration.**

It is a small round positive wave.

- **Cause.**

It occurs due to slow repolarization of papillary muscle.

- **Duration**

of U wave when present is 0.08 s.

- **Amplitude**

of U wave is about 0.2 mV.

- **Significance.**

It is rarely seen normally. It becomes prominent in hypokalemia.

Note: Since atrial repolarization coincides ventricular depolarization, so it is merged with QRS complex and thus not recorded as a separate wave.

Intervals and segments of ECG

P–R interval

It is measured from the onset of P wave to the onset of the QRS complex. Actually it is PQ interval but Q wave is frequently absent therefore it is called P–R interval.

- It measures the *AV conduction time*, including the AV nodal delay.
- Its *duration* varies from 0.12 to 0.21 sec depending on the heart rate.
- *Clinical significance.* Prolonged PR interval indicates AV conduction block. First degree block is produced when PR interval is between 0.2 and 0.3 s and second degree block is produced when PR interval is

increased (0.3–0.45 s).

J point

J point refers to the point on ECG which coincides with the end of depolarization and start of repolarization of ventricles, i.e. it occurs at the end of QRS complex. At this point, since all parts of the ventricles are depolarized no current flows around the heart. Therefore, at J point the potential of ECG is exactly zero voltage.

QT interval

It is the time from the start of the QRS complex to the end of T wave.

- It indicates total *systolic time of ventricles*, i.e. ventricular depolarization and repolarization.
- *Duration* of QT interval is about 0.4 s (QRS duration and ST segment duration).
- *Clinical significance*. Ischaemia and any ventricular conduction defects prolong the QT interval. In hypocalcaemia also QT interval is prolonged.

TP interval

It is measured from the end of T wave to the beginning of P wave.

- It measures the *diastolic period* of the heart.
- Variable TP interval indicates AV dissociation.

P–P interval

P–P interval is the interval between two successive P waves. Equal P–P intervals indicate rhythmic depolarization of the atria.

ST segment

It is an isoelectric period between the end of QRS complex and beginning of T wave.

- Its *duration* is about 0.32 s.
- It corresponds with *ventricular repolarization*.

- *Clinical significance.* ST segment is elevated in patients with MI. In fact, whenever there is current of injury the TP segment shifts away from the zero and so it does not remain at the same potential level as ST segment. However, since in ECG, TP is considered as reference potential level, so whenever a current of injury is evident in ECG, it is called ST segment shift.

Characteristic features of ECG complex in unipolar chest leads

The ECG complex produced in unipolar chest leads (V_1 – V_6) represents the electrical activity of the part of the heart which lies nearest to the active electrode (Fig. 4.2-13).

FIGURE 4.2-13 Pattern of QRS complex in chest leads (V_1 – V_6).

P wave

is positive in all the leads because the excitation wave moves from SA node to AV node, i.e. posterior to anterior.

QRS complex

represents the electrical activity of ventricles and so its configuration changes in different leads are as below.

- In V_1 and V_2 (which reflect right ventricular activity), the main QRS complex is *negative*.
- In V_3 and V_4 (which reflect activity of both ventricles including interventricular septum), the main QRS complex is *biphasic*.
- In V_5 and V_6 (which reflect left ventricular activity), mainly the main QRS complex is *positive*.

Thus as shown in [Fig. 4.2-13](#),

• R wave

gradually increases in size from V_1 to V_6 leads. In leads V_1 , R wave represents activity of right ventricle and in V_6 of left ventricle.

• S wave

gradually decreases in size from lead V_1 to V_6 . In lead V_1 , S wave represents activity of left ventricle and in lead V_6 of right ventricle.

Characteristic features of ECG complex in unipolar limb leads and augmented limb leads

The ECG complex in unipolar limb leads and augmented limb leads is characterized by the electrical activity of that part of the heart which faces the active electrode of that particular unipolar limb lead as:

Lead VF and aVF.

These leads reflect the electrical activity of inferior surface of the heart which is formed by parts of both right and left ventricles and interventricular septum. Therefore, QRS complex in these leads like that of V_3 and V_4 is predominantly *biphasic* ([Fig. 4.2-12A](#)).

Lead VL and aVL.

These leads reflect the electrical activity of left outer side of the heart which is mainly formed by the left ventricle. Therefore, QRS complex in these leads like that of V_6 is predominantly *positive* (Fig. 4.2-12B).

Lead VR and aVR.

These leads reflect the activity of the cavity of the ventricles, irrespective of the position of heart. Therefore, *P wave, QRS complex and T wave* all are *negative deflection* (Fig. 4.2-12C).

Vectorial analysis of electrocardiogram and vector cardiography

In the discussion until this point, we have studied the configuration of various positive and negative waves of the ECG complex and their clinical significance. In addition to the information gained from the changes in the configuration of various waves, the vectorial analysis of the electrocardiogram also provides many useful information pertaining to cardiac abnormalities. The concept of cardiac vector, methods of vector analysis and their clinical significance are discussed.

Concept of cardiac vectors

- During cardiac cycle (depolarization and repolarization of heart), current flows in the heart at every instant. The magnitude and direction of the potential generated can be represented in the form of an arrow which is called a vector. By convention, the arrow head points towards the direction and the length of the arrow is drawn proportional to the voltage of the potential.
- During most of the cycle of ventricular depolarization, direction of electrical potential (negative to positive) is from the base of ventricles towards the apex. This preponderant direction of potential during depolarization is called the *mean QRS vector* (mean electrical axis (MEA) of the heart) and is drawn through the centre of the ventricles in a direction from the base of the heart toward the apex (Fig. 4.2-14).
- The *instant vector*, however, represents the magnitude and direction of potential at a particular instant during the cardiac cycle. The instantaneous vectors of 5 different instants during the process of

ventricular depolarization are shown in [Figure 4.2-15](#).

FIGURE 4.2-14 Instantaneous mean vector during ventricular depolarization.

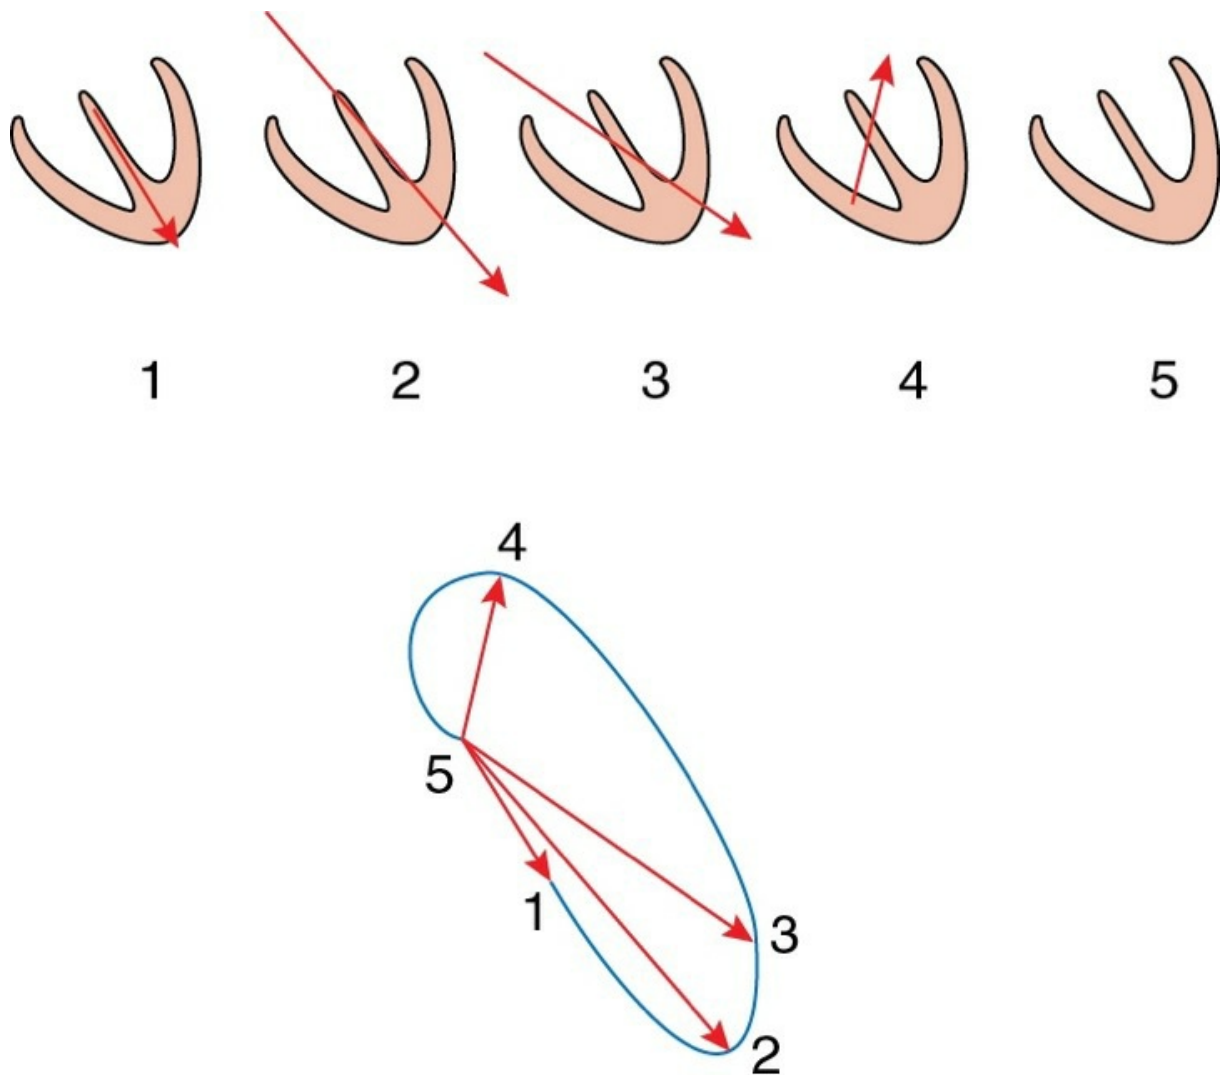

FIGURE 4.2-15 The instantaneous mean vector of five different instants during process of ventricular depolarization and construction of QRS vector cardiogram.

Calculating the MEA from standard lead electrocardiogram

As discussed earlier, the MEA refers to the *mean vector* produced during a cardiac cycle (i.e. by P, QRS and TP, ECG complex).

- In the frontal plane, MEA can be calculated from any two standard (i.e. bipolar) limb leads (using Einthoven's triangle or triaxial reference system) or any two augmented limb leads (using hexa-axial reference system).
- The MEA in the horizontal plane is derived using the precordial (chest) leads.

Triaxial reference system

involves moving the sides of Einthoven's triangle so that they intersect at the centre of triangle. Lead I then divides the system into an upper (negative) and a lower (positive) hemisphere. The triaxial system of representation reveals that (Fig. 4.2-16B):

- The axis of lead I is 0° , because the electrodes lie in the horizontal direction with positive electrode to the left,
- The axis of lead II is about 60° as the electrodes are placed on the right arm (negative) and left leg (positive) and
- The axis of lead III is about 120° , as the electrodes are placed on the left arm (negative) and left leg (positive).

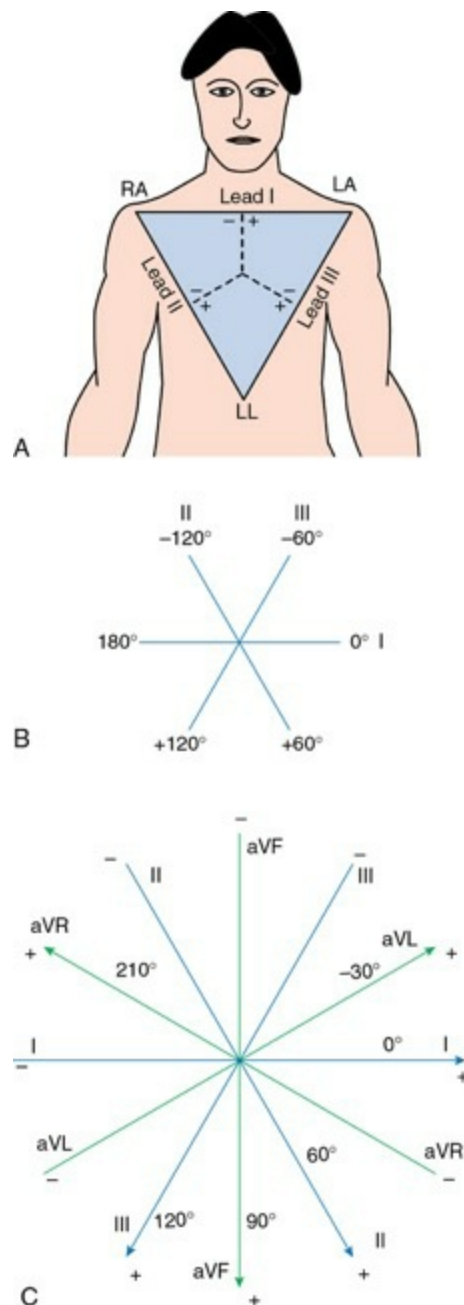

FIGURE 4.2-16 Schematic drawing for calculating the mean electrical axis (MEA): **A**, Einthoven triangle and connections of bipolar limb leads; **B**, the triaxial reference system in which lead I, II and III collapsed into their respective zero points and **C**, the hexa-axial reference system obtained by adding augmented unipolar limb leads (aVR, aVL and aVF) to triaxial system.

The hexa-axial reference system

involves super-imposition of the axis of augmented limb leads on the triaxial system. The hexa-axial system of vector representation reveals that (Fig. 4.2-16C):

- The axis of lead aVF is 190° ,
- The axis of lead aVR is 210° and
- The axis of lead aVL is -30° .
- *Clinically the frontal MEA of the QRS complex is more useful and is determined from the two standard limb leads as:*
- The Q and S waves (negative values) are added algebraically to the R wave (positive value) for each of two leads. The result gives the magnitude and the direction of the QRS vector (+ or -) in each lead. For example:
 - In lead I, the algebraic sum of Q (-3), R (+13), S (-5) = $-3 + 13 - 5 = 5$ mV and
 - In lead III, the algebraic sum of the Q (-1), R (+15), S (-0) = $-1 + 15 - 0 = +14$ mV.
- The QRS magnitude is plotted along the respective leads from the zero point towards the appropriate polarity with the arrow pointing towards the correct pole (positive or negative using the Einthoven triangle (Fig. 4.2-17) or the triaxial reference system.
- Perpendiculars are then drawn from the leads of the two vectors until they intersect.
- The intersection marks the head of the mean electrical vector. The MEA is then drawn from the centre of the triangle (electrical zero for the system) to the perpendiculars' intersection. The length of this arrow represents the magnitude of the MEA, and its direction in degrees represents the electrical axis in the frontal plane.

- The MEA of normal ventricles lies between -30° and $+120^{\circ}$ when plotted on the hexa-axial reference system or (2 and 7 O'clock, respectively, if the hexa-axial system is considered a clock face Fig. 4.2-18A). Usually, the normal MEA is 59° , i.e. 5 O'clock positive (Fig. 4.2-17).

FIGURE 4.2-17 Plotting the mean electrical axis (MEA) of the ventricles from two electrocardiographic leads (leads I and III).

FIGURE 4.2-18 **A**, Mean electrical axis (MEA) in the frontal plane (using hexa-axial system) showing normal axis, right axis deviation (RAD) and left axis deviation (LAD); and **B**, QRS complexes (normal in RAD and in LAD) seen in leads I, II and III.

Abnormalities of MEA

1. Right axis deviation (RAD)

is said to be present when the MEA lies between $+120^\circ$ and $+180^\circ$ (7 and 9 O'clock position). [Figure 4.2-18](#) shows QRS complex that occurs in RAD.

Causes of RAD include:

- Right ventricular hypertrophy secondary to chronic lung disease or pulmonary valve stenosis.
- RBB block causing delayed activation of the right ventricle and
- Posterior (or inferior) MI.

2. Left axis deviation (LAD)

is said to be present when the MEA lies between -30° and -90° (or 2 and 12 O'clock). [Figure 4.2-18](#) shows typical QRS complex that occurs in LAD.

Causes of LAD are:

- Left ventricular hypertrophy,
- Obesity,
- Left bundle branch block and
- Anterolateral MI.

Vector cardiography

As discussed earlier, the vector of current flow through the heart changes rapidly as the impulse spreads through the myocardium. The vector changes into two aspects:

- Increase or decrease in length corresponding to change in voltage (magnitude) and
- Changes its direction because of changes in the average direction of the electrical potential of the heart.

[Figures 4.2-15](#) and [4.2-19](#) show the instant vectors of 8 different successive instants during the process of ventricular depolarization (i.e. in a normal QRS complex). On joining the positive ends of the vectors a loop is obtained which is called *vector cardiogram*.

FIGURE 4.2-19 Instant vector of eight arbitrary stages of ventricular depolarization and reconstruction of QRS complex from QRS loop for three bipolar limb leads. Arrows indicate the direction of loop recording.

A continuous record of all the vectors is made using an *oscilloscope*. The procedure is called vector cardiography and the record obtained in the form of a loop called vector cardiogram (similar to P, QRS and T that described above). Three loops can be recorded during one cardiac cycle (Fig. 4.2-20). Atrial depolarization cannot be recorded with standard technique of vector cardiography because of the prolonged time course and small voltages involved.

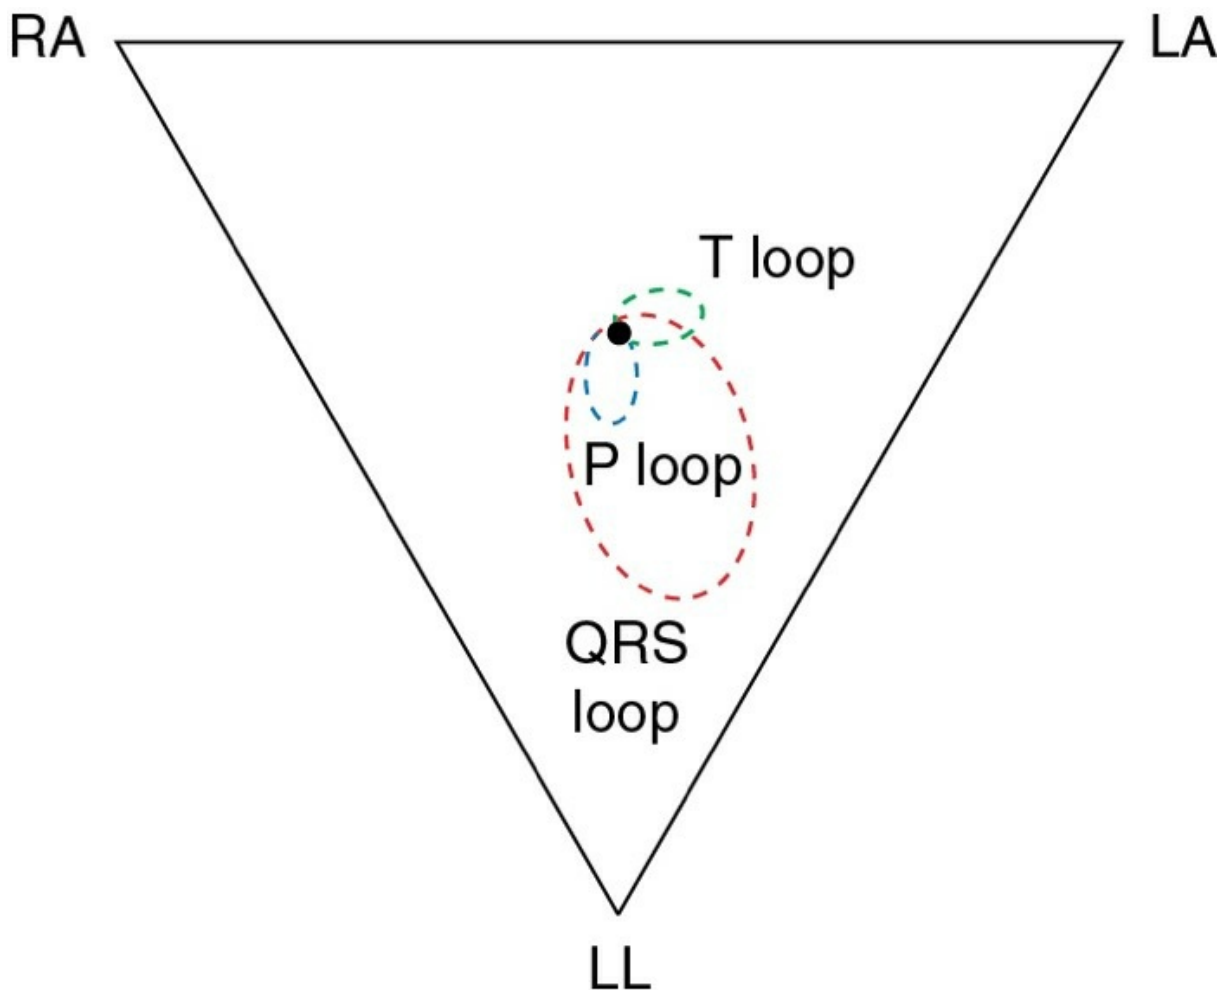

FIGURE 4.2-20 The vector cardiographic loops P, QRS and T.

1. P loop.

It is caused by atrial depolarization. It is small and is directed leftward and inferiorly, resulting in a positive P wave in three bipolar limb leads.

2. QRS loop.

It is caused by ventricular depolarization. The normal QRS loop is inscribed counterclockwise and is directed leftward, inferior and posterior. [Figure 4.2-19](#) shows, how the QRS loop generates the QRS complex in three limb leads.

3. T loop.

It results from ventricular repolarization, which is roughly opposite in direction to the depolarization. This reversal of direction results in T wave that normally is in the same direction as the QRS complex.

His bundle electrogram

- His bundle electrogram (HBE) refers to recording the electrical activity of the heart obtained through the intracardiac ring electrodes placed near the tricuspid valve.
- It is accomplished with a catheter containing ring electrodes at its tip that is passed through a vein to the right side of heart and manipulated into a position close to the tricuspid valve. Three or more standard electrocardiographic leads are recorded simultaneously.
- Normal HBE shows the following deflections ([Fig. 4.2-21](#)).
- *A deflection*, which corresponds to activation of AV node,
- *H spike*, is due to transmission of impulse through the His bundle and
- *V deflection* is produced during ventricular depolarization.

FIGURE 4.2-21 Normal His bundle electrogram (HBE) with simultaneously recorded ECG.

Uses of HBE

It is especially useful in patients with heart blocks. From the HBE and ECG from standard leads it is possible to accurately time the following three intervals:

- **PA interval.**

It is the time from the first appearance of atrial depolarization to the A wave in HBE. It represents conduction time from the SA node to AV node. Normal value of PA interval is 27 ms.

- **AH interval.**

It is the time from the A wave to the start of H spike in HBE. It represents the AV nodal conduction time. Normal value of AH interval is 92 ms; the higher value of AH interval shows relative slowness of conduction in the

AV node.

- **HV interval.**

It is the time from the start of the H spike in HBE to the start of QRS complex deflection in the ECG. It represents conduction in the bundle of His and the bundle branches. Normal value of HV interval is 43 ms.

Clinical applications of electrocardiography

ECG is an indispensable tool in the diagnosis, prognosis and planning treatment in most of the cardiac disorders. The important applied aspects which need special mention are:

- Cardiac arrhythmias,
- Myocardial infarction,
- Hypertrophy of various cardiac chambers and
- Effects on ECG of changes in the ionic composition of blood.

Cardiac arrhythmias

Cardiac arrhythmias refers to disruption of the normal cardiac rhythm. The normal cardiac rhythm implies a regular sinus rhythm with a normal cardiac rate, between 60 and 100 beats/min (average 72 beats/min). *Sinus rhythm* is said to be present when the SA node is pacemaker, and each P wave is followed by a normal QRS complex, the P–R and Q–T intervals are normal, and R–R interval is regular. Cardiac arrhythmias may be discussed as:

- Abnormal sinus rhythm,
- Conduction disturbances (heart blocks) and
- Ectopic cardiac rhythm.

Abnormal sinus rhythm

Sinus arrhythmia

- Sinus arrhythmia (Fig. 4.2-22B) is characterized by a normal sinus rhythm except for the R–R interval (cardiac rate) which varies in a set

pattern.

- Sinus arrhythmia is usually, but not always synchronized with respiration. Usually, heart rate increases during inspiration and decreases during expiration, as a result of variations in vagal tone that affect the SA node. During inspiration, impulses from lung stretch receptors carried by vagii inhibit cardioinhibitory area (vagal centre) in the medulla, resulting decrease in tonic vagal discharge (vagal tone) and rise in heart rate.
- Sinus arrhythmia is common in children and in endurance athletes with slow heart rates.

FIGURE 4.2-22 Electrocardiogram tracings showing: **A**, normal sinus rhythm; **B**, sinus arrhythmia; **C**, sinus tachycardia; and **D**, sinus bradycardia.

Sinus tachycardia

- Sinus tachycardia (Fig. 4.2-22C) is characterized by a normal sinus rhythm except for increased heart rate (i.e. decreased but regular R–R

interval). Tachycardia is labelled when heart rate is more than 100 beats/min.

- Sinus tachycardia is a normal response to exercise and is also associated with fever, hyperthyroidism and as a reflex response to low arterial pressure.

Fever. The heart rate increases by 10 beats/min for each degree Fahrenheit (18 beats/min/°C) rise in body temperature up to 105 °F (40.5 °C); with further rise in body temperature, heart rate may decrease due to debility of heart muscle. Tachycardia in fever occurs due to increase in metabolic rate of SA node which directly increases its excitability.

Sympathetic activity. Factors which increase sympathetic activity also lead to tachycardia, e.g. hypovolemic shock (as a reflex response to low arterial pressure), exercise, hyperthyroidism. For details see page 256.

Sinus bradycardia

- Sinus bradycardia (Fig. 4.2-22D) is characterized by a normal sinus rhythm except for decreased heart rate (i.e. increased but regular R–R interval). Bradycardia is labelled when heart rate becomes less than 60 beats/min.
- Sinus bradycardia is more commonly seen in highly trained endurance athletes due to increased vagal tone, sometimes it may be abnormal.

Carotid sinus syndrome.

In patients with carotid sinus syndrome, the baroreceptors present in carotid sinus are very sensitive, even mild pressure on the neck elicits strong baroreceptor reflex to cause bradycardia, sometimes heart may stop for 5–10 s. For baroreceptor reflex details see page 340.

Sick sinus syndrome

- Sick sinus syndrome refers to a condition characterized by marked bradycardia accompanied by dizziness and syncope.
- *Causes* of sick sinus syndrome include:
- Sinus bradycardia that does not improve with sympathetic stimulation or vagal inhibition.

- SA nodal block (see below) and
- Sinus arrest, i.e. complete stoppage of sinus discharge.
- *Treatment*, when the condition causes severe symptoms, consists of implantation of artificial pacemaker. Sinus node dysfunction accounts for over half of the pacemaker implants.

Pacemakers are the electronic devices that sense and pace the activity of the chambers of the heart by programming in most physiological way to maintain the cardiac output. The artificial pacemakers are the stimulators planted underneath the skin and electrodes are usually connected to right ventricles to provide rhythmical impulses to ventricles.

Conduction disturbances (heart blocks)

Heart blocks refer to slowing down or blockage of cardiac impulse (generated from SA node) along the cardiac conductive pathway. Conduction blockage may occur as:

- SA nodal block,
- AV nodal block and
- Bundle branch block.

SA nodal block

- SA nodal block or the so-called SA block is characterized by the blockage of impulse conduction from SA node to atria.
- It occurs in the elderly and in patients recovering from coronary artery occlusion.
- It occurs suddenly and initially the heart stops (i.e. neither atria nor ventricles contract for a while). After an interval of approximately two cardiac cycles, the AV node becomes the pacemaker, and the heart starts functioning again. This is called *AV nodal rhythm*.
- SA block may manifest as *sick sinus syndrome* (described above).

- AV nodal rhythm also called *junctional rhythm* (Fig. 4.2-23) is characterized by inverted P wave and normal QRS complex, and the rate is slower than sinus rhythm.

FIGURE 4.2-23 AV nodal rhythm seen in SA node blockage.

AV nodal block.

AV nodal blockage may occur as *incomplete heart block* (which includes first-degree and second-degree heart blocks) or complete heart block (third-degree heart block). AV nodal blockages are associated with following conditions:

- *Coronary insufficiency* can cause AV nodal ischaemia.
- *Compression of AV node* by scar tissue or by calcification.
- *Inflammation of AV node* results due to myocarditis can depress conduction of impulse from atria to ventricles.
- *Vagal excitation* results due to strong stimulation of baroreceptors in carotid sinus syndrome.

First-degree AV nodal block.

First-degree AV nodal (or heart) block is characterized by slowing of conduction at the level of AV node. Though all the atrial impulses reach the ventricles but the PR interval is abnormally long, i.e. more than 0.21 s (Fig. 4.2-24B), but seldom increases more than 0.30 s.

FIGURE 4.2-24 Various types of AV nodal blocks: **A**, normal sinus rhythm; **B**, first-degree AV block; **C**, second-degree AV block (2:1); **D**, 3:1 block; and **E**, complete AV block (third degree).

Second-degree AV nodal block.

In second-degree AV nodal block (Fig. 4.2-24C and D), not all atrial impulses are conducted to ventricles. It is usually associated with organic heart diseases. Consequently, there may be one ventricular contraction after every 2, 3 or 4 atrial contractions producing the so-called 2:1, 3:1 or

4:1 block (*constant block*). Other forms of second degree heart blocks are:

- **Wenckebach phenomenon (mobitz type I block).**

It is characterized by a progressive lengthening of the P–R interval in successive beats and finally a failure of one impulse to be transmitted.

- **Periodic block (mobitz type II).**

It is characterized by an occasional failure of conduction that results in an atrial to ventricular rate of for example 6:5 or 8:7. The P–R interval is constant.

Third-degree (complete) AV nodal block.

- In third-degree complete AV block, no impulse from atria can pass to the ventricles.
- Therefore, ventricles start beating at their own rhythm (about 40 beats/min) called idioventricular rhythm.
- The atria, however, continues to beat at the normal sinus rhythm of about 72 beats/min. Thus, ECG shows that there is complete dissociation between P waves and QRS complexes called *atrioventricular dissociation*. (Fig. 4.2-24E).
- Third-degree block is *caused* by organic heart diseases, septal myocardial infarction and damage to bundle of His during surgical repair of congenital interventricular septal defects.
- Third-degree block may be associated with prolonged ventricular standstill (asystole) until a ventricular focus begins firing. The asystole, lasting for a minute may result in cerebral ischaemia producing dizziness and fainting (syncope), the condition is termed *Stokes–Adams' syndrome*. Even death may also occur due to prolonged cerebral ischaemia.

Treatment. Mostly these patients are provided with artificial pacemakers.

Bundle branch block

- Bundle branch block refers to conduction blocks in one or more

branches of the bundle of His.

- In this condition, excitation passes normally down the bundle on the intact side and then sweeps back through the muscle to activate the ventricle on the blocked side.
- Therefore, the ventricular rate is normal, but the QRS complexes are prolonged (beyond 0.12 s) and deformed (Fig. 4.2-25). The characteristic features of the branch involved are:

FIGURE 4.2-25 Electrocardiogram characteristics in bundle branch blocks: **A**, right bundle branch block; and **B**, left bundle branch block.

- **Right bundle branch block (RBBB)**

may occur in otherwise healthy individuals or secondary to chronic pulmonary disease. The activation of right ventricle is delayed and ECG may show features of RAD (Fig. 4.2-25A).

- **Left bundle branch block (LBBB)**

is usually associated with organic heart disease. It is best diagnosed using left precordial leads (Fig. 4.2-25B).

- **Hemiblock or fascicular block**

refers to block in either anterior or posterior fascicle of LBB. Left anterior hemiblock (LAH) produces abnormal LAD in ECG, whereas left posterior hemiblock (LPH) produces abnormal RAD.

- **Bifascicular block,**

i.e. RBBB with LAH or LPH is not uncommon.

- **Trifascicular block,**

i.e. RBBB with LAH and LPH may also occur.

Note: HBE is useful for detailed analysis of the site of block when there is a defect in the conduction system.

Ectopic cardiac rhythm

Ectopic cardiac rhythm refers to abnormal cardiac excitation produced either by an ectopic focus or a re-entry phenomenon. Ectopic cardiac rhythm includes the following conditions:

A. Atrial arrhythmias

1. Atrial extra systole,
2. Paroxysmal atrial tachycardia,
3. Atrial flutter and
4. Atrial fibrillation.

B. Ventricular arrhythmias

1. Ventricular extrasystole,
2. Paroxysmal ventricular tachycardia and
3. Ventricular fibrillation.

Mechanisms of development of cardiac arrhythmias

Cardiac arrhythmias may result from *ectopic foci of excitation* and/or re-entry mechanism.

1. Ectopic foci of excitation

Under normal circumstances, SA node acts as a pacemaker since its rate of rhythmic discharge is more rapid than the rate of discharge of other parts of conduction system and myocardium of heart. However, in certain abnormal conditions, the His–Purkinje fibres or the myocardial fibres become hyperexcitable and discharge spontaneously. In these conditions, increased automaticity of the heart is said to be present. The site in the heart which becomes hyperexcitable is called an *ectopic focus* which may behave as:

- **Single discharge.** When the irritable ectopic focus discharges once, an *extra systole* or *premature* beat is caused before the next normal beat. Depending upon the site of ectopic focus the premature beat may be atrial, nodal or ventricular.
- **Repetitive discharge.** If the ectopic focus discharge impulses repeatedly at a rate higher than that of SA node, the tachycardia with very high rate (tachyarrhythmias) results. Depending upon the rate and rhythm and the site of ectopic focus, the tachyarrhythmias are named as:
 - Paroxysmal tachycardia (atrial, nodal and ventricular),
 - Atrial flutter,
 - Atrial fibrillation and
 - Ventricular fibrillation.

2. Re-entry mechanism

Re-entry mechanism or the circus movement refers to a phenomenon in which the wave of excitation propagates repeatedly (continuously) within a closed circuit. It is a more common cause of tachyarrhythmias. Re-entry of excitation wave is known to occur under two situations: (1) in the presence of transient block in the conduction pathway and (2) in the presence of an abnormal extra bundle of conducting tissue called bundle of Kent.

Re-entry due to transient block in the conduction system

- Normally, during depolarization of a ring of cardiac tissue, the impulse

spreads in both directions of the ring (Fig. 4.2-26A) and the tissue behind each branch of the impulse is refractory and thus the impulse cannot go down the other side.

- When there is a transient block on one side, the impulse can go down on the other side of ring (Fig. 4.2-26B), because this portion is not depolarized and so not refractory.
- If the transient block is worn off, the impulse from retrograde direction is conducted through this (previously blocked) area and then continues to circle indefinitely. This phenomenon is called circus movement or re-entry phenomenon (Fig. 4.2-26C).
- The site of re-entry keeps on producing impulses continuously. If the re-entry is in AV node, the re-entrant activity depolarizes the atrium and the resulting atrial beat is called an *echo beat*. In addition, the re-entrant activity in the node propagates back down to ventricles producing paroxysmal nodal tachycardia. The re-entrant activity can also become established in atrial muscle fibres (producing atrial tachycardias, flutter or fibrillation) and in ventricular muscle fibres (producing ventricular tachycardia or ventricular fibrillation).

FIGURE 4.2-26 Re-entry phenomenon or circus movements, a cause of cardiac arrhythmias; **A**, normal depolarization of a ring cardiac tissue; **B**, spread of wave of excitation in presence of transient block; and **C**, circus movement.

Re-entrant activity in the presence of bundle of Kent

- Bundle of Kent is an abnormal extra bundle of conducting tissues present in some individuals. This bundle connects the atria and ventricles directly, so the conduction is very rapid than through the regular conductive system.
- If a transient block develops in the normal conductive system, the impulse from SA node reaches the ventricle through the bundle of

Kent and produces excitation. If the blockage in the normal conduction system wears off, then the excitation wave from the ventricle travels in the opposite direction and re-enter the AV node and a circus movement is established (Fig. 4.2-27).

- This re-entrant activity produces echo beat in atria and nodal paroxysmal tachycardia or the so-called supraventricular tachycardia.
- The nodal paroxysmal tachycardia occurring in patients with bundle of Kent is called *Wolff–Parkinson–White syndrome*, producing short PR interval, prolonged slurred QRS deflection but normal PJ interval (start of P wave to end of QRS complex).

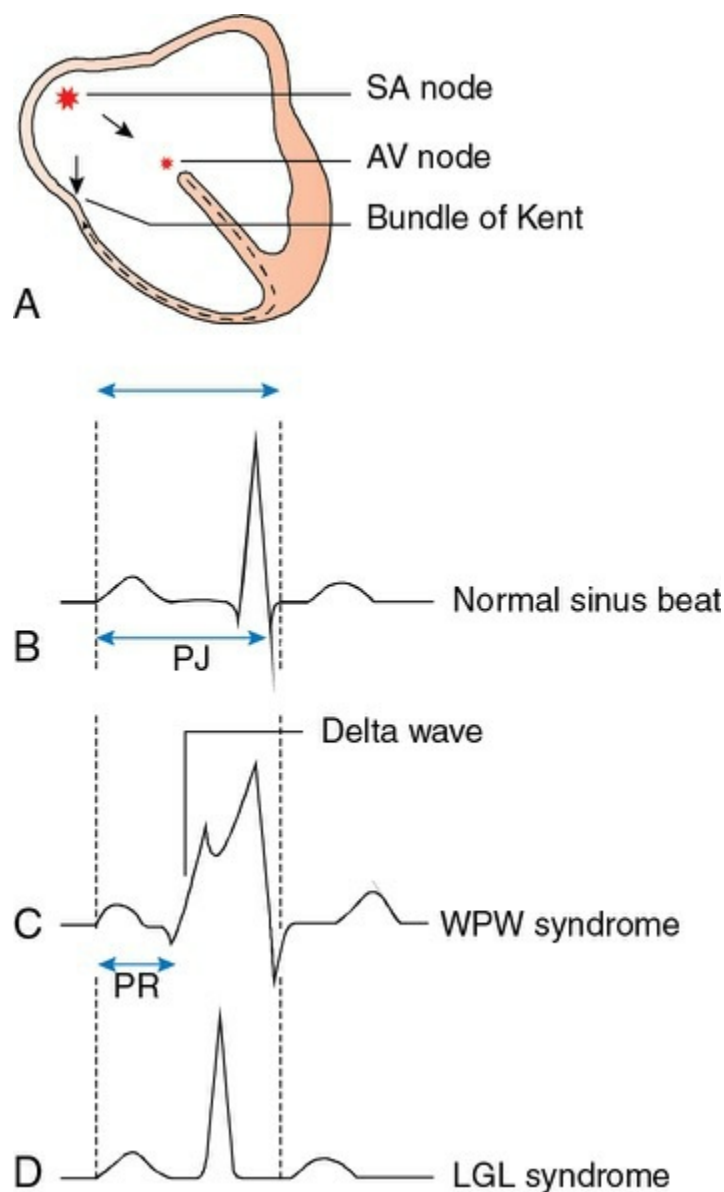

FIGURE 4.2-27 Re-entry phenomenon in the presence of bundle of Kent (A) and electrocardiogram record in a patient

with bundle of Kent showing short PR interval, wide and slurred. QRS complex with normal PJ interval (Wolff-Parkinson-White (WPW) syndrome) **(C)** and Lown-Ganong-Levine (LGL) syndrome **(D)**.

Salient features of cardiac arrhythmias

Extra systole

Extra systole (premature beat, premature contraction or ectopic beat) refers to the contraction of the heart prior to the time that normal contraction would have been expected. It is caused by some ectopic focus in the atria or ventricles and thus the premature beat may be atrial or ventricular.

Causes of extra systole: The main cause of ectopic foci is mechanical irritation, which occurs due to ischaemia of local area of heart, calcified plaques, cardiac catheterization and local toxic irritation caused by drugs, nicotine, caffeine, etc.

Atrial extra systole (premature beat)

Cause. Atrial premature beat is caused by an ectopic focus in the atrium which becomes pacemaker for one beat. Atrial premature beats may occur frequently in healthy persons. In athletes, lack of sleep, increased consumption of coffee, smoking etc.

ECG appearance (Fig. 4.2-28B) of atrial premature beat is characterized by:

- A premature P wave occurs early and has an aberrant configuration and an abnormal short PR interval because of the different path of atrial depolarization.
- QRS complex and T wave are normal.
- Interval between premature beat and next succeeding beat is slightly prolonged called compensatory pause.
- The subsequent cardiac rhythm is shifted and reset, because the premature beat discharges the SA node, which then repolarizes and fires after the normal interval.

FIGURE 4.2-28 Electrocardiographic record in extra systole: **A**, normal ECG; **B**, ECG with atrial premature beat (atrial extra systole); and **C**, ECG with ventricular premature beat.

Significance. Since atrial extra systole occurs normally, the patient may or may not be aware of an occasional irregularity in the cardiac rhythm.

Ventricular extra systole

Cause. Ventricular extra systoles can arise from any portion of the ventricular myocardium and occasionally occur in otherwise healthy individuals. Frequently ventricular premature beats occur with many forms of heart disease, especially coronary artery disease (because ischaemia increases the irritability of the myocardium).

ECG appearance of ventricular premature beat is characterized by (Fig. 4.2-28C):

- Absence of P wave preceding the QRS complex.

- QRS complex is prolonged and bizarre shaped because of the slow spread of the impulse from the ectopic focus through the ventricular muscle to the rest of the ventricle.
- T wave is usually oppositely directed from the QRS complex.
- Compensatory pause is often long. Since retrograde transmission of depolarization to the atria usually does not occur with premature ventricular beat, so, the atrial rate remains unaltered. The atrial depolarization that follows the premature ventricular beat arrives while the AV node is still refractory and, therefore, it is not conducted to the ventricles, creating a pause in the ventricular rhythm. This pause is usually fully compensatory so that R–R interval of the beat preceding the premature ventricular beat interval together equals two normal cycle lengths. Thus, the ventricular premature beats do not interrupt the regular discharge of the SA node, whereas atrial premature beats often interrupt and “reset” the normal rhythm.

The beat following ventricular premature beat is usually stronger than the normal because of the added stroke volume and thus usually detected by the patient.

Interpolated beats. When the patient’s sinus rhythm is slow, in that case a premature ventricular beat may occur without altering the normal R–R interval. Such a premature ventricular beat is termed an interpolated beat.

Pulse deficit.

Ventricles contract ahead of time in atrial and ventricular premature beats. Sometimes by that time ventricles are not filled with blood and stroke volume output during the contraction is therefore decreased or even absent. During such a contraction, pulse wave passing to periphery may be so weak that it is not felt at the radial artery. A deficit in the number of pulses felt in the radial pulse in relation to the number of contraction in the heart is called pulse deficit.

Atrial arrhythmias

• Atrial tachycardia

(Fig. 4.2-29A) occurs when an atrial site (outside the SA node) becomes the dominant pacemaker. It is characterized by very regular rates ranging from 140 to 220 beats/min. Atrial tachycardia may be caused by

overindulgence in caffeine, nicotine or alcohol and may also occur during anxiety attack.

FIGURE 4.2-29 Electrocardiographic record in atrial arrhythmia: **A**, atrial tachycardia; **B**, paroxysmal atrial tachycardia – onset in middle of record (lead I); and **C**, atrial fibrillation.

- **Paroxysmal atrial tachycardia (PAT)**

as the name indicates occurs in paroxysms, which usually begin suddenly and lasts for few seconds. PAT may result from discharge of a single *ectopic site* or a *re-entry phenomenon* (described on page 265).

ECG appearance of PAT is characterized by an inverted P wave before each QRS complex, and this P wave is partially superimposed on to the normal T wave of the preceding beat (Fig. 4.2-29B)

• Atrial flutter

is said to occur with atrial rates of 220–350 beats/min. During atrial flutter, AV node is unable to transmit all of the atrial impulses and therefore the ventricular rate may be half, one-third or one-fourth of the atrial rates. Like atrial tachycardia, atrial flutter may result either from a single ectopic focus or a re-entry phenomenon.

ECG appearance in atrial flutter: the P wave is strong and QRS-T complex follows once after two P waves or three P waves (2:1 or 3:1 rhythm).

• Atrial fibrillation

(Fig. 4.2-29C) is characterized by a totally irregular, rapid rate (350–500 beats/min). In it, there occurs contraction of only small portion of the atrial musculature at one time because large portion of the atria are still in refractory period. *Ventricular rate* is completely irregular because only a fraction of the atrial impulses that reach the AV node are transmitted to the ventricles.

ECG appearance is characterized by:

- Small irregular oscillations called F waves. There are no recognizable P waves
- R–R interval is irregularly irregular
- QRS complex and T wave are normal because the impulses that are transmitted through the AV node are conducted normally through the ventricles.

Causes. Atrial fibrillations are frequently associated with enlarged atria secondary to AV valve diseases.

Treatment. Atrial fibrillations can be converted back to normal rhythm by cardioversion/defibrillation. A strong single electric shock of alternating current is passed through the heart for a fraction of second. All action potential stop and heart remains quiescent for few seconds (3–5 s) or refractoriness of heart. After that it begins to beat with normal rhythm.

Complications. Long-term fibrillation is associated with *thrombi* in the atrial appendages.

Nodal arrhythmia

Nodal paroxysmal tachycardia

is similar to atrial tachycardia and may be indistinguishable on ECG. They are called *supraventricular tachycardia* ECG appearance: almost normal QRS–T complexes, but P wave is either totally missing or obscured, but can be distinguished from the paroxysmal ventricular tachycardia by HBE. In supraventricular tachycardia, there is a His bundle (H) deflection whereas in ventricular tachycardia, there is none.

Wolff–Parkinson–White syndrome

(Fig. 4.2-27C) also known as accelerated AV conduction refers to occurrence of repeated attacks of nodal paroxysmal tachycardia due to presence of bundle of Kent. The *bundle of Kent* is aberrant musculature or nodal tissue which connects the atria and ventricles directly. This bundle conducts more rapidly than the slowly conducting AV node, and one ventricle is excited early. The presence of *bundle of Kent* rapidly establishes re-entry phenomenon (circus movement) in prone patients (see page 265).

Lown–Ganong–Levine syndrome

(Fig. 4.2-27D). It is characterized by attacks of paroxysmal supraventricular tachycardia, usual nodal tachycardia in individuals with short PR intervals and normal QRS complexes. In this condition, depolarization presumably passes from the atria to the ventricles via an *aberrant bundle* that bypasses the AV node but enters the intraventricular conducting system distal to node.

Ventricular arrhythmias

Paroxysmal ventricular tachycardia

occurs when a ventricular site discharges rapidly and repetitively, usually as a result of *re-entry phenomenon*. Alterations in vagal tone (by carotid sinus massage or Valsalva manoeuvre) do not affect ventricular tachycardia because the ventricles do not receive any efferent vagal innervation.

Causes. Ventricular tachycardias are usually associated with serious heart disease or drug toxicity.

ECG appearance is characterized by (Fig. 4.2-30B):

- Wide, bizarre QRS complexes that occur at rapid rate and
- P waves are usually indistinguishable.

FIGURE 4.2-30 Electrocardiographic record in ventricular arrhythmias: **A**, normal; **B**, paroxysmal ventricular tachycardia; and **C**, ventricular fibrillation.

Significance. Ventricular tachycardia is more serious because cardiac output is decreased, sustained ventricular tachycardia can be a life-threatening when it degenerates into ventricular fibrillation.

Ventricular fibrillation

occurs when small segments of ventricular myocardium show rapid, irregular ineffective contractions. In this condition, cardiac output is zero and so the peripheral pulse is absent. ECG is must to differentiate ventricular fibrillation from the cardiac standstill.

Causes. Ventricular fibrillation is very common during electric shock and during ischaemia of conductive system. Other causes are coronary occlusion, trauma to heart, chloroform anaesthesia and improper handling of heart during cardiac surgery.

ECG appearance (Fig. 4.2-30C) is characterized by:

- Undulating waves of varying frequency and amplitude. The voltage of the ECG waves in ventricular fibrillation is about 0.2-0.5 mV or less.
- Ventricular premature beats are usually seen as the precipitating cause, one of which falls on the *vulnerable period* of the T wave (i.e. the interval near the peak of T wave when the ventricle is partially repolarized). A premature beat during the vulnerable period produces fibrillation because the chances of re-entry occurring are more.

Significance. Ventricular fibrillation is the most common cause of sudden death in patients with myocardial infarcts.

Treatment. Cardiopulmonary resuscitation must be started immediately to prevent tissue death. For details see page 471.

Immediate electric or electronic defibrillation (cardioversion) should be performed.

- *T* cardioversion/defibrillation is done by applying electrodes directly to two sides of the heart or on the chest wall using 110 volts of 60 cycles at alternating current for 0.1 s or 1000 volts of direct current for thousandth of a second.

Techniques for evaluation of arrhythmia

1. Electrocardiographic monitoring

is the ideal way of establishing a correlation between symptoms and a rhythm disturbance, but this is not always easy because symptoms are usually sporadic.

- When episodes of arrhythmia are infrequent, then continuous 24-h monitoring may be helpful.
- Exercise testing may be helpful if symptoms are associated with stress or exertion.

2. Heart rate variability (HRV)

refers to beat to beat variation of heart rate. The R–R interval variations during resting condition represents a fine tuning of beat to beat control mechanisms. HRV reflects fluctuations rather than absolute levels of sympathetic and parasympathetic impulse. The analysis of beat to beat

variation in heart rate is used to investigate sympathovagal imbalance, i.e. integrity of autonomic activity and vulnerability to various cardiovascular disorder resulting from autonomic imbalance. HRV is recorded by ECG lead II on Polyrite D system and its time domain and frequency domain variables are analyzed. Details of HRV are beyond the scope of the book.

3. Electrophysiological testing

intracardiac, electrocardiographic recordings is useful in diagnosis and management of complex arrhythmia.

4. Autonomic testing

is an important component of evaluation in patients with recurrent syncope. Autonomic testing can be done by simple Head up tilt test (HUT), also called as Tilt Table Test.

5. Tilt table testing

is based on the fact that in upright posture, there is venous pooling in lower limbs that reflexly increases heart rate and vasoconstriction (compensatory mechanism). Head-up-tilt-testing can identify the syncope due to vasovagal /autonomic imbalance.

Treatment of arrhythmia

1. Mechanical Measures

are used to interrupt the attack. These include: Valsalva manoeuver and carotid sinus massage. These manoeuvres stimulate the vagus nerve, delays A–V conduction and block the re-entry mechanism, and ultimately terminating arrhythmia.

2. Anti Arrhythmic Drugs

have limited efficiency due to frequent side effects. Broadly antiarrhythmic drugs are divided into four classes based on their electropharmacological actions:

- **Class I agents** block membrane sodium channels, thus slowing conduction and prolonging the refractoriness. These include: Quinine and procainamide.
- **Class II agents** are beta adrenergic blockers, which decrease

automaticity, prolong AV conduction. Examples are propranolol and metoprolol.

- **Class III** agents block K^+ channels and prolong repolarization and prolonging QT interval.
- **Class IV** agents are calcium channel blockers, which decrease automaticity and A–V conduction, e.g. Verapamil.

3. Radiofrequency Ablation:

Cardiac catheter with electrodes attached to its tip is passed into the chambers of the heart, and exact location of ectopic focus or accessory bundle responsible for arrhythmia is identified. The ablation can be done by applying radiofrequency band (300–3000 kHz) with catheter tip. Radiofrequency is particularly useful in conditions that cause supraventricular tachycardias, Wolff–Parkinson–White syndrome and atrial flutter.

The radiofrequency generates energy for biomedical applications like coagulation and cauterization of the tissue.

Myocardial infarction

Myocardial infarction refers to the ischaemic necrosis of a part of myocardium which occurs when coronary blood flow ceases or is reached below a critical level (see page 360). The ECG is very useful for diagnosing and localizing areas of myocardial infarction.

ECG appearance.

The ECG undergoes a series of changes following the myocardial infarction. These changes must be recorded daily with ECG tracing for diagnostic purpose. The *hallmark of acute myocardial infarction* is:

- *Elevation of ST segment* (Fig. 4.2-31 LI) in the leads overlying the area of infarct and
- *Depression of ST segment* (Fig. 4.2-31 LII) in the leads on the opposite side of area of infarct.

FIGURE 4.2-31 Electrocardiographic record in anterior wall ischaemia in lead I and II respectively: A_I and A_{II}, normal ECG; B_I and B_{II}, ECG within few hours of ischaemia, note ST segment elevation in lead I and depression in lead II (reciprocal); and C_I and C_{II}, ECG after several weeks, note ST segment returns to normal and Q wave appears.

ECG appearance in old cases of myocardial infarct is characterized by:

- ST segment returns to normal,
- Appearance of Q wave (Fig. 4.2-31 LI and LII) in some of the leads in which it was not previously present and
- An increase in the size of normal Q wave in some of the other leads.

Physiological basis of ECG changes in acute myocardial infarction

The alterations in ECG pattern seen in acute myocardial infarction are attributed to *injury current* which flows from the affected to the unaffected part of myocardium. This happens because of the fact that the affected part of myocardium gets depolarized partly or completely but does not get repolarized rapidly. The three major abnormalities that cause ECG changes (ST segment elevation) in acute myocardial infarction are:

1. Decline in Resting Membrane Potential.

The ischaemic necrosis of the myocardial fibres results in breakdown of cell membrane producing increased K⁺ efflux and increase in Na⁺ influx. Therefore, inside of the infarcted cells becomes less negative as compared to the unaffected area. Therefore, during ventricular diastole, the *zcurrent* flows into the infarct from the unaffected area (Fig. 4.2-32B). This results in

a depression of TQ segment of the ECG in the leads overlying the infarcted area. However, the electronic arrangement in electrocardiographic recorders is such that TQ segment depression is recorded as ST segment elevation.

2. Delayed Depolarization

of infarcted cells causes the infarcted area to be positive relative to the unaffected area. Therefore, current flows out of infarcted area into the unaffected area ([Fig. 4.2-32C](#)).

FIGURE 4.2-32 Physiological basis of ECG changes (ST segment elevation) in acute myocardial infarction: **A**, normal resting state; **B**, decline in resting membrane potential in infarct area as compared to normal neighbouring (unaffected) region; **C**, delayed depolarization of infarct area as compared to neighbouring areas; and **D**, rapid repolarization of infarct area in comparison to normal neighbouring areas.

3. Rapid Repolarization.

The repolarization in infarcted cells occurs rapidly as compared to unaffected area due to accelerated opening of K^+ channels. Because of the rapid repolarization in the infarct, the membrane potential of the affected area becomes greater than that of the unaffected area. Extracellularly, current therefore flows out of the infarct into normal unaffected area (Fig. 4.2-32D). This current flow toward electrodes over the injured area, causing increased positivity between the S and T waves of ECG. Consequently, leads on the opposite side of the heart show ST segment depression.

Physiological basis of ECG changes in old cases of myocardial infarction

After some days or weeks of infarction, the dead myocardium and scar tissue become electrically silent. Therefore, the affected area becomes negative relative to the unaffected normal myocardium during systole, and it fails to contribute its share of positivity to the electrocardiographic complexes. The occurrence of Q wave in some leads (which normally lack) and deepening of Q wave in other leads is one of the manifestations of this negativity.

Localization of area of myocardial infarction

1. *Anterior myocardial infarction*

- Leads showing changes of MI are LI, aVL and V_3-V_5
- Leads showing reciprocal changes are LII, LIII and aVF.

2. *Posterior (inferior) myocardial infarction*

- Leads showing changes of MI include LII, LIII and aVF.
- Leads showing reciprocal changes are LI, aVR, aVL and V_1-V_6 .

3. *Lateral myocardial infarction*

- Leads showing changes of MI include LI, aVL and V_6 and
- Leads showing reciprocal change are LII, LIII, aVF and V_1 .

4. *Septal myocardial infarction*

- Leads showing changes of MI are V_1 – V_3 .

Complications

Complications of myocardial infarction are ventricular arrhythmias which mainly occur due to re-entrant activity during the first 30 min of infarction, and increased automaticity after 12 h.

Important Note

- The infarcts which affect epicardial part of myocardium damages the sympathetic nerves resulting in denervation hypersensitivity to catecholamines in the area beyond the infarct.
- On the other hand, endocardial lesions interrupt vagal activity, therefore unopposed sympathetic fibres activity results.

Ventricular hypertrophy

Ventricular hypertrophy occurs when the work of the ventricle is increased sufficiently. In ventricular hypertrophy, the number of myocardial cells remains the same, but the diameter of the individual cells increases, raising the diffusion distance for O_2 and other metabolites.

Left ventricular hypertrophy (LVH)

occurs in patients with systemic hypertension or aortic valve stenosis. Right ventricular hypertrophy (RVH) occurs in patients with pulmonary hypertension, pulmonary valve stenosis and some congenital heart disease.

ECG appearance

is characterized by (Fig. 4.2-18B) the following.

1. *R wave*. There is direct correlation between the thickness of ventricular wall and the height of R wave in the overlying leads. Therefore:

- In LVH, the R wave is tall in leads I, aVL, V₅ and V₆ and
- In RVH, the R wave is tall in lead III, aVR, V₁ and V₂.

2. *QRS duration* is increased slightly due to the increased muscle mass. It is usually less than 0.12 s, but occasionally may exceed this value.

3. *Mean electric axis (MEA)* shows (Fig. 4.2-18A):

- LAD in LVH and
- RAD in RVH.

Effect of changes in the ionic composition of blood on electrical activity of heart

The electrical activity of the heart depends upon the distribution of ions like Na⁺, K⁺ and Ca²⁺ in the ECF. Therefore, changes in the ECF concentration of these ions will affect the potentials of myocardial fibres and produce changes in the ECG as described:

Plasma level of sodium

Low plasma (ECF) levels of Na⁺ may be associated with low voltage ECG complexes.

Plasma levels of potassium

Depending upon the levels of plasma K⁺ following ECG changes are seen:

1. *With normal plasma levels of K⁺ (4–5.5 mEq/L)*. The normal ECG tracings (Fig. 4.2-33A) are produced with PR interval = 0.16 s; QRS interval = 0.06 s, QT interval = 0.4 s.

2. *Hyperkalaemia*, i.e. increase in plasma K⁺ is very dangerous and potentially lethal condition because of its effects on heart.

FIGURE 4.2-33 Electrocardiographic changes in relation to plasma levels of potassium: **A**, normal tracing (plasma K⁺ 4–5.5 mEq/L); **B**, hyperkalaemia (plasma K⁺ 7.0 mEq/L); **C**, hyperkalaemia (plasma K⁺ 8.0 mEq/L); and **D**, hypokalemia (plasma K⁺ 2.5–3.5 mEq/L).

Hyperkalaemia with plasma K⁺ ± 7.0 mEq/L, the PR and QRS intervals are within normal limits. The T wave become tall and peaked (Fig. 4.2-33B), which is a manifestation of altered repolarization.

- *In hyperkalaemia with plasma K⁺ levels, 8.5 mEq/L the ECG shows (Fig. 4.2-33C).*
- Broad and slurred QRS complex with a QRS interval of 0.2 s occurs due to paralysis of atria.
- T wave remains tall and slender.
- A further increase in plasma K⁺ levels may result in ventricular

tachycardia and ventricular fibrillation.

- As the extracellular K^+ concentration increases, the resting membrane potential of the muscle fibres decreases. Eventually the fibres become unexcitable, and the heart stops in diastole.

3. *Hypokalaemia*, i.e. decrease in the plasma levels of potassium is a serious condition but it is not as rapidly fatal as hyperkalaemia. It produces the following changes in ECG (Fig. 4.2-33D):

- PR interval is prolonged,
- U waves become prominent,
- ST segment is depressed,
- Late T wave inversion may occur in the precordial leads and
- If the T and U waves merge, the apparent QT interval is often prolonged, but if the T and U waves are separated, the true QT interval is of normal duration.

Long QT syndrome. Long QT syndrome occurs due to genetic abnormality which blocks one type of K^+ channels $KVLQT_1$ resulting in slow K^+ efflux, prolonging cardiac action potential and hence QT interval. The incidence of ventricular arrhythmia and sudden death is more with prolonged QT interval.

Normally this K^+ channel (protein), in the heart is responsible for normal QT interval, and in the stria vascularis for maintaining the high concentration of K^+ in the endolymph.

Mutation of $KVLQT_1$ results in long QT interval syndrome. In this syndrome patients are deaf and also predispose to ventricular arrhythmia (because vulnerability of heart for irregular repolarization is high). This syndrome is also caused by certain drugs and electrolyte abnormality.

Plasma levels of calcium

- **Hypercalcaemia,**

i.e. increased in extracellular Ca^{2+} , clinically is rare if ever high enough to affect the heart. However, when large amounts of calcium are infused into experimental animals, the heart relaxes less during diastole and eventually stops in systole (*calcium rigor*).

- **Hypocalcaemia,**

i.e. decreased plasma level of Ca^{2+} produces prolongation of the ST segment and consequently the QT interval is also increased.

CHAPTER

4.3

Heart as a pump: Cardiac cycle, cardiac output, and venous return

CARDIAC CYCLE

- Introduction
- Phases of cardiac cycle
 - Atrial systole
 - Atrial diastole
 - Ventricular systole
 - Ventricular diastole
- Events during cardiac cycle
 - Pressure changes in the ventricles
 - Pressure changes in the atria
 - Pressure changes in the pulmonary artery
 - Volume changes in the ventricles
 - Valvular events (heart sounds)
 - Pressure-volume loop

- Duration of systole and diastole vis-a-vis heart rate
- Effect of heart rate
- Clinical indices
- Arterial pulse

CARDIAC OUTPUT AND VENOUS RETURN

- Definition
- Measurement of cardiac output
- Variations in cardiac output
- Regulation of cardiac output
- Cardiac output control mechanisms
- Role of heart rate in control of cardiac output
- Integrated control of cardiac output
- Heart-lung preparation
- Cardiac and vascular function curves

Cardiac cycle

Introduction

The heart as a pump can be considered actually comprising of two separate pumps in the series: a *right heart* that pumps the blood through the lungs and a *left heart* that pumps the blood through the peripheral organs. Further, each sided pump consists of an atrium and a ventricle. The atria act as *primary pumps* for the ventricles, helping to move the blood into the ventricles. The ventricles in turn provide the major force that propels the blood through pulmonary and systemic circulations. To act as a pump, the heart contracts and relaxes rhythmically. The terms *systole* (contractile phase) and *diastole* (relaxation phase) usually refer to ventricular events but may be prefixed by 'atrial' to refer to atrial contraction and relaxation, respectively. The heart has an *intrinsic contraction rate* because it contains its own pacemaker normally located in the SA node. As discussed in [Chapter 4.2](#), the cardiac impulse arising from the SA node spreads in the whole heart. The electrocardiogram

records the *electrical events* that precede and initiate the corresponding *mechanical events* as:

- *P wave* is caused by spread of depolarization through the atria, and this is followed by *atrial contraction*.
- *QRS waves* which appear 0.16 s after the onset of P wave are caused by depolarization of the ventricles which initiates *contraction of the ventricles*.
- *T wave* represents the stage of repolarization of the ventricles at which time the ventricular muscle fibres begin to relax. Therefore, T wave occurs slightly before the end of ventricular contraction.

The cardiac cycle, thus includes both electrical and mechanical events that occur from the beginning of one heart beat to the beginning of the next.

Cardiodynamics is the study of the mechanical events associated with the contraction and relaxation of the heart. These include:

- pressure changes in the ventricles,
- pressure changes in the atria,
- pressure changes in the aorta,
- volume changes in the ventricles and
- valvular events, i.e. production of heart sounds.

Phases of cardiac cycle

Duration of each cardiac cycle at a normal heart rate of 75 beats/min, is $60/75 = 0.8$ s.

During each cardiac cycle, both atria contract (*atrial systole*) and relax (*atrial diastole*), and both ventricles contract (*ventricular systole*) and relax (*ventricular diastole*).

Therefore, each cardiac cycle can be considered to consist of simultaneously occurring atrial and ventricular cycles with following phases (Figs 4.3-1 and 4.3-2).

FIGURE 4.3-1 Duration of phases of cardiac cycle.

FIGURE 4.3-2 Phases of cardiac cycle.

Atrial cycle

1. Atrial systole or atrial contraction phase (0.1 s)
2. Atrial diastole (0.7 s).

Ventricular cycle

Ventricular systole (0.3 s) consisting of:

1. Isovolumic (isometric) contraction phase (0.05 s) and
2. Phase of ventricular ejection which can be further divided into rapid ejection phase (0.1 s) and slow ejection phase (0.15 s).

Ventricular diastole (0.5 s) consisting of:

1. Protodiastole (0.04 s),
2. Isovolumic (isometric) relaxation phase (0.06 s),
3. Rapid passive filling phase (0.11 s),
4. Reduced filling phase or diastasis (0.19 s) and
5. Last rapid filling phase which coincides with the atrial systole (0.1 s).

Atrial cycle

Atrial systole

- Atrial systole or the atrial contraction phase lasts for 0.1 s and coincides with the last rapid filling phase of ventricular diastole (Figs 4.3-1 and 4.3-2).
- Before the beginning of atrial systole, the ventricles are relaxing, AV valves are open and blood is flowing from the great veins into the atria and from the atria into the ventricles. Thus the atria and ventricles are forming a continuous cavity.
- When the atrial contraction begins, about 75% of the blood has already flown into the ventricles. Thus, atrial contraction usually causes an

additional 25% filling of the ventricles. Therefore, even if the atria fail to function, it is unlikely to be noticed unless a person exercises.

The contraction of atria causes:

- *Increase in intra-atrial pressure* by 4–6 mmHg in right atrium and 7–8 mmHg in left atrium. The pressure rise in right atrium is reflected into the veins and is recorded as *a-wave* from the jugular vein.
- *Increase in the ventricular pressure* occurs slightly due to pumping of blood in the ventricles.
- *Narrowing of great veins* at the origin (inferior vena cava and superior vena cava opening in right atrium, and pulmonary veins opening in left atrium) decreasing venous return to the heart. Some regurgitation of the blood occurs into the great veins as no valves are present at their entrance into the atria.

Atrial diastole

After the atrial systole, there occurs atrial diastole (0.7 s). This period coincides with the ventricular systole and most of the ventricular diastole (Fig. 4.3-1).

- During atrial diastole, atrial muscles relax and there occurs gradual filling of the atria due to continuous venous return and the pressure gradually increases in the atria and drops down to almost zero with the opening of AV valves (Fig. 4.3-3). Then the pressure again rises and follows the ventricular pressure during the rest of atrial diastole.

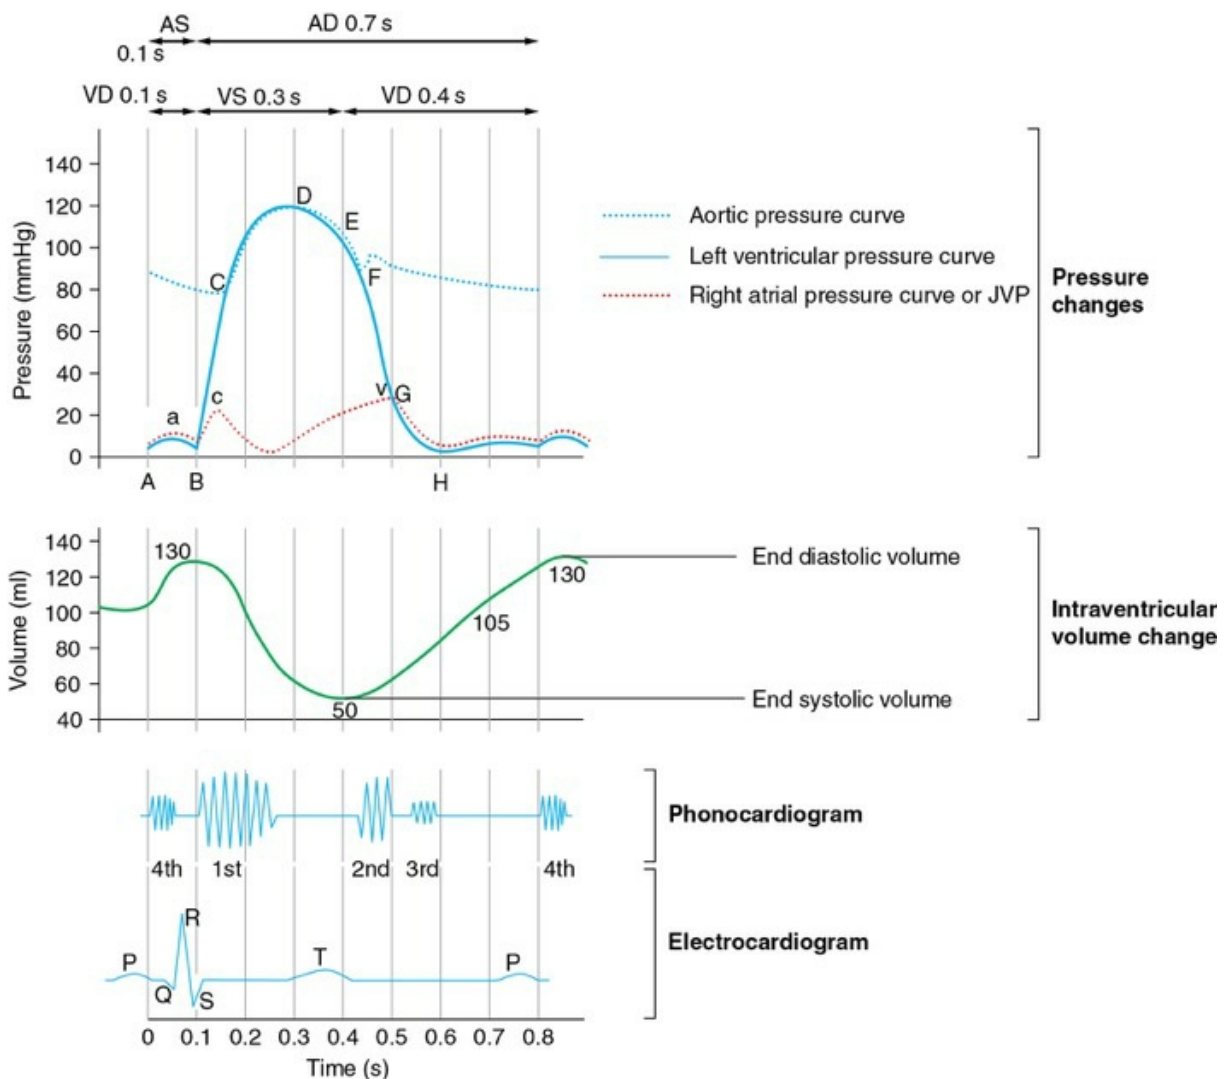

FIGURE 4.3-3 Phases and events during cardiac cycle.

Ventricular cycle

Ventricular systole

After the atrial contraction phase is over, the ventricles get excited by the impulse travelling along the conduction system and the ventricles start contracting. The ventricular systole lasts to 0.3 s, and has the following phases.

1. Phase of isovolumic (isometric) contraction

- With the beginning of ventricular contraction, the ventricular pressure exceeds atrial pressure very rapidly causing closure of AV valves (this event is responsible for production of first heart sound).
- Since the AV valves have closed and semilunar valves have not

opened, the ventricles contract as a closed chamber and the pressure inside the ventricles rises rapidly to a high level.

- As the ventricles contract, the volume of blood in the ventricles does not change; hence this phase is called *isovolumic contraction phase*.
- During this phase, due to sharp rise in ventricular pressure, there occurs bulging of AV valves into the atria producing a small but sharp rise in intra-atrial pressure called *c-wave*.
- This phase lasts for 0.05 s, until the pressure in the left and right ventricles exceeds the pressure in the aorta (80 mmHg) and pulmonary artery (10 mmHg) and the aortic and pulmonary valves open.

2. Phase of ventricular ejection

The ventricular ejection phase begins with the opening of semilunar valves and lasts for about 0.25 s. It can be further divided into two phases.

Rapid ejection phase.

As soon as the semilunar valves open, the blood is rapidly ejected out for about 0.1 s. About two-thirds of the stroke volume is ejected in this rapid ejection phase. Pressure rises to 120 mmHg in the left ventricle and to 25 mmHg in the right ventricle. The right ventricular ejection begins before that of left and continued even after left ventricular ejection is complete. As both the ventricles almost eject the same volume of blood, the velocity of right ventricular ejection is less than that of the left ventricle.

Slow ejection phase

refers to the latter two-thirds of systole (about 0.15 s) during which rate of ejection declines. About one-third of the stroke volume is ejected during this phase. The intraventricular pressure starts declining and falls to a value slightly lower than in aorta, but for a short period momentum keeps the blood flowing forward.

Volume changes. At the end of each diastole the ventricular volume is about 130 ml. This is called end-diastolic volume. About 80 ml of blood is ejected out by each ventricle during each systole. This is called *stroke volume*. Thus, about 50 ml of the blood is left in each ventricle at the end of systole. This is called *end-systolic volume*.

Ventricular diastole

1. Protodiastole

When the ventricular systole ends, the ventricles start relaxing and intraventricular pressure falls rapidly. This phase lasts for 0.04 s. During this phase, the elevated pressure in the distended arteries (aorta and pulmonary artery) immediately pushes the blood back towards ventricles which snaps the semilunar valves to close. Closure of semilunar (i.e. aortic and pulmonary) valves prevents the movement of blood back into the ventricles and produces the *second heart sound* (S_2). It also causes *dicrotic notch* in the down slope of aortic pressure called the *incisura*.

2. Isovolumic or isometric relaxation phase

- This phase begins with the closure of semilunar valves and lasts for about 0.06 s.
- Since semilunar valves have closed and the AV valves have not yet opened, the ventricles continue to relax as closed chambers in this phase. This causes rapid fall of pressure inside the ventricles (from 80 mmHg to about 2–3 mmHg in left ventricle).
- As in this phase, the ventricular volume remains constant, so this phase is called isovolumic or isometric relaxation phase.
- This phase ends when the AV valves open, as indicated by the peak of *v-wave* on the atrial pressure tracing (Figs 4.3-2 and 4.3-3).

3. Rapid passive filling phase (0.11 s)

- During ventricular systole, the atria are in diastole and venous return continues so that the atrial pressure is high when the AV valves open. The high atrial pressure causes a rapid, initial flow of blood into the ventricles. The rapid passive filling phase produces the *third heart sound* (S_3), which is not normally audible in adults but may be heard in children.
- Once the AV valves open, the atria and ventricles are a common chamber and pressure in both cavities falls as ventricular relaxation continues.

4. Reduced filling and diastasis (0.19 s)

In this phase, pressure in atria and ventricles reduces slowly and remains little above zero. This decreases the rate of blood flow from atria to ventricle causing a very slow filling or virtually cessation of ventricular filling called *diastasis*.

Note. It is important to note that about 75% blood passes from atria to ventricles during rapid filling and reduced filling phases of ventricular diastole.

5. Last rapid filling phase (0.1 s)

The last rapid filling phase of ventricular diastole coincides with the atrial systole. As described in the beginning, the atrial systole brings about the last rapid filling phase and pushes the additional 25% blood in the ventricles. With this phase, the ventricular cycle is completed.

Important Note

Cardiac cycle: Right versus left heart

Both ventricles pump the same volume of blood over any significant time period; therefore, by and large events on the two sides of the heart are similar. However, there exists a minor asynchronicity between the two sides as:

- Right atrial systole precedes left atrial systole, but right ventricle starts contracting after the left ventricle. However, right ventricular ejection begins before the left ventricular ejection, because the pulmonary arterial pressure is lower than the aortic pressure.
- The pulmonary and aortic valves close at the same time during expiration, but the aortic valve closes slightly before the pulmonary valve during inspiration. The slower closure of pulmonary valve during inspiration is because of two factors:
- Decrease in the resistance of pulmonary vascular tree with prolonged ejection, and
- An increase in systemic venous return which prolongs ejection.

Events during cardiac cycle

The events associated with contraction and relaxation of the heart during a cardiac cycle include pressure changes in the ventricles, atria and aorta; volume changes in the ventricles and valvular events. Most of these have been described during various phases of the cardiac cycle; however, they are once again repeated to highlight them.

Pressure changes in the ventricles

Pressure changes in the ventricles during cardiac cycle are consistent with the maintenance of systemic and pulmonary circulation. The intraventricular pressure can be measured with the help of cardiac catheterization. Pressure changes observed during various phases of cardiac cycle are as depicted in [Figs 4.3-2](#) and [4.3-3](#).

During atrial systole

Before the onset of atrial systole, i.e. during diastasis the pressure inside the ventricles is a little above zero. During atrial systole, there occurs a slight increase in the intraventricular pressure (about 6–7 mmHg in right ventricle and about 7–8 mmHg in left ventricle) due to pumping of blood in the ventricles. In the intraventricular pressure curve ([Fig. 4.3-3](#)), the segment AB represents the pressure changes during atrial systole. The point A denotes the onset of atrial systole and the point B denotes the closure of AV valve.

During ventricular systole

During phase of isovolumic (isometric) contraction,

since the AV valves have closed and semilunar valves have not opened, so the ventricles contract as a closed chamber and pressure inside them rises rapidly to a high level. In the intraventricular pressure curve ([Fig. 4.3-3](#)), this phase is represented by the segment BC. The point C denotes the opening of semilunar valves and commencement of ventricular ejection phase.

During rapid ejection phase

the ventricles contract at a rate greater than the rate at which blood is ejected so a great rise in the pressure occurs. Pressure rises to maximum of 120 mmHg in the left ventricle and 25 mmHg in the right ventricle. The maximum pressure in the left ventricle is 4–5 times more than in the right ventricle. This is because of the thick wall of the left ventricle. In the intraventricular pressure curve ([Fig. 4.3-3](#)), this phase is denoted by the

segment CD. The point D denotes the peak point of intraventricular pressure after which it starts declining.

During slow ejection phase

there is no further ventricular contraction and the pressure starts declining (Fig. 4.3-3, segment DE).

During ventricular diastole

During protodiastole,

the intraventricular pressure drops rapidly as the ventricles start relaxing. When the intraventricular pressure falls below that of aorta and pulmonary artery, the semilunar valves are closed due to back flow of blood. In the intraventricular pressure curve (Fig. 4.3-3) this phase is represented by segment EF, and the point F denoted the closure of semilunar valves.

During isovolumic (isometric) relaxation phase,

since the semilunar valves have closed and AV valves have not yet opened up so the ventricles relax as closed chamber and there occurs a rapid fall in the intraventricular pressure (from 80 mmHg to about 2–3 mmHg in left ventricle). When the pressure inside the ventricles fall below the pressure in atria, the AV valves open up and the phase of rapid passive filling commences. In the intraventricular pressure curve (Fig. 4.3-3), the segment FG represents this phase and the point G coincides with the opening of AV valve.

During rapid passive filling phase,

the intraventricular pressure further falls since the ventricles are relaxing though blood is being filled in them (segment GH in Fig. 4.3-3).

During reduced passive filling phase,

there is no turbulence and the blood flows very slowly and smoothly and virtually there occurs cessation of ventricular filling (*diastasis*). The ventricular pressure remains a little above zero.

Pressure changes in the atria

The intra-atrial pressure can be studied by recording with the help of intracardiac catheterization. The left atrial pressure can also be determined indirectly by measuring the pulmonary capillary wedge

pressure. The tracing of the jugular venous pulse is also similar to the intra-atrial pressure curve, and it has three positive waves called a, c and v and two descents namely x, z and y (Fig. 4.3-3). Relationship of intra-atrial pressure changes with the phases of cardiac cycle is:

During atrial systole

Before the onset of atrial systole, the intra-atrial pressure is slightly above zero and is slightly greater than the ventricular pressure. During atrial systole there occurs a sharp rise in intra-atrial pressure (by 4–6 mmHg in right atrium and by 7–8 mmHg in left atrium) and causes a pressure wave recorded as *a wave* from the jugular vein ('a' stands for atrial systole). Immediately after atrial systole the intra-atrial pressure falls due to start of atrial relaxation in atrial diastole. 'a' wave becomes prominent during inspiration due to decreased intrathoracic pressure (Fig. 4.3-3).

During ventricular systole

During phase of isovolumic (isometric) contraction,

Due to sharp rise in intraventricular pressure, AV valves bulge into the atria producing a small but sharp rise in atrial pressure producing the so-called *c wave* ('c' stands for contraction of the ventricle).

During ventricular ejection phase,

the intra-atrial pressure drops sharply in rapid ejection phase. This happens so, because the papillary muscles (attached to the cusps of AV valves by chordae tendineae) contract when the ventricular walls contract and pull down the fibrous AV ring causing enlargement of atrial lumen and thus decreasing the intra-atrial pressure. This drop in the intra-atrial pressure produces the *X descent*. The 'x' descent occurs due to both relaxation of atria and downward pull of tricuspid valve during ventricular systole (ejection phase). Therefore, as the ventricles contract, the atria get slowly filled with blood flowing in from the great veins and the atrial pressure starts rising.

During ventricular diastole

During isovolumic (isometric) relaxation phase,

the atrial pressure continues to rise as long as AV valves remain closed, i.e. till the end of isovolumic relaxation. This results in the third positive wave called *v wave* ('v' stands for venous filling). This shows a gradual

increase in atrial pressure.

During rapid passive filling phase,

The AV valves open allowing rapid flow of blood from atria to ventricles. So, the atrial pressure drops sharply to a little above zero level and remains so till the beginning of next atrial systole. This fall in atrial pressure produces the 'y' descent.

Important Note

Clinical significance of jugular vein pulsations: A careful inspection of the pulsations of jugular vein may give useful information in following clinical conditions:

- Large 'a' wave occurs in tricuspid stenosis.
- *Giant a-wave* (cannon wave) may be observed in patients with complete heart block and
- Differentiation between atrial and ventricular premature beats may be made by inspection of jugular pulse. It will show *a wave* in atrial premature beats and not in ventricular premature beats.
- 'a' wave is absent in atrial fibrillations.
- Prominent 'v' wave is observed in tricuspid regurgitation.

Pressure changes in the aorta

Pressure in the aorta varies between 80 to 120 mmHg during the cardiac cycle and can be recorded by using catheter. Aortic pressure changes during various phases of cardiac cycle (Fig. 4.3-3) are explained below.

During atrial systole

During atrial systole, the pressure in the aorta is about 80 mmHg.

During ventricular systole

During ventricular systole the intraventricular pressure rises and reaches above that of the aorta during beginning of the *ventricular ejection phase* when the aortic semilunar valve opens and blood starts flowing from the left ventricle into the aorta. Hence, the aortic pressure starts rising along with the intraventricular pressure during rapid ejection phase and reaches maximum (120 mmHg) at the end of rapid ejection phase. It is

important to note that during most of the rapid ejection phase, the aortic pressure remains slightly lesser than the ventricular pressure *during reduced ejection phase* and the aortic pressure starts falling along with the ventricular pressure.

During ventricular diastole

During protodiastole,

aortic pressure is slightly higher than that in the left ventricle. This causes backward flow of blood and closure of aortic semilunar valve. Due to sudden closure of semilunar valve, the back flowing blood collides against the closed aortic valve. This collision causes a small but sharp rise in aortic pressure. This small rise produces a notch called *incisura*. This sharp pressure rise is recordable even from peripheral arteries and is called *dicrotic notch*.

During rest of the diastole,

the aortic pressure smoothly declines. By the time the aortic pressure declines to about 80 mmHg, another ventricular systole boosts the aortic pressure again.

Pressure changes in pulmonary artery

Pressure curve in the pulmonary artery is similar to that of aorta but pressures are low (about one-sixth of that in aorta). Pulmonary artery systolic pressure averages 15–18 mmHg and its pressure during diastole is 8–10 mmHg.

Volume changes in the ventricles during cardiac cycle

During atrial systole

Atrial systole coincides with the last rapid filling phase of ventricular diastole. When the atrial contraction begins about 105 ml (75%), the blood has already flown into the ventricles. The atrial contraction causes additional 25 ml (25%) filling of the ventricles. In the ventricular volume curve (Fig. 4.3-3), this phase is represented by the AB segment. Thus at the end of atrial systole, i.e. at the end of ventricular diastole, the ventricular volume is about 130 ml. This is called *end-diastolic volume*.

During ventricular systole

During isovolumic contraction phase,

as the name suggests, there occurs no change in the ventricular volume (Fig. 4.3-3, segment BC).

During ventricular ejection phase,

about 80 ml of the blood is ejected out by each ventricle. This is called *stroke volume* (Fig. 4.3-3, segment CD). The percentage of the end-diastolic volume that is ejected out with each stroke during systole (about 65%) is called *ejection fraction*. Thus, about 50 ml of the blood in each ventricle at the end of ventricular systole is called *end-systolic volume*.

During protodiastole and phase of isovolumic relaxation,

there occurs no change in the ventricular volume (Fig.4.3-3, segments DE and EF).

During rapid filling phase and slow filling phase,

the ventricular volume changes rapidly and then slowly, respectively. About 75% of the ventricular filling (105 ml of blood) occurs during these phases (Fig. 4.3-3, segment FG and GH).

Valvular events (heart sounds)

A total four heart sounds (first, second, third and fourth) are produced by certain mechanical activities during each cardiac cycle. The study of heart sounds has important diagnostic value in many heart diseases. There are three methods to study the heart sounds:

1. *Auscultation with stethoscope*. The first and second heart sound can be heard normally with the help of stethoscope.
2. *By using microphone*, the amplified heart sounds (first, second and third) can be heard using a loudspeaker.
3. *Phonocardiogram* is the graphical record of all the four heart sounds. This is achieved by placing an electronic sound transducer over the chest and connecting it to a recording device like polygraph. The four heart sounds are described below.

First heart sound (HS₁)

Cause.

First heart sound is produced by vibrations set up by the sudden closure

of AV valves at the start of ventricular systole, during phase of isovolumic contraction (Fig. 4.3-3).

Characteristics.

The first heart sound is long and soft when heart rate is low, and loud when the heart rate is high. Its duration is about 0.15 s and frequency is 25–45 Hz. It sounds like the spoken word 'LUBB'.

Site for auscultation.

It can be heard by auscultation of the chest with stethoscope. It is best heard over mitral and tricuspid areas. *Mitral area* is located in the fifth intercostal space just internal to mid clavicular line. *Tricuspid area* is located in the fifth intercostal space near the sternum (Fig. 4.3-4).

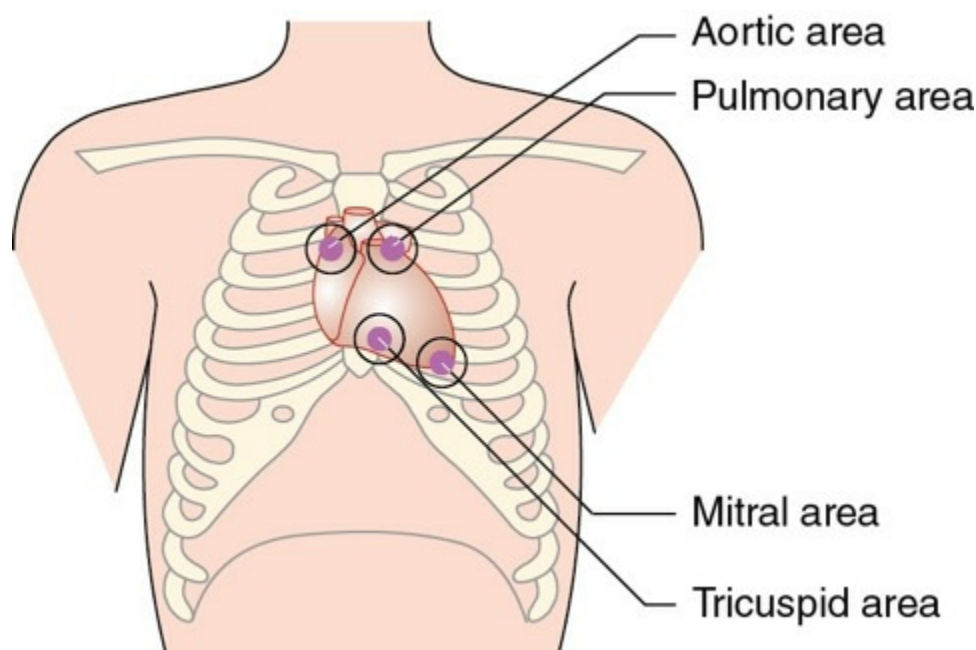

FIGURE 4.3-4 Auscultatory areas over the chest.

In phonocardiogram,

the first heart sound is recorded as a single group of 9–13 waves. The amplitude of the waves is small to start with but later rapidly rises to fall to form *crescendo and diminuendo* series of waves (Fig. 4.3-3).

Correlation with ecg.

First heart sound coincides with peak of R wave in ECG.

Second heart sound (HS₂)

Cause.

It is caused by vibrations associated with closure of the semilunar valves just at the onset of ventricular diastole.

Characteristics.

The second heart sound is a short, loud, high pitched sound. Its duration is 0.12 s and frequency is 50 Hz. It sounds like the spoken word 'DUBB'.

Site for auscultation.

It can be heard by auscultation of the chest with stethoscope. It is best heard over the aortic and pulmonary areas. *Aortic area* lies in the right second intercostal space near the sternum, *pulmonary area* is in the left second intercostal space close to sternum (Fig. 4.3-4).

In phonocardiogram,

second heart sound is recorded as a single group of 4–6 waves having same amplitude (Fig. 4.3-3).

Correlation with ECG.

Second heart sound usually coincides with end of T wave in ECG.

Note I: During inspiration, time interval between closure of aortic and pulmonary valve is prolonged. Therefore second heart sound is to be reduplicated, which is called *physiological splitting of second heart sound*.

Third heart sound (HS₃)

Cause.

Third heart sound is caused by vibrations set up in the cardiac wall by the inrush of blood during *rapid filling phase* of ventricular diastole.

Characteristics.

Third heart sound is a short, soft and low pitched sound. Its duration is 0.1 s. Normally, it cannot be heard by auscultation with stethoscope.

In phonocardiogram,

the third heart sound is found with only 1–4 waves grouped together (Fig. 4.3-3).

Correlation with ECG.

The third heart sound appears between T and P waves of ECG.

Fourth heart sound (HS₄)

Cause.

It is caused by vibrations set up during atrial systole which coincides with last rapid filling phase of ventricular diastole.

Characteristics.

It is normally not audible. Sometimes it can be heard immediately before the first sound when atrial pressure is high or when ventricle is stiff in condition such as ventricular hypertrophy. It is a short and low pitched sound. Its duration is about 0.03 s and frequency about 3 Hz.

In phonocardiogram,

the fourth heart sound merges with first heart sound many times. When it appears as a separate entity, it has 1–2 waves with very low amplitude (Fig. 4.3-3).

Correlation with ECG.

Fourth heart sound coincides with the interval between the end of P wave and onset of Q wave.

Note II: Heart sound HS₃ and HS₄ are comparatively less important, because normally they are inaudible.

Cardiac murmurs

Cardiac murmurs are the abnormal heart sounds produced during the cardiac cycle.

Mechanism of production.

Cardiac murmurs are produced by a turbulent blood flow or by change in the direction of blood flow. Normally, the blood flows through the heart and blood vessels as *laminar flow* which is streamlined and silent. The *turbulent flow*, on the other hand, produces vibrations in the tissues that are heard as murmurs.

Causes.

Murmurs are caused in following conditions:

- *Valvular stenosis*, i.e. narrowing of any of the cardiac valve (mitral, tricuspid, aortic or pulmonary valve).
- *Valvular insufficiency*, i.e. regurgitation of any of the cardiac valve.
- *Ventricular septal defect (VSD)*, i.e. a congenital hole in the ventricular septum.
- *Atrial septal defect (ASD)*, i.e. a congenital hole in the interatrial septum.
- *Coarctation of aorta*, i.e. congenital narrowing of systemic aorta.
- *Patent ductus arteriosus (PDA)*, i.e. a congenital disorder in which there is backward flow of blood from aorta into the pulmonary artery.

Types.

Depending upon the timing of appearance these have been classified as (Fig. 4.3-5).

- *Systolic murmur*, which is produced during systole,
- *Diastolic murmur*, which is produced during diastole and
- *Continuous murmur*, which is produced continuously.

FIGURE 4.3-5 Cardiac murmurs on phonocardiography: A, normal phonocardiogram; B, systolic murmur (in aortic stenosis); C, systolic murmur (in mitral regurgitation); D, diastolic murmur (in aortic regurgitation); E, diastolic murmur (in mitral stenosis); and F, continuous murmur (in patent ductus arteriosus).

The types of murmur produced depend upon the site and type of abnormality ([Table 4.3-1](#)).

TABLE 4.3-1

Types of Murmurs Depending on Site and Type of Abnormality

Site of abnormality	Type of abnormality	Type of murmur
• Aortic or pulmonary valve	Stenosis	Systolic
	Insufficiency	Diastolic
• Mitral or tricuspid valve	Stenosis	Diastolic
	Insufficiency	Systolic
• Interventricular septum	Congenital hole	Systolic
• Aorta	Coarctation	Systolic
• Ductus arteriosus	Patent	Continuous
• Blood	Anaemia	Systolic

Site of auscultation.

The murmurs are best heard by placing the stethoscope on the chest wall closest to their origin, e.g. aortic area, pulmonary area, mitral area or

tricuspid area.

Note: Abnormal vascular sounds heard over blood vessels are called *bruit*. Bruits can be heard in the following conditions.

- In case of highly vascular goiter.
- In atherosclerosis, bruit can be heard over carotid artery when its lumen gets narrowed or distorted.
- Over an aneurysm (dilation of a large artery).

Pressure–volume loop

Ventricular pressure–volume loop refers to the graph obtained in the form of a loop by plotting pressure along the ordinate and volume along the abscissa at various stages of cardiac cycle. Thus, the pressure–volume loop is an alternate method of representing the cardiac cycle. Normal ventricular pressure–volume loop is shown in [Fig. 4.3-6](#).

- **Segment AB** represents the rapid, passive filling phase, reduced filling phase and last rapid filling phase (atrial systole) of the ventricular diastole. This segment reveals that:
 - Ventricular volume at the end of diastole (at point B) is about 130 ml (end-diastolic volume). Point B marks the closure of AV valves.
 - Ventricular pressure rises from 2–3 mmHg point A to about 6–7 mmHg at point B (end of atrial systole).
- **Segment BC** represents the isovolumic contraction phase of ventricular systole. This segment reveals that during this phase:
 - Volume remains same, i.e. about 130 ml, but the pressure rises from 6–7 mmHg to about 80 mmHg.
- **Segment CE** represents the ventricular ejection phase of ventricular systole. Point C marks the opening of semilunar valves. The segment CD represents the rapid ejection phase and segment DE represents the *slow ejection phase*. The segment CE reveals that:

- During rapid ejection phase (segment CD), the ventricular pressure increases rapidly up to a maximum of 120 mmHg and then falls during slow ejection phase (segment DE) to about 80 mmHg.
- During ventricular ejection phase (segment CE), the ventricular volume decreases from about 130 ml to about 50 ml, called as *end-systolic volume*.
- *Segment EA* of the pressure–volume loop represents the phase of *isovolumic relaxation*. Point E marks the closure of semilunar valves. This segment reveals that:
 - Ventricular pressure falls rapidly from about 80 mmHg to about 2–3 mmHg.
 - Ventricular volume remains unchanged.

FIGURE 4.3-6 Pressure–volume loop of left ventricle.

Disadvantage of pressure–volume loop.

In this, the time dimension is eliminated and therefore it is not possible to tell from this loop how fast the events are occurring.

Advantage of pressure–volume loop

is that the work done by the heart is instantly apparent from the area enclosed by the loop.

Clinical significance.

The pressure–volume loop can be utilized in changed haemodynamic state like exercise, heart failure, etc. to understand pressure–volume events during cardiac cycle.

Duration of systole and diastole vis-a-vis heart

rate

Normal duration

- Duration of each cardiac cycle at a normal heart rate of 75 beats/min is $60/75 = 0.8$ s,
- Duration of ventricular systole is 0.3 s and
- Duration of ventricular diastole is 0.5 s.

Effect of heart rate

- Cardiac muscle has the unique property of contracting and repolarizing faster when the heart rate is high.
- Therefore, when the heart rate increases, the total duration of cardiac cycle decreases, e.g. at a heart rate of 200 beats/min the total duration of cardiac cycle is $60/200 = 0.3$ s.
- It is important to note that though the duration of all phases of the cardiac cycle decreases at high heart rate, but the *duration of diastole* decreases much more than the duration of systole. For example, when the heart rate increases from 75 to 200 beats/min, the duration of systole decreases from 0.3 to 0.16 s while that of diastole decreases from 0.5 to 0.14 s (Table 4.3-2).

TABLE 4.3-2

Change in Duration of Various Events of Cardiac Cycle with Increase in Heart Rate

Event	Duration in seconds	
	At heart rate of 75 beats/min	At heart rate of 200 beats/min
Cardiac cycle	0.8	0.3
Systole	0.3	0.16
Diastole	0.5	0.14

This fact has following important physiologic and *clinical implications*:

- It is during diastole that the heart muscle rests, and coronary blood flow to the subendocardial portion of the left ventricle occurs only during diastole. Therefore, at very high rate, there occurs reduction in cardiac perfusion and there are chances of myocardial ischaemia.

- Furthermore, most of the ventricular filling occurs in diastole. At heart rate up to 180 beats/min, filling is adequate as long as there is ample venous return and cardiac output per minute is increased by an increase in heart rate. However, at very high heart rate, filling may be compromised to such a degree that cardiac output per minute falls and symptoms of heart failure develop.

Clinical indices

Information about the duration of isovolumic ventricular contraction is of considerable clinical importance in many cardiac disorders. However, exact measurement of the duration of isovolumic ventricular contraction is difficult in clinical situations. Therefore, certain other indices have been evolved from which indirectly required information can be obtained. These indices given below are relatively easy to measure from the recording of ECG, phono-cardiogram and carotid pulse simultaneously (Fig. 4.3-7).

- *Total electromechanical systole (QS₂)* is the period from the onset of QRS complex to the closure of the aortic valve, as determined by the onset of second heart sound.
- *Left ventricular ejection time (LVET)* is the period from the beginning of the carotid pressure rise to the dicrotic notch.
- *Pre-ejection period (PEP)* is the difference between QS₂ and LVET and represents the time for the electrical as well as the mechanical events that precede systolic ejection.
- *Ratio of PEP/LVET* is normally about 0.35, and it increases without a change in QS₂, when left ventricular performance is compromised in many cardiac diseases.

FIGURE 4.3-7 Durations of systolic time interval.

Arterial pulse

Arterial pulse is also an event related to cardiac cycle. The blood forced into the aorta during systole not only moves the blood in the vessels forward but also sets up a pressure wave that is transmitted along the *arteries to the periphery*. The pressure wave expands the arterial walls as it travels, and expansion is palpable as the *pulse*.

Velocity of transmission of pulse wave

Velocity of transmission of pulse wave is independent of and much higher than the velocity of blood flow, the maximum value of which in larger arteries is only 50 cm/s. The rate of travel of pulse wave is about:

- 4 m/s in the aorta and its branches,
- 8 m/s in the large arteries and
- 16 m/s in the small arteries of young adults.

Consequently, the pulse is felt at the arteries after short interval of the peak of systolic ejection into the aorta (Fig. 4.3-8). This interval can be measured accurately by recording and is directly proportional to the distance of artery from the heart. For the common carotid artery, this period is about 0.02 s while for the radial artery at the wrist, it is about 0.1 s. With the advancing age, the arteries become more rigid and the pulse wave moves faster.

FIGURE 4.3-8 Velocity of transmission of pulse wave.

Methods of recording arterial pulse

The tracings of arterial pulse can be made by following techniques of recording:

1. Manometric technique.

It is used in animals. In this technique, a cannula is inserted into the dissected artery and is connected to manometer or any other recording device to obtain the arterial pulse tracing.

2. Dudgeon's sphygmograph method.

In this method arterial pulse is recorded from the radial artery with the help of Dudgeon's sphygmograph which is tied to the wrist in such a way that a small plate rests on the skin overlying the artery. A series of levers used in this instrument magnify the movements of arterial wall and record on a moving strip of smoked paper.

3. Electronic transducer method.

The electronic transducer is placed on the skin overlying any artery. The transducer throws light on the artery and the light reflected from the flowing blood is deducted by the sensor of the transducer. The arterial pulse in the form alterations in the frequency of reflected light rays are amplified and recorded by connecting the transducer to a recording device like polygraph.

Interpretation of arterial pulse tracing

The pulse tracing recorded from the carotid artery shows following characteristics (Fig. 4.3-9).

- *Ascending limb*, also known as *anacrotic limb* or primary limb, is due to the rise in pressure during systole.
- *Descending limb*, also known as *catacrotic limb* represents the fall in pressure during diastole.
- *Percussion wave (P)* corresponds to ejection phase of ventricular systole.
- *Tidal wave (T)* is due to falling blood column during slow ejection phase.
- *Dicrotic notch (N)* is due to closure of aortic valve and marks end of ventricular systole.

- *Dicrotic wave (D)* is due to rebound of blood column from closed aortic valve.

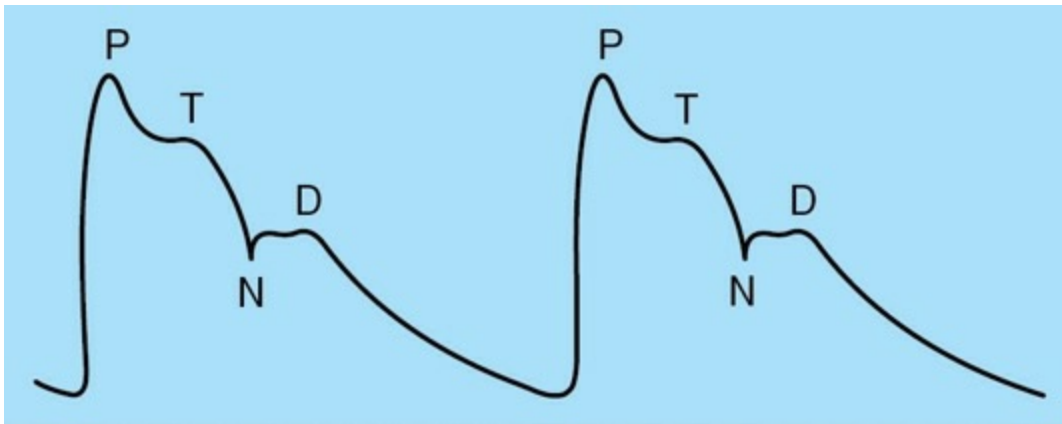

FIGURE 4.3-9 Record of arterial pulse from carotid artery: (P) percussion wave; (T) tidal wave; (N) dicrotic notch; and (D) dicrotic wave.

When the record is taken from peripheral arteries at a distant place from the heart, e.g. femoral or radial arteries, the contour or shape of record changes. In arterioles and capillaries the waves disappear.

Examination of arterial pulse

Examination of the arterial pulse is an essential feature of clinical examination. Arterial pulse can be palpated from any superficial artery, e.g. radial, femoral, dorsalis pedis, carotid, etc. Most frequently, pulse is examined from the radial artery because it is conveniently approached without exposing the body, and can be easily palpated as it is placed superficially against the bone.

Examination of the pulse should include following aspects:

1. Pulse rate

refers to the number of pulses per minute. It is a convenient method of determining heart rate.

- *Normal pulse rate* varies with age being 150–180 min in fetus, 130–140 min at birth, about 90 min at the age of 10 years and about 72/min in adults.
- *Increased pulse rate* represents tachycardia and occurs during exercise, in anxiety, in fever, in hyperthyroidism and in atrial and ventricular tachycardias.

- *Decreased pulse rate* represents bradycardia and is seen in hypothyroidism and incomplete heart blocks.

2. Volume of pulse

also known as strength of arterial pulse or amplitude or impact can be felt. It represents stroke volume or the pulse pressure (i.e. systolic–diastolic pressure). Pulse pressure is mainly affected by stroke output, compliance (distensibility) of the arterial tree, and to some extent by the character of ejection of blood from the heart. Therefore pulse pressure is determined by the ratio of stroke output to compliance of arterial tree. For details see page 323.

- *Rapid and thready pulse* occurs in hypovolaemia as in severe haemorrhage and there is marked reflex vasoconstriction.
- *Increased volume pulse* is seen during exercise and in ventricular hypertrophy.

3. Rhythm of pulse

is noted as regular or irregular. Under normal conditions and during sinus bradycardia or sinus tachycardia pulse appears at regular intervals.

- *Irregular pulse rhythm* is a feature of extra systole, atrial fibrillation and other cardiac arrhythmias, type of arrhythmia is confirmed only on ECG (see page 269). The irregular pulse rhythm may be regularly irregular or irregularly irregular.

4. Character of pulse

is felt on palpation. It denotes the tension and waves in the pulse. Feeling of different characters of the pulse can be learnt by subjective experience.

- *Normal character* (Fig. 4.3-10A) of the pulse is sinuous on examination, i.e. an upstroke is followed by downstroke. Normally, it is not possible to feel the different waves of the pulse or slight variations in the character. However, in certain heart diseases and valvular defects, the normal character is altered and can be easily felt while palpating the peripheral arterial pulse.

A few *abnormal characters* of the pulse are described as:

- *Water hammer pulse* (Fig. 4.3-10B) also known as collapsing pulse is

characterized by a sudden upstroke followed by a sudden downstroke without insuria. It is best felt by raising the patient's arm and holding it by grasping the wrist with palm of the observer. Sometimes the upstroke is so strong that it leads to head nodding with each heart beat, called as Corrigan sign or Corrigan pulse.

Cause of water hammer pulse is aortic insufficiency or regurgitation.

Mechanism of water hammer pulse in aortic regurgitation is as follows:

- When the aortic valve closes, blood regurgitates from the aorta into the left ventricle. So, aorta empties earlier and this is the cause of sudden downstroke.
- Due to regurgitation of blood from aorta into left ventricle, the end-diastolic volume is increased. So next beat is forceful (due to Frank–Starling mechanism), and this is the cause of sudden upstroke of next beat.
- **Anacrotic pulse** (Fig. 4.3-10C). Normally, there is a single upstroke in the arterial pulse. In anacrotic pulse, there are two upstrokes. It occurs in patients with aortic stenosis. First upstroke in anacrotic pulse is due to slow rise in ventricular systole owing to aortic stenosis and second is due to dicrotic wave which normally occurs on the downstroke.
- **Bisferiens pulse** (Fig. 4.3-10E). This a combination of anacrotic and collapsing pulses, both can be felt distinctly. It is found in conditions when aortic stenosis and incompetency are combined.
- **Pulsus alternans** (Fig. 4.3-10D). In this condition, every normal pulse alternates with a weak pulse. This is because of alternate variation in the force of ventricular contraction. The rhythm and rate of pulse is normal. It occurs in severe myocardial diseases.
- **Pulsus paradoxus**. The pulse becomes smaller or even disappears at the end of inspiration when the patient breathes deeply, but heart sounds may be heard on auscultation. It occurs in pericardial effusion and in constrictive pericarditis.

FIGURE 4.3-10 Character of arterial pulse: **A**, normal character; **B**, water hammer pulse; **C**, anacrotic pulse; **D**, pulsus alternans; and **E**, pulsus bisferiens.

Cardiac output and venous return

Definition of cardiac output and related terms

The main function of the heart is to pump blood to meet the metabolic needs of the body. The measure of the heart's ability to pump blood is cardiac output. The *cardiac output* refers to the amount of blood ejected by each ventricle per minute. The *stroke volume* is the amount of blood

pumped out by each ventricle per beat or per contraction. Therefore, cardiac output (CO) can be calculated by multiplying the stroke volume (SV) by the heart rate (HR):

$$CO = SV \times HR$$

Under normal conditions, the average heart rate is about 70 beats/min and stroke volume is about 80 ml and thus cardiac output is $80 \times 70 = 5.6$ l.

The cardiac output is expressed in litres per minute and normally varies from 5–6 l/min. In health, the right and left ventricular outputs are nearly equal. Thus, each ventricle pumps about 5–6 l of blood into the circulation per minute. This is made possible because of the fact that the right and left side pumps act in series.

Cardiac index is the cardiac output expressed in relation to the body surface area. The normal cardiac index is about 3.2 l/min/m².

Distribution of the cardiac output

Of the total cardiac output, about 75% is distributed to the vital organs of the body and rest 25% to the skeletal muscle, other organs of the body and skin. The distribution of the cardiac output to various organs of the body is shown in [Table 4.3-3](#).

TABLE 4.3-3

Distribution of Cardiac Output to Various Organs

Body organ	Amount of blood flow (ml/min)		Percentage of total cardiac output	
Liver	1500		25	75
Kidney	1300		about 25	
Brain	750	1		
Heart	250		1500	25
Lungs	500			
Skeletal muscles and other body organs	1000	1	1500	25
Skin	500			

Cardiac reserve

- The cardiac reserve refers to the maximum increase in the cardiac output above the normal value. It is usually expressed in percentage.
- Value of cardiac reserve observed are:
- In healthy young adults : 300–400%
- In old age : 200–250%
- In athletes : 500–600%
- The cardiac reserve is:
- Maximum during heavy exercise and
- Minimum or nil in cardiac diseases.

Measurement of cardiac output

Cardiac output, in experimental animals, can be measured directly with the help of an electromagnetic flowmeter placed on the ascending aorta. However, in human, only indirect methods are possible and include:

- Methods based on Fick's principle,
- Indicator or dye dilution method,
- Thermodilution method,
- Method employing inhalation of inert gases and
- Physical methods such as:
- Doppler technique echocardiography,
- Ballistocardiography and
- Cineradiographic technique.

Methods based on fick's principle

Fick's principle

The Fick's principle states that the amount of a substance taken up by an organ (or by the whole body) per unit of time is equal to the arterial level of the substance (A) minus the venous level (V) times the blood flow (F), i.e.

$$Q = (A - V)F$$

or

$$F = \frac{Q}{(A - V)}$$

This principle can be of course, only in situations in which the arterial blood is the sole source of the substance taken up. The Fick's principle can be used to measure cardiac output by two methods:

- Fick's principle direct method and
- Fick's principle indirect method.

Fick's principle (direct method)

In this method ([Fig. 4.3-11](#)), cardiac output is determined by measuring the pulmonary blood flow. As we know:

- Pulmonary blood flow/min = right ventricular output and
- Right ventricular output = left ventricular output (cardiac output).

FIGURE 4.3-11 Estimation of cardiac output by Fick's principle. PAO₂, oxygen content of pulmonary artery blood and PVO₂, oxygen content of pulmonary vein blood.

Measurement of pulmonary blood flow can be made by measuring the amount of O₂ taken by the blood from the lungs, O₂ concentration of the venous blood from pulmonary artery (PAO₂) and O₂ concentration of the arterial blood from the pulmonary vein (PVO₂).

- Amount of O₂ uptake/min is determined with the help of a spirometer,
- PAO₂ is measured from the venous blood sample taken from the pulmonary artery directly with the help of a cardiac catheter. The cardiac catheter is inserted into a vein at the forearm and is then guided up under fluoroscopic control through the venous channels into the right atrium, right ventricle and pulmonary artery.
- PVO₂ because of practical difficulty in taking sample from pulmonary vein, is measured from the arterial blood sample taken from any peripheral artery, e.g. brachial artery (the O₂ content of all the major arteries is same as that of pulmonary veins). According to Fick's

principle:

$$\text{Pulmonary blood flow} = \frac{\text{Amount of O}_2 \text{ taken by the lungs/min}}{\text{PVO}_2 - \text{PAO}_2}$$

or

$$\text{Cardiac output} = \frac{\text{O}_2 \text{ taken by the lungs/min}}{\text{PVO}_2 - \text{PAO}_2}$$

For example, if O₂ uptake is 250 ml/min, PVO₂ is 19 ml/100 ml and PAO₂ is 14 ml/100 ml, then

$$\begin{aligned} \text{Cardiac output} &= \frac{250 \times 100}{19 - 14} \\ &= \frac{25000 \text{ ml/min}}{5} \\ &= 5000 \text{ ml/min} \\ &= 5 \text{ l/min.} \end{aligned}$$

Disadvantages of Fick's principle (direct method)

- It is an invasive technique, so there are risks of infection and haemorrhage.
- The cardiac output estimated may be somewhat higher than normal as the patient becomes conscious of the whole technique.
- A fatal complication like ventricular fibrillation may occur if the indwelling catheter irritates the ventricular walls, especially when the cardiac output is being measured during heavy exercise.

Fick's principle (indirect method)

In this method, arterial puncture and right heart catheterization are

avoided and CO₂ excretion by the lungs is used instead of O₂ uptake:

- CO₂ excretion by the lungs is measured by spirometry,
- Arterial CO₂ (PACO₂) is estimated from alveolar air and
- Mixed venous blood CO₂ (PVCO₂) is estimated by rebreathing into a closed bag. With rebreathing, the CO₂ in the bag will come into equilibrium with the venous blood in lungs. The breathing should be done in an interrupted manner so that the blood level of CO₂ is not increased.

According to Fick's principle:

$$\text{Cardiac output} = \frac{\text{CO}_2 \text{ output/min}}{\text{PACO}_2 - \text{PVCO}_2}$$

Indicator or dye dilution method

Principle

In this method, a known amount of the dye is injected into a large vein or preferably into right atrium by cardiac catheterization. By its passage through heart and pulmonary circulation it will be evenly distributed in the blood stream. Its mean concentration during the first passage through an artery can be determined from successive samples of blood taken from artery. The blood flow in l/min (F) is given by the following formula:

$$F = \frac{Q}{Ct}, \text{ where:}$$

F = Blood flow in l/min,

Q = Quantity of the dye injected,

C = Mean concentration of dye and

t = Time duration in seconds of the first passage of dye through the artery.

Prerequisites for an ideal indicator

The indicator (dye) used should have following characteristics:

- It should be nontoxic.
- It must mix evenly in the blood.
- It should be relatively easy to measure its concentration.
- It should not alter the cardiac output or haemodynamics of blood flow.
- Either it must not be changed by the body during mixing period or the amount changed must be known.
- The dye commonly used in humans for determining the cardiac output is *Evans blue* (T-1824) or radioactive isotopes.

Procedure

Injection of dye.

A few millilitre of venous blood is withdrawn from the antecubital vein and it is mixed with 5 mg Evans blue dye. The blood containing dye is then injected rapidly into the vein.

Estimation of duration of first passage of dye (t) and mean concentration (C) of dye in arterial blood.

Serial samples of arterial blood from the brachial artery are taken every 2 s and the dye concentration is determined.

- When the dye concentration is plotted as a function of time, a curve shown in Fig. 4.3-12 as A, B, C and D is obtained. The curve shows that the dye concentration reaches a peak and then steadily declines only to rise again (CD part of the curve) owing to recirculation of the dye.
- *Time duration of first passage of dye through the artery (t)* is determined by extrapolation of the descending limb (BC) of the curve to time scale axis. The point (E) on the time scale where the extrapolated limb meets it, tells the time (AE) of first circulation of dye in seconds.

- *The mean concentration (C) of the dye is determined by representing the triangle area ABE as a rectangle ACFG with same area and one of its arm being AE. The height of the rectangle (AG) tells the mean concentration (C) of dye.*
- *Calculation of cardiac output is then made using the formula described above. For example, when:*
- Amount of dye injected (Q) is 5 mg,
- Time duration for first circulation is 40 s and
- Mean concentration of dye (C) = 15 mg/l, then

$$\text{Cardiac output} = \frac{Q \times 60}{C \times t} = \frac{5 \times 60}{1.5 \times 40} = \frac{300}{60} = 5 \text{ L/min}$$

FIGURE 4.3-12 Estimation of cardiac output by indicator (dye) dilution method.

Earlier the dye curves were used for investigating cardiac septal defects but, now a days due to availability of sophisticated non invasive techniques this method is not usually used.

Thermodilution method

Principle.

It is also an indicator dilution technique in which instead of a dye, 'cold saline' is used as an indicator. The cardiac output is measured by determining the resultant change in the blood temperature in pulmonary artery.

Procedure.

In this technique, two thermistors, one each in the inferior vena cava and pulmonary artery are placed with the help of cardiac catheter.

- A known volume of sterile cold saline is then injected into the inferior vena cava.
- Temperature of the blood entering the heart from inferior vena cava and that of the blood leaving the heart via pulmonary artery is determined by the thermistors.
- The cardiac output is then measured from the values of temperature by applying the principle of indicator dilution technique.

$$F = \frac{V_I \times (T_B - T_I)}{\Delta T_B} \times t$$

where:

F – blood flow in litre per second,

V_I – volume of the injectate,

T_B and T_I – temperature of blood and injectate, respectively,

ΔT_B – mean change in the pulmonary artery blood,

t – duration of first passage of injectate in seconds.

Note: The advantage of thermal dilution over dye dilution method is that withdrawal of blood for sampling is not required. Therefore, this method is useful for estimating cardiac output in infants and small children in whom the blood volume is limited.

Method employing inhalation of inert gases

- In this technique, an inert gas which dissolves in plasma but does not combine with Hb or other constituents of the blood is used as an indicator. Such gases include nitrous oxide and acetylene; the last one gives more accurate results.
- The pulmonary blood flow (which is equal to the cardiac output) is then determined from the following values:
- The quantity of gas absorbed in the given time,

- The partial pressure of the gas in the alveolar air,
- The solubility of the gas (a known factor).

Physical methods

Physical methods developed to measure the cardiac output include the following.

Echocardiography

Echocardiography refers to ultrasonic evaluation of cardiac functions. It is a noninvasive technique that does not involve injections or insertion of a catheter. It involves B-scan ultrasound at a frequency of 2.25 MHz using a transducer which also acts as receiver of the reflected waves. The recording of the echoes displayed against time on an oscilloscope provides a record of:

- The movement of the ventricular wall and septum, and valves during the cardiac cycle.
- When combined with Doppler techniques, echocardiography can be used to measure velocity and volume of flow through the valves.
- Thus, it is particularly useful in evaluating end-diastolic volume (EDV), end-systolic volume (ESV), cardiac output (CO) and valvular defects.

Ballistocardiography method

This method is not used practically. Ballistocardiography refers to graphical record of the pulsations created due to ballistic recoil of the pumping heart. The ballistic recoil occurs in accordance with Newton's third law of motion, i.e. when heart pumps blood into aorta and pulmonary artery, recoil is given to the heart and the body in the opposite direction. This is similar to that of ballistic recoil when a bullet is fired from the rifle.

The ballistic recoil pulsations can be recorded graphically by making the subject to lie on a suspended bed movable in the long axis of the body. The cardiac output is determined by analyzing the graph obtained.

Variations in cardiac output

Physiological causes of variations in cardiac output

- **Age.** Because of less body surface area, children have more cardiac index than adults.
- **Sex.** Since the body surface area is less in females, they have more cardiac index than the males.
- **Diurnal variation.** In the early morning, cardiac output is low which increases in the day time depending upon the basal condition of the individual.
- **Environmental temperature.** Moderate change in environmental temperature does not cause any change in cardiac output. A high environmental temperature is associated with an increase in the cardiac output.
- **Anxiety and excitement** are reported to increase the cardiac output by 50–100%.
- **Eating** is associated with an increase in cardiac output approximately by 30%.
- **Exercise** may increase the cardiac output up to 700% depending upon the vigorousness of exercise.
- **Pregnancy.** An increase in cardiac output to the tune of 45–60% is reported during the later months of the pregnancy.
- **High altitude.** The cardiac output is increased at high altitude due to release of adrenaline as a consequence to hypoxia.
- **Posture change.** Sitting or standing from lying down position may decrease the cardiac output by 20–30% because of pooling of blood in lower limbs.

Pathological causes of variations in cardiac output

- **Increase in cardiac output** is seen in following conditions:
- **Fever**, due to increased oxidative processes,

- *Anaemia*, due to hypoxia and
- *Hyperthyroidism*, due to increased metabolism.
- *Decrease in cardiac output* may occur in following conditions:
 - *Rapid arrhythmias*, due to incomplete filling,
 - *Congestive cardiac failure*, due to weak contractions of heart,
 - *Cardiac shock*, due to poor pumping and circulation,
 - *Incomplete heart block*, owing to defective pumping action of the heart,
 - *Haemorrhage*, because of decreased blood volume and
 - *Hypothyroidism*, due to decreased basal metabolism.

Regulation of cardiac output

The cardiac output increases or decreases in various physiological and pathological conditions as described above. The variations in the cardiac output are brought out by certain factors operating through certain mechanisms by an integrated role.

The cardiac output (CO), as we know, is the product of stroke volume (SV) and heart rate (HR), i.e. $CO = SV \times HR$. Therefore, variations in the cardiac output can be produced by the factors that change stroke volume or heart rate, or both. The main factors affecting cardiac output are venous return, myocardial contractility, peripheral resistance and heart rate (Fig. 4.3-13).

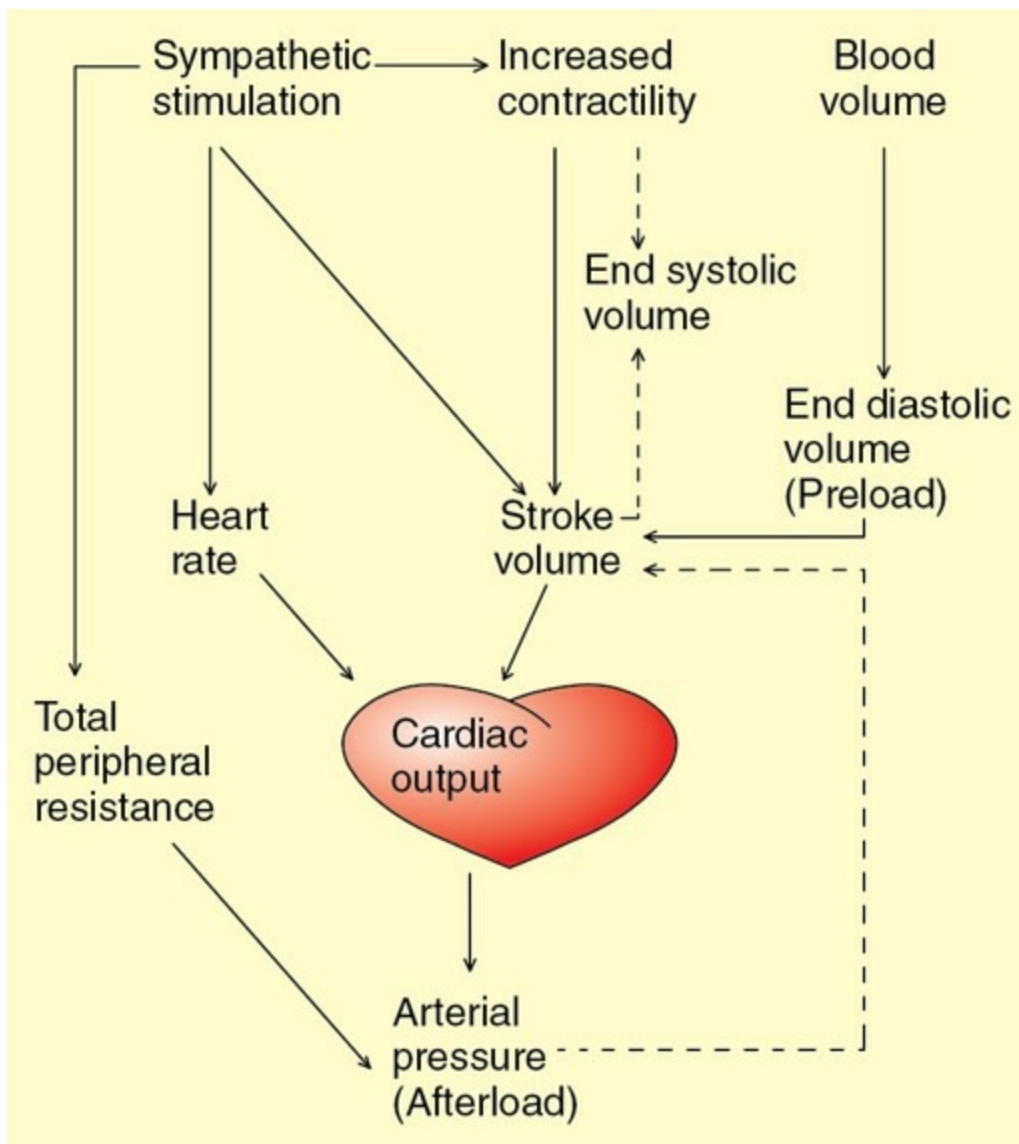

FIGURE 4.3-13 Interaction between the factors that regulate cardiac output and arterial pressure. Solid lines indicate increase and dotted lines indicate a decrease.

Cardiac output control mechanisms

The cardiac output is regulated by two mechanisms: intrinsic and extrinsic.

1. Intrinsic autoregulation (Frank–Starling mechanism)

The force of contraction of cardiac muscle fibres like that of skeletal muscle fibres depends upon its preload. The preload determines the initial length (resting length) of the muscle fibres. According to *Frank–Starling law* of heart, ‘within physiological limits’ the force of contraction of *cardiac muscle* is proportionate to the initial length of muscle fibres. In the heart, end-diastolic volume forms the preload. Thus, the stretching of

the cardiac muscle fibres to increase their initial length depends upon the end-diastolic volume. Therefore, precisely, the Frank–Starling law of heart can be stated as, within physiological limits the force of cardiac contraction is proportional to its end-diastolic volume (EDV). This fact was demonstrated about a century ago by Frank and Starling on the heart–lung preparation in a dog described on page 293. Since, in this intrinsic regulation mechanism, cardiac muscle fibres are stretched to increase their initial length, it is also termed as *heterometric mechanism*.

The relationship between ventricular stroke volume and end-diastolic volume is called the *Frank–Starling curve* (Fig. 4.3-14). Details of the effect of preload on force of myocardial contraction including the *length–tension relationship* are described in detail on page 245.

FIGURE 4.3-14 Frank–Starling curve (A) and factors affecting end-diastolic volume. Arrows on the left (green) indicate increase and arrows on right (blue) indicate decrease (B).

Factors affecting end-diastolic volume

The end-diastolic volume refers to the *venous return* to the heart during diastole. Therefore, the factors that normally operate to regulate end-diastolic volume, i.e. the degree to which cardiac muscle is stretched are the same which affect the venous return.

Up to physiological limits the cardiac output is directly proportional to the venous return. Thus, over any significant period of time, venous return must equal cardiac output. For individual at rest, the cardiac output and venous return are approximately 5 l/min. A complicated interaction of neural, humoural and physical factors determine the flow rate. Factors affecting venous return (Fig. 4.3-14) are:

1. Respiratory pump.

Normally the intrapleural (intrathoracic) pressure at the end of expiration is about -2 mmHg. During inspiration, the intrathoracic pressure becomes more negative (about -5 mmHg) due to which the diameter of inferior vena cava is increased and pressure inside it is reduced; and there occurs descent of diaphragm which increases the intra-abdominal pressure. The decreased pressure inside the inferior vena cava coupled with increased intra-abdominal pressure during inspiration results in increased flow of blood into the right atrium. This mechanism of increased blood flow during inspiration is called *respiratory pump*. This respiratory pump operates strongly in forced respiration and in severe muscular exercise increasing the venous return.

2. Cardiac pump.

The cardiac pump influences the venous return by two kinds of forces: 'vis-a-tergo' and 'vis-a-fronte'.

- *Vis-a-tergo* refers to the forward push from behind, i.e. the propelling force which pushes the blood from veins into the right atrium. Vis-a-tergo results from the myocardial contraction during systole and is supplemented by the elastic recoil of the arterial wall (windkessel effect, see page 314).
- *Vis-a-fronte* refers to the suction force acting from the front which basically pulls the blood from the great veins into the right atrium. This suction force is created by ventricular contraction and has following two components:
 - *Ventricular systolic suction* results from pulling down of the fibrous AV ring causing enlargement of atrial lumen and thus decreasing the intra-atrial pressure which sucks blood from the inferior vena cava and superior vena cava. The fibrous AV ring is pulled down due to contraction of papillary muscles.
 - *Ventricular diastolic suction* results from the opening of AV valves allowing rapid flow of blood from atria to ventricles. The sudden decrease in atrial pressure in turn sucks blood from the great veins.

- So, a decrease in ventricular compliance, i.e. an increase in the ventricular stiffness produced by myocardial infarction, infiltrative diseases and other abnormalities will decrease the venous return.

3. Muscle pump.

The muscle pump mechanism is responsible for flow of blood from the veins of the limbs to the heart. Therefore, increased pumping action of skeletal muscles will increase the venous return and decreased pumping of skeletal muscles will decrease the venous return.

Working of muscle pump is now explained. Two types of veins are present in the limbs: superficial and deep veins. Blood flows from the superficial veins into deep veins through communicating veins. Due to the presence of valves in the limb veins the blood flows in one direction, i.e. from periphery towards heart and not in reverse direction.

- *When the skeletal muscles contract*, the deep veins present in between the muscles are compressed and due to increased pressure the valve present proximal to the contracting muscle is opened up while the valve present on distal end is tightly closed and in this way the blood is propelled up towards the heart (Fig. 4.3-15A).
- *When the skeletal muscle relaxes*, a negative pressure is created in the segment of veins. So, due to back flow the proximal valve is closed and the distal valve is opened and blood is sucked up (Fig. 4.3-15B).
- *With rhythmic contractions of skeletal muscles* in this way, the blood is squeezed out of the limbs towards the heart.

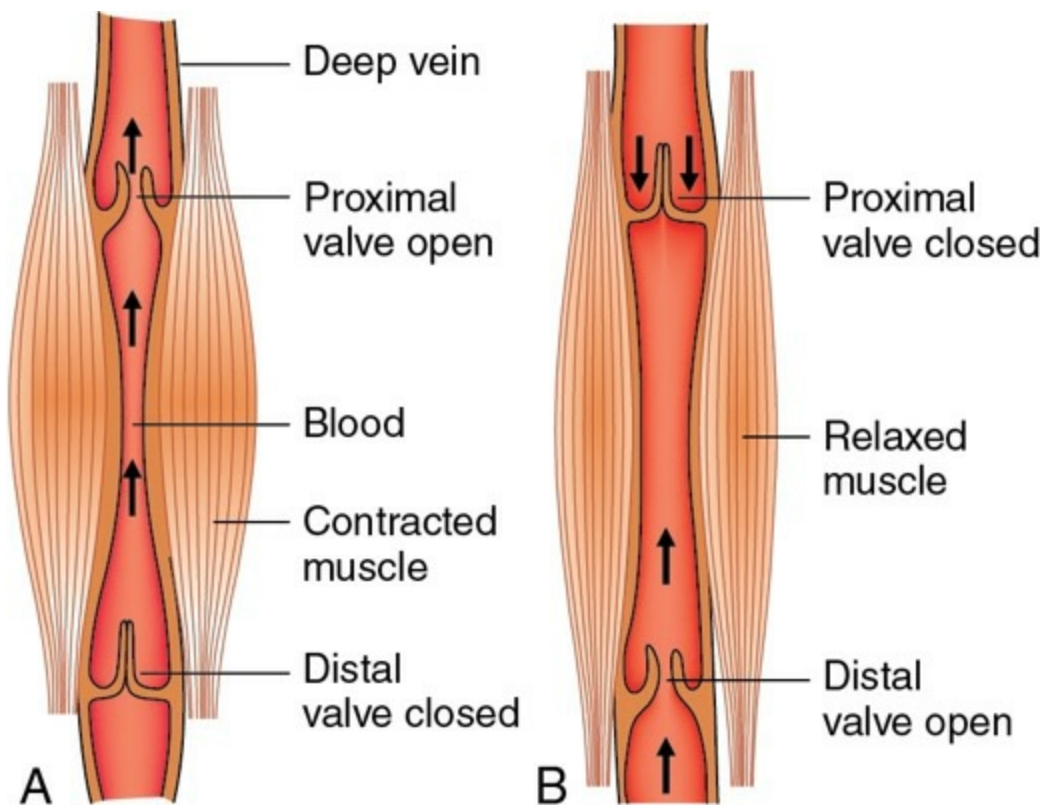

FIGURE 4.3-15 Mechanism of muscle pump: **A**, during contraction of muscles; and **B**, during relaxation of muscles.

Applied Aspect

In certain professions (e.g. nurses, traffic police, etc.) the individuals have to keep standing for a long time of a day. In such persons, sometimes the excessive venous pressure stretches the veins of the legs to such an extent that their diameter increases and the venous valves become incompetent. The venous pressure further increases and gradually the veins of lower limbs become large, tortuous and bulbous. This condition is called *varicose veins*.

4. Blood volume.

The mean circulating filling pressure (MCFP) which is equivalent to mean systemic filling pressure (MSFP) refers to the equilibrated pressure measured everywhere as a result of stoppage of blood flow in systemic circulation when heart stops pumping. The level of MSFP influences the venous return. Greater the MSFP more the venous return and lower the MSFP lesser the venous return (Fig. 4.3-16).

FIGURE 4.3-16 Venous return curve showing relationship with mean systemic filling pressure.

The MCFP in turn depends upon the level of blood volume. When relationship of blood volume and MCFP is plotted, the graph (Fig. 4.3-17) shows that:

- At blood volume of 4 l the MCFP is nearly zero because the veins are unstressed,
- At blood volume of 5 l the MCFP raises to 7 mmHg and
- At higher blood volume there is linear increase in MCFP.

FIGURE 4.3-17 Relationship between mean circulatory filling pressure and blood volume.

Thus, the increased blood volume increases the venous return and a decreased blood volume decreases the venous return.

5. Sympathetic discharge.

On sympathetic stimulation, there occurs increase in the venous tone which decreases the capacity of the venous system (veins are capacitance vessels). Due to decrease in the venous capacity the MCFP rises which increases the venous return. At normal blood volume, a strong sympathetic stimulation raises the MCFP from 7 to 17 mmHg. And inhibition of sympathetics decreases the MCFP from 7 to 4 mmHg (due to venous dilatation) and thus decreases the venous return.

6. Standing body position

is associated with a decreased venous return due to peripheral pooling of the blood.

7. Resistance to venous return.

Normally, 2/3rd resistance to venous flow is offered by veins and 1/3rd by the arteries. Resistance decreases the venous return. The venous resistance is considered to be more important regarding venous return, as the veins being capacitance vessels, rise in the venous pressure is less effective to push the blood towards the heart. On the other hand, as with increased resistance in arterioles or small arteries, with little accumulation of blood in the arteries there is great increase in the pressure (30 times as compared to veins) which overcomes the effect of increase in resistance. As shown in Fig. 4.3-18, decrease in the resistance to venous return to one half of the normal increases the venous return two times and rotates the curve upwards (Fig. 4.3-18B); while an increase in the resistance to venous flow twice the normal decreases the venous return to half and rotates the curve downwards (Fig. 4.3-18C).

FIGURE 4.3-18 Venous return curve showing relationship between venous return and resistance to it: A, at normal resistance; B, at resistance one half of the normal; and C, at resistance twice as that of normal.

Clinical significance of Frank–Starling mechanism

For small, momentary adjustments necessary for keeping the outputs of two ventricles equal

and adjusting them to match the venous return the intrinsic regulation works continuously. For example, if the output of the right ventricle increases momentarily, the venous return to left heart will increase, which in turn will increase the output of the right ventricle. The accuracy with which this adjustment is made can be understood by considering what would happen if the right ventricular output exceeds left ventricular output by as little as 0.1 ml/beat, i.e. 7 ml/min. Then, in a period of 3 h, the pulmonary blood volume will be increased by more than 1 l ($7 \times 60 \times 3 = 1260$ ml). This will prevent the optimal exchange of gases across the lungs and result in severe pulmonary insufficiency.

Maintenance of constant stroke volume when the peripheral resistance is increased is carried out by intrinsic mechanism.

When the peripheral resistance (blood pressure) is increased, initially the heart is unable to pump all the blood it normally does. The accumulated blood in the ventricle stretches the muscle fibres leading to great force of contraction and thus the stroke volume is restored to normal in spite of greater resistance to the outflow.

Intrinsic control mechanism serves as a life-saving device in cardiac failure.

Left ventricular failure causes accumulation of blood within left ventricle, thereby decreases blood supply to vital organs. Soon, accumulation of blood in the left ventricle, increases the initial length of muscle fibres leading to greater cardiac output according to Frank–Starling mechanism. However, when accumulation of blood is too great, the Frank–Starling law will fail to operate leading to decrease in blood supply to the vital organs and ultimately death may occur.

2. Extrinsic regulation (autonomic neural mechanism)

In this mechanism, stroke volume increases due to *increased myocardial contractility* without any increase in the initial muscle length. Therefore, it is also called *homometric mechanism*. The homometric regulation is governed by autonomic neural mechanism as:

Sympathetic activity

Stimulation of the sympathetic nerves to the heart results in increased

myocardial contractility and is known as *positive inotropic effect*. The positive inotropic effect of the norepinephrine liberated at the sympathetic nerve endings is augmented by circulating norepinephrine.

Positive inotropic effect also can be defined as an increase in the *maximal velocity* of shortening (V'_{max}) when it is plotted as a function of afterload. For the ventricles, the afterload is the arterial pressure during the ejection phase. During any muscle contraction, the velocity of shortening and the force developed are inversely related. For details of the effect of afterload and the *force velocity curve*, see page 253.

Inhibition of sympathetic system has opposite effects. Under normal conditions, there is continuous slow rate of discharge through sympathetic fibres to the heart which maintains pumping 30% above with no sympathetic stimulation. Therefore, when sympathetic activity is inhibited, the ventricular force of contraction decreases.

In intact animals, stimulation of sympathetic nerves produces a marked increase in the heart rate and a moderate increase in the stroke volume leading to a manifold increase in the cardiac output.

Characteristics of increased myocardial contractility

Characteristics of homometric regulation.

The increased myocardial contractility achieved by homometric regulation differs from the increase in force of contraction of myocardium achieved by heterometric regulation. Its characteristic features are:

- The ventricles contract more forcefully and more rapidly, i.e. velocity of shortening of muscle is increased. As a result, the ventricles are able to do more work per stroke, i.e. ejection fraction increases at the same end-diastolic volume (without increase in venous return).
- Due to more complete emptying of ventricles during each systole, the *end-systolic volume is decreased*.
- Due to increased stroke output, *arterial pressure is increased*.

Mechanism of effects of sympathetic stimulation.

Sympathetic stimulation increases the myocardial contractility by causing *activation of* β_1 adrenergic receptors and Gs. Activation of β_1

receptors results in activation of adenylyl cyclase and increased intracellular cyclic AMP, which in turn:

- Increases the concentration of Ca^{2+} within the myocardial cells causing a more rapid and forceful contraction and
- Via protein kinase causes more rapid intake of Ca^{2+} by sarcoplasmic reticulum (SR), which shortens the duration of both the action potential and contraction.

Parasympathetic activity.

There is a negative inotropic effect of parasympathetic (vagal) stimulation. This effect, however, is not much because vagal fibres are mainly distributed to the atria and not much to the ventricles.

Role of heart rate in control of cardiac output

The cardiac output and heart rate both are increased during exercise, proportionate to its severity. Since, cardiac output is the product of stroke volume and heart rate, it is tempting to attribute the increase in cardiac output to increase in the heart rate. However, in fact it is not so. It has been seen that when heart rate alone is increased, e.g. by change in the frequency of discharge of an artificial cardiac pacemaker, the cardiac output does not increase at all. As shown in [Fig. 4.3-19](#), the progressive increase in the heart rate is associated with a proportionate decrease in stroke volume because of reduced diastole time and thus reduced end-diastolic volume. Conversely, when the heart rate is reduced the ventricular diastole is prolonged leading to more ventricular filling and thus an increased stroke volume.

FIGURE 4.3-19 Effect of increase in heart rate through an artificial pacemaker on stroke volume and cardiac output.

During exercise, the sympathetic stimulation produces a marked increase in the heart rate (200–300%) due to positive chronotropism and moderate increase (50–60%) in the stroke volume due to positive inotropism leading to manifold increase in cardiac output.

Integrated control of cardiac output

In intact animals and humans, the intrinsic and extrinsic mechanisms described above operate simultaneously in an integrated way to maintain cardiac output. Therefore, in a given situation, depending upon the status of end-diastolic volume and status of myocardial contractility, the individual will have one of the curves from the ‘family of Frank–Starling curves’.

Interaction of Frank–Starling mechanism and myocardial

contractility

Factors causing increased myocardial contractility shift the Frank–Starling curve to the left (Fig. 4.3-20). Increased contractility (positive inotropism) refers to greater contraction force at a given preload or end-diastolic volume. Factors increasing myocardial contractility are:

1. *Sympathetic stimulation* increases myocardial contractility by causing activation of β_1 adrenergic receptors, as discussed above.
2. *Catecholamines* also exert their positive inotropic effect via their action on cardiac β_1 adrenergic receptors by a mechanism similar to that of sympathetic stimulation.
3. *Xanthines* such as caffeine and theophylline exert their positive inotropic effect by inhibiting the breakdown of cyclic AMP.
4. *Glucagon* causes positive inotropic effect by increasing the formation of cyclic AMP.
5. *Digitalis and related drugs* exert their positive inotropic effect by their inhibitory effect on $\text{Na}^+\text{--K}^+$ ATPase in the myocardium. The inhibition causes an increase in intracellular Na^+ , which in turn increases the availability of Ca^{2+} in the cell. Digitalis which was initially prepared from the plant *Digitalis purpurea* has been used for centuries to treat heart failure.

FIGURE 4.3-20 Effect of changes in myocardial contractility on Frank–Starling curve. The factors which increase the contractility shift the curve to left and those decrease the contractility shift the curve to right.

Factors causing decreased myocardial contractility

shift the Frank–Starling curve to the right (Fig. 4.3-20). The decreased contractility (negative inotropism) represents a decrease in the force of contraction at any fibre length or ventricular volume. Its causes are:

1. *Parasympathetic (vagal) stimulation*. Since the vagal fibres are distributed mainly to atria and not to ventricles, vagal stimulation causes negative inotropic effect on the atrial muscles and indirectly mild negative

inotropic effect on the ventricles reducing strength of heart contraction by 20–30%.

2. *Heart failure* is also associated with reduced myocardial contractility due to intrinsic depression. The cause of this depression is not known.

3. *Myocardial infarction* may result in fibrotic and nonfunctional area in myocardium resulting in reduction of total ventricular performance.

4. *Hypercapnia, hypoxia and acidosis* produce negative inotropic effect by causing a decrease in the formation of cyclic AMP.

5. *Drugs* such as quinidine, procainamide and barbiturates depress myocardial contractility.

Relative contribution of intrinsic and extrinsic mechanism in controlling cardiac output

under some common situations are given below.

- *During rest in a normal person*, an equilibrium is maintained between the intrinsic and extrinsic control mechanisms of stroke volume and the sinus rhythm (heart rate). In this way, about 5–6 l blood is received by the heart (venous return) and the same amount is ejected out (cardiac output) in a minute at a normal heart rate of about 70–80 beats/min.

Regulation of cardiac output when venous return increases in the absence of stimulation of heart (e.g. as occurs immediately after a change of posture from standing to lying) is carried out by the Frank–Starling mechanism.

- *During exercise in normal persons*, both intrinsic and extrinsic mechanisms are geared up. Actual measurements of end-diastolic and end-systolic volumes have revealed no change or even a decrease in the end-diastolic volume in mild to moderate exercise. At the same time, there is evidence of increased sympathetic discharge to heart in the form of decreased end-systolic volume and tachycardia. It has been explained that the increased venous return produced by skeletal muscle pump action and increased respiration is tackled by improved

pumping of the heart. Therefore, it can be concluded that, in mild to moderate exercise, the pumping ability of the heart is enhanced mainly by greater sympathetic discharge. In severe exercise, when the venous return is large enough to raise the end-diastolic volume, Frank–Starling mechanism also comes into play over and above the increased sympathetic discharge thus result in very high cardiac output.

- *In patients with transplanted hearts.* Frank–Starling mechanism is practically the only mechanism regulating the cardiac output since there is absence of cardiac innervation (Fig. 4.3-21). During exercise, the increase in cardiac output seen in these patients is not so rapid, and their maximal increase is smaller than in normal individuals but is appreciable.

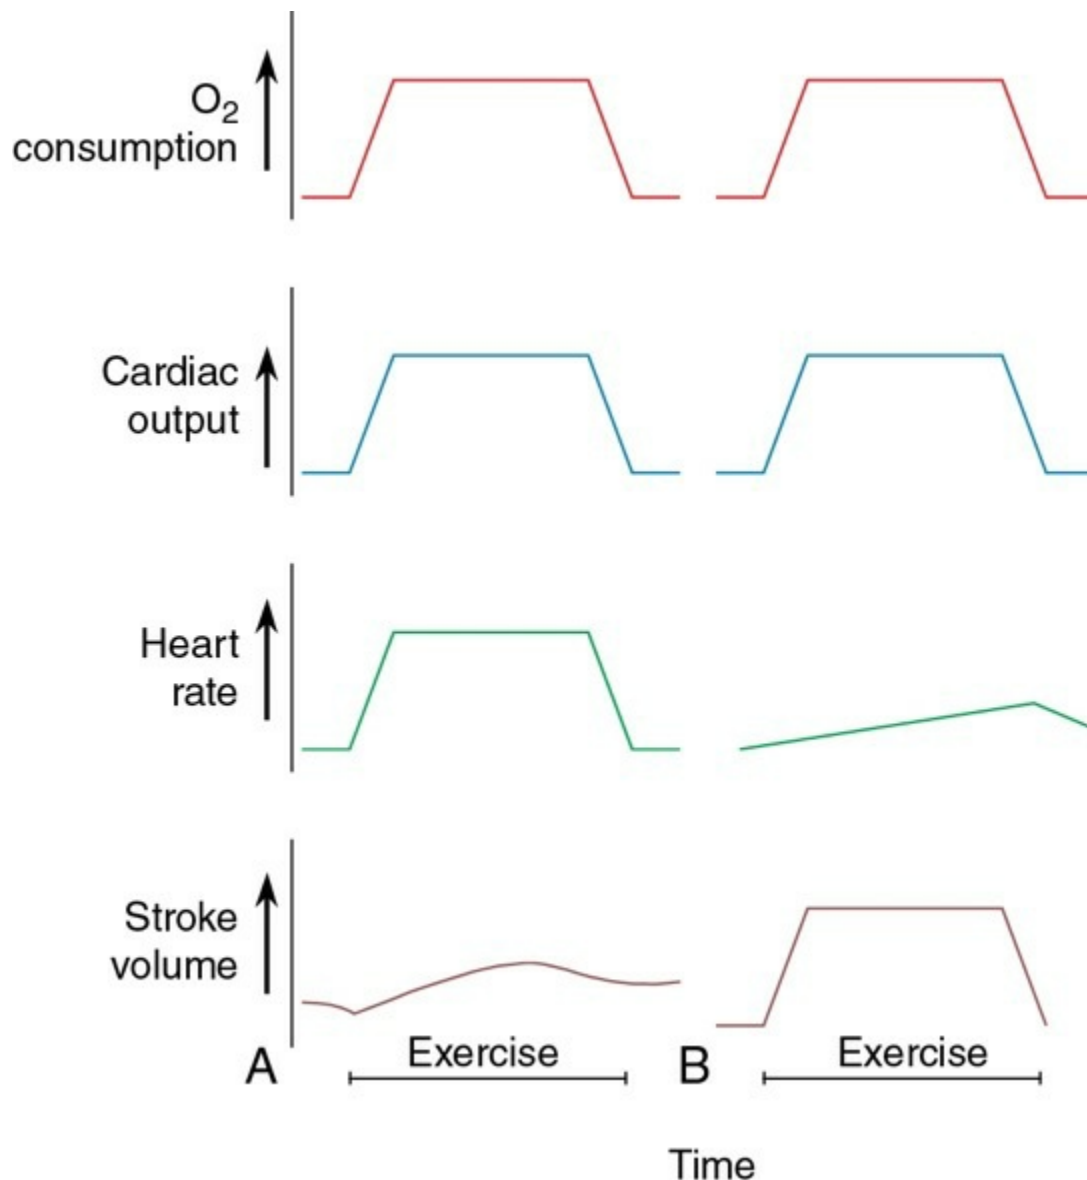

FIGURE 4.3-21 Cardiac response to moderate exercise: A, in normal human; and B, in patients with transplanted heart.

Heart–lung preparation

The Frank–Starling’s heart–lung preparation is an experimental set up in a dog, devised to demonstrate the effects of various factors on the activities of heart. In this preparation, as the name suggests, blood does not flow to any part of the body except the heart and lungs. The animal is actually dead and heart is functionally denervated.

Experimental set-up

Experimental set up (Fig. 4.3-22) of the heart–lung preparation includes following essential steps:

- *Trachea* is cannulated and lungs are artificially ventilated.
- *Aorta* is ligated beyond the origin of innominate artery so that systemic circulation of the body is blocked.
- *Innominate artery* is cannulated and connected to mercury manometer to measure the arterial blood pressure and also through a series of tubes to:
- *Elastic vessel*, which provides elasticity artificially similar to that of arterial wall,
- *Resistance vessel*, which is used to provide resistance artificially. The resistance applied can be measured through the attached manometer.
- *Warming glass coil*, which is kept inside a water bath with a heater. The temperature of the water bath is controlled, so that the temperature of blood can be maintained.
- *Flowmeter* which determines the amount of blood

flowing through it (cardiac output).

- *Venous reservoir* which represents the peripheral venous system. It is connected through a tube to the superior vena cava. A screw type clamp is fitted to the rubber tube. It is used to adjust the amount of blood returning to heart (venous return).

FIGURE 4.3-22 Heart–lung preparation.

Thus, the blood ejected from the left ventricle after passing through the above attachment ultimately reaches the right atrium. From there the blood flows to the right ventricle, pulmonary artery, lungs and back to heart through the pulmonary veins.

- *Inferior vena cava* is attached to manometer to record the right atrial pressure.
- *Bell's cardiometer* is fitted to the ventricle for measuring the stroke volume of the heart. The recording is made through *Marey's tambour* connected to the cardiometer.

Uses of heart–lung preparation

In the heart–lung preparation, heart works as an isolated organ. It can be used to demonstrate the effect of various factors on the heart's activities as:

1. Effect of venous return on stroke volume (Frank–Starling mechanism).

Venous return to the heart is changed through the venous reservoir and stroke volume at different levels of venous return is recorded through the cardiometer. The record shows:

- An increase in stroke volume with increase in venous return, (Fig. 4.3-23) and
- A decrease in stroke volume with decrease in venous return.

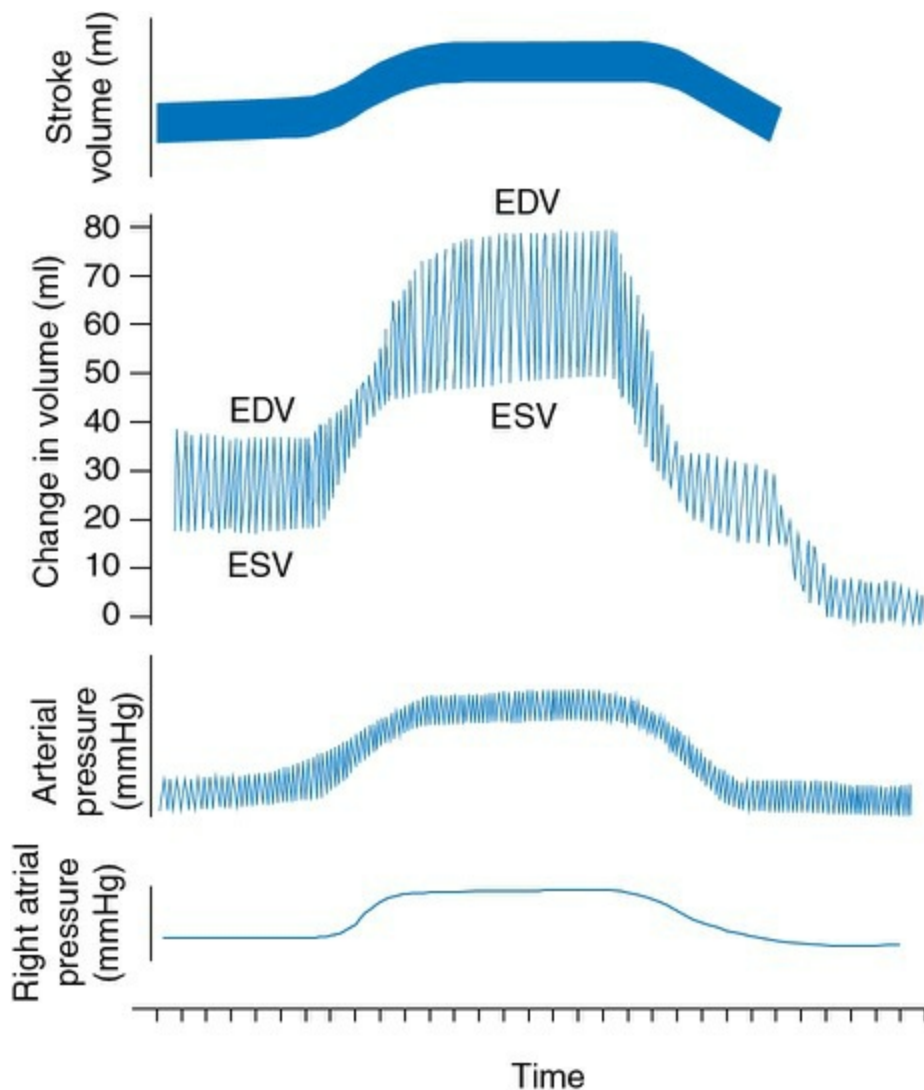

FIGURE 4.3-23 Tracings from heart–lung preparation demonstrating the effect of venous return on stroke volume, end-diastolic volume, end-systolic volume, arterial pressure and venous pressure.

These observations demonstrate the Frank–Starling’s law (intrinsic mechanism controlling stroke volume).

2. Effect of sympathetic stimulation on stroke volume

when the stellate ganglion (cardiosympathetic nerve) is stimulated without any change in the venous return, the stroke volume is increased but with lower end-systolic and end-diastolic volume (Fig. 4.3-24). This activity demonstrates the extrinsic control mechanism of stroke volume. Right atrial pressure is also reduced. It is due to increased suction of blood from the atria by the vigorously contracting ventricle.

FIGURE 4.3-24 Tracings from heart–lung preparation demonstrating the effect of sympathetic nerve stimulation on stroke volume, end-diastolic volume, end-systolic volume, arterial pressure and venous pressure.

3. Combined effect of increase in end-diastolic volume and sympathetic stimulation on stroke volume.

At a given rate of sympathetic stimulation, the end-diastolic volume is gradually increased and the resulting stroke volume is plotted against the end-diastolic volume, to give a Frank–Starling curve with different rates of sympathetic stimulation (0/S–10/S) a family of such curves is obtained (Fig. 4.3-25). From these curves, it can be inferred that even during sympathetic stimulation an increase in end-diastolic volume increases the stroke volume of heart.

FIGURE 4.3-25 Family of Frank–Starling curves obtained by combined effect to increase in end-diastolic volume and sympathetic stimulation on stroke volume on heart–lung preparation.

4. To demonstrate the effect of peripheral resistance on cardiac output.

Resistance is increased through the resistance vessel and its effect on cardiac output is recorded:

- With increase in the peripheral resistance cardiac output is increased and
- With decrease in the peripheral resistance the cardiac output is decreased.

5. Cardiac function curves

can also be recorded using a heart–lung preparation. These include:

- The cardiac output curves,
- The venous return curves and
- The cardiovascular curves.

Cardiac and vascular function curves

The cardiac and vascular function curves provide the graphic analysis of cardiac output, capacity of the ventricles to pump and relationship between cardiac output and central venous pressure (CVP). Such a graphical analysis provides useful information in patients with cardiac failure. Most of the curves are obtained from animal experiments by using heart–lung preparation. However, they do represent the function of ventricles in human heart. These curves include:

- Cardiac function curves,
- Vascular function curves and
- Cardiovascular function curves.

Cardiac function curves

The cardiac function curves reflect the relationship between CVP, i.e. right atrial pressure and the cardiac output (Frank–Starling curve). Three types of cardiac function curves are:

1. Normal cardiac function curve.

As shown in [Fig. 4.3-26A](#), the plateau level of normal cardiac function curve is about 13 l/min, i.e. 2.5 times the normal cardiac output (5 l). This means that the normal heart, functioning without any excess nervous stimulation can pump an amount of venous return up to about 2.5 times the normal venous return before the heart becomes a limiting factor in the control of cardiac output.

FIGURE 4.3-26 Cardiac function curve: **A**, normal; **B**, hyper effective and **C**, hypoeffective.

2. Hyper-effective cardiac function curve.

As shown in Fig. 4.3-26B, the hyper-effective heart pumps better than normal. Factors resulting in a hyper-effective heart are:

- *Sympathetic stimulation of heart*, which can raise the plateau level of the cardiac output curve to almost twice the plateau of normal curve.

- **Heart hypertrophy**, which occurs in trained athletes, e.g. marathon runners is similar to the skeletal muscle hypertrophy occurring due to heavy exercise. This increases the plateau level of cardiac output curve, sometimes 50–100%, and therefore, allows the heart to pump much greater than usual amount of cardiac output. When combined with sympathetic excitation, the effect can allow the heart to pump 30–40 l/min. This increased level of pumping is one of the most important factors in determining the runner running time.

3. Hypo-effective cardiac function curve

(Fig. 4.3-26C) results due to the factors that decrease the heart's ability to pump blood. These factors include:

- Reduced sympathetic discharge,
- Decreased ventricular compliance as in myocardial infarction, myocarditis,
- Insufficient pumping as in valvular or septal defects of the heart,
- Reduced ventricular filling as in pericardial effusion or cardiac tamponade,
- Increased load on the heart, as in hypertension.

Vascular function curves

The vascular function curves reflect the relationship between venous return and venous pressure. Normal vascular function curve and the factors affecting are depicted in Fig. 4.3-27, which can be interpreted as:

- As shown in Fig. 4.3-27A, in a *normal curve*, the venous pressure decreases as venous return increases because the transfer of blood from the venous to the arterial system increases. When venous return is zero, venous pressure is maximum and is referred to as the mean circulatory filling pressure (MCFP).
- The MCFP increases with increase in blood volume (Fig. 4.3-17) and also increases with increase in sympathetic stimulation (which increases venous tone). These factors, which increase the MCFP, cause the vascular function curve to shift to the right (Fig. 4.3-27B).

- *Changes in arteriolar resistance* alter the slope of the vascular function curve. An increased resistance reduces the cardiac output (venous return) and a decreased resistance increases the venous return (Fig. 4.3-27C).

FIGURE 4.3-27 Vascular function curves: **A**, normal; **B**, effect of increased blood volume and sympathetic stimulation; and **C**, effect of change in arterial resistance.

Cardiovascular function curves

The cardiovascular function curves refer to the coupled cardiac and vascular function curves. Since both venous return and cardiac output depend on the venous pressure, the cardiac and vascular function curves can be combined into a single group. The intersection of the two curves gives the operant value of cardiac output and venous pressure (Fig. 4.3-26A and 4.3-28). Any change in cardiac contractility, blood volume or vascular resistance will cause the operating point to shift, but *cardiac output and venous return will always be equal*. Exercise and congestive heart failure (described below) are just two of many conditions that can alter the operating point of the system.

FIGURE 4.3-28 Cardiovascular function curves: A, normal; B, during exercise; and C, in congestive heart failure.

Effect of exercise on cardiovascular function curve.

The overall effect of exercise is an increase in cardiac output that is

proportional to the exercise intensity as shown in [Fig. 4.3-28B](#).

- *Activation of sympathetic system* increases ventricular contractility and heart rate causing the *cardiac output curve to shift to left* (i.e. upward) and *vasodilation*, which occurs in the skeletal muscles, reduces the total peripheral resistance or afterload, causing the *vascular function curve to shift to right*. Thus, the operating point shifts from 1 to 2 ([Fig. 4.3-26B](#)) depicting thereby that with increase in venous return the cardiac output is increased proportionately.

Cardiovascular function curve in congestive heart failure.

In congestive heart failure, the output of one or both ventricles is not sufficient to supply the needs of the body ([Fig. 4.3-28C](#)).

- *Decreased contractility of the heart* is the primary defect in the congestive heart failure (e.g. in myocarditis and valvular heart disease), reducing cardiac output and thus shifting the cardiac function curve downwards. Point 2 in [Fig. 4.3-26C](#) and [4.3-28C](#) reflects the reduction in cardiac output from the normal level (Point 1).
- *Increase in blood volume*, due to retention of fluids and electrolytes by the kidneys in response to renin–angiotensin–aldosterone axis, increases the venous return (shifting the vascular function curve to right) and raises the venous pressure. The cardiac output, thus, returns toward normal (Point 3 in [Fig. 4.3-26C](#)), but it is at the expense of an enlarged ventricle.
- High venous pressure produces oedema. Left ventricular failure results in pulmonary oedema and right ventricular failure may lead to ankle swelling and fluid accumulation in viscera.

Introduction

Dynamics of circulation is concerned with flow of blood and lymph and also the pressure in the various segments of the vascular system of the body. For descriptive purposes, the 'dynamics of circulation' is discussed under the following headings:

- Functional organization and structure of vascular system,
- Haemodynamics,
- Blood flow and pressure in different segments of circulatory system and

- Blood pressure

Functional organization and structure of vascular system

Organization of vascular system

The vascular system, which consists of different types of blood vessels, constitutes the transport system of the body whose *primary functions* are: (i) distribution of nutrients and oxygen to all body cells, and (ii) collection of waste products and CO₂ from different body cells and to carry them to excretory organs for excretion. *Secondary functions* subserved by the vascular system are thermoregulation, distribution of hormones to the target tissues and distribution of antibodies and cells concerned with defence mechanism to various parts of the body.

To perform the above functions, the vascular system is organized into two separate circulations, systemic and pulmonary, arranged in series (Fig. 4.4-1). In addition, parallel to the circulation of blood is the disposed circulation of lymph which helps the blood circulation to perform its various functions.

FIGURE 4.4-1 A schematic illustration of the organization of cardiovascular system depicting the series arrangement of pulmonary and systemic circulation and parallel arrangement of vessels supplying blood to organs.

Systemic circulation

supplies blood to various systemic organs through parallel distribution channels (Fig. 4.4-1). This parallel arrangement of vessels ensures the supply of blood of the same arterial composition (i.e. same O_2 and CO_2 tension, pH, glucose level and essentially the same arterial pressure) to

various body organs. In systemic circulation, from the left ventricle, blood is pumped through the arteries and arterioles to the capillaries, where it equilibrates with the interstitial fluid. The capillaries drain through the venules into the veins and ultimately to the right atrium.

Pulmonary circulation

is meant for oxygenation of blood. Since pulmonary circulation is arranged in series with systemic circulation, it receives the same amount of blood over any significant time period. Such a balanced output is achieved by the intrinsic property of the cardiac muscle known as Frank-Starling mechanism which has been described in the section on cardiac output (page 288). In pulmonary circulation, from the right ventricle, blood is pumped through the pulmonary arteries to the pulmonary capillaries. In the pulmonary capillaries, the blood equilibrates with the O_2 and CO_2 of alveolar air. The capillaries then drain the oxygenated blood through venules and then through pulmonary veins into the left atrium.

Lymphatic circulation

which is disposed in parallel to the circulation of blood can be considered a third type of circulation. Some tissue fluid enters the lymphatic channels as lymph, which is ultimately drained into the venous system via the thoracic lymphatic duct and the right lymphatic duct.

Systemic vascular tree

The arrangement of systemic circulation permits wide variations in regional distribution of blood. For descriptive purposes and from a functional point of view, the systemic vascular tree can be divided into the following types of blood vessels:

- *Large elastic arteries* (Windkessel vessels) include aorta and its main branches such as carotid, iliac and axillary arteries,
- *Large muscular arteries* (distribution vessels) which include most of the arteries of the body, e.g. arteries like radial, ulnar and popliteal,
- Arterioles and precapillary sphincters (resistance vessels),
- Meta-arterioles and capillaries (exchange vessels),

- Venules (postcapillary resistance vessels),
- Veins (capacitance vessels) and
- Arteriovenous anastomoses (shunt or thoroughfare vessels).

Structure of blood vessels

Structural characteristics

General structural characteristics

Histologically, walls of most of the blood vessels except the capillaries consist of three coats. General structural characteristics of a large artery are (Fig. 4.4-2):

FIGURE 4.4-2 Histological structure of an artery.

1. Tunica intima.

It is the innermost coat of the vessel wall. In large arteries, from inside-out, it consists of:

- *Endothelial lining*, which is very smooth and silky, and consists of single layer of cells. It lies in contact with blood.
- *Basal lamina* is a thin layer of glycoprotein which lines the external aspect of the endothelium.

- *Subendothelial connective tissue* is a delicate layer of connective tissue which lies outside the basal lamina.
- *Internal elastic lamina* is a thin membrane formed by elastic fibres.

2. Tunica media.

It is the middle, thickest coat of the vessel wall. It consists of smooth muscles and elastic tissue. The ratio of these two tissues varies from vessel to vessel. On the outside, tunica media is limited by a membrane formed by elastic fibres called the *external elastic lamina*.

3. Tunica adventitia.

It is the outermost coat of the vessel wall. It is made of connective tissue in which collagen fibres are prominent. This layer prevents undue stretching or distension of the blood vessel.

Important points to be noted are:

- Fibrous elements in the intima and adventitia (mainly collagen) run longitudinally (i.e. along the length of the vessel).
- Elastic tissue and smooth muscles forming tunica media run circularly.
- Elastic fibres forming internal and external elastic laminae are often in the form of fenestrated sheets.

Specific structural characteristics

- *Large (elastic) arteries*, in their tunica media, have dominant elastic tissue which provides them property of distensibility and elastic recoil.
- *Medium size arteries*. In these arteries, the elastic tissue, both in intima and media, is much less and thus the proportion of smooth muscles increases.
- *Arterioles* have characteristically no elastic tissue. Their media consists of a thick layer of smooth muscles and they have a *relatively narrow lumen*. Because of their structural characteristics, they act as resistance vessels.
- *Meta-arterioles* are relatively high-resistance conduits between arterioles and veins.

- **Capillaries** arise directly from arterioles or meta-arterioles. A cuff of smooth muscle cells called the *precapillary sphincter* surrounds the origin of capillaries in some region. The capillary wall does not contain any tunica media and adventitia. It is formed essentially by endothelial cells which are lined on the outside by a basal lamina (glycoproteins), branching perivascular cells called *pericytes*. Further details of capillaries are described in the section on microcirculation.
- **Postcapillary venules**, which measure 20–60 μm in diameter, are the *most permeable part* of microcirculation.
- **Veins** are relatively thin-walled structures that contain very small amount of elastic tissue and smooth muscles compared with arteries. These are highly distensible part of the vascular system and that is why also form the so-called *reservoir vessels*.

Essential characteristics

Essential characteristics of blood vessels like lumen diameter, wall thickness, approximate total cross-sectional area and percentage of blood volume contained are shown in [Table 4.4-1](#).

TABLE 4.4-1

Essential Characteristics of Various Types of Blood Vessels

Types of blood vessels	Lumen diameter	Cross-sectional area (cm ²)	Velocity of blood flow	Pressure as cumulative blood volume %
• Aorta	2.5 cm	4.5	20 cm/s	2
• Arteries	0.4 cm	20	4 cm/s	8
• Arterioles	30 μm	400	2 mm/s	1
• Capillaries	05 μm	4500	0.2 mm/s	5
• Venules	20 μm	4000	0.2 mm/se	
• Vein	0.5 cm	40	2 cm/s	54
• Vena cava	3 cm	18	4.5 cm/s	

Vascular smooth muscle

Vascular smooth muscle (VSM) is a key structure in the physiology of vascular system and thus needs special emphasis.

Arrangement in tunica media of the vessels

Vascular smooth muscle is found in all segments of vascular tree, except the capillaries. Arrangement of vascular smooth muscles, however, varies in different segments:

- *In the Windkessel vessels*, they are disposed in a spiral fashion.
- *In the arterioles*, they are arranged more circularly and so on contraction may cause complete obliteration of the lumen.

Types of VSM.

From a functional point of view, VSM is of two types: single unit (visceral type) and multiunit. The visceral type VSM fibres have inherent property of myogenic activity to stretch and are mainly present in small arteries, arterioles and meta-arterioles. The multiunit smooth muscle fibres are not excited by stretch.

Innervational characteristics

- Smooth muscles of the blood vessels are innervated by sympathetic fibres. These muscles contain α -adrenergic receptors. Therefore, noradrenaline causes contraction of muscle fibres leading to vasoconstriction.
- Sympathetic fibres exert tonic effect even at rest, resulting in the existence of vasomotor tone in the blood vessels.
- Stimulation of sympathetics increases the vasomotor tone, as a result the vessels are constricted and narrowed.
- Inhibition of sympathetic discharge results in decreased vasomotor tone and hence vasodilation.
- Skeletal muscle arterioles also contain β_2 receptors in addition to the α receptors; therefore, adrenaline causes dilation of these vessels.
- Besides α -adrenergic receptors, smooth muscles of the blood vessels are also stimulated by other agents like O_2 tension, lactic acid, etc. which are described in local control (page 349).

Excitation and contraction characteristics of VSM

- *Resting membrane potential (RMP)* is rather low in VSM compared with

cardiac and skeletal muscles.

- *Typical action potential (AP)* is absent in VSM, nevertheless, with activity, some changes in membrane potential, resembling action potential, are seen.
- *Cause of development of AP* in VSM is entry of Ca^{2+} from ECF to ICF; therefore, calcium channel blockers like *nifedipine* powerfully prevent VSM contraction. That is why these drugs are extremely popular in the treatment of hypertension.
- *Contraction*, once developed in the VSM, takes long time to relax again, i.e. there occurs *sustained contraction*. Thus, sympathetic stimulation elevates blood pressure which tends to stay for some time.

Haemodynamics

Haemodynamics, which refers to study of blood flow in various segments of the vascular system, can be discussed under the following headings:

- General principles governing (factors affecting) blood flow,
- Circulation time,
- Types of blood flow,
- Measurement of blood flow,
- Distribution of blood flow to various regions of the body and
- Regulation of blood flow in different situations.

General principles governing (factors affecting) blood flow

Flow- pressure--resistance relationship

Relationship between flow of a fluid with the pressure and resistance offered to it through a rigid tube was studied by a French physiologist Poiseuille in 1842. Hagen, a contemporary of Poiseuille, worked further

with the problem and found out the mathematical expression. Poiseuille's results (and their mathematical expression) were based on the measurement of the flow of a Newtonian fluid, i.e. a fluid that showed a viscosity which was unaffected by flow rate, through rigid tubes under the influence of steady head of pressure. The relationship studied is known as Poiseuille's law or Poiseuille–Hagen law.

Poiseuille's law

Poiseuille's law expressing the relation between the flow (Q) and pressure gradient (ΔP) in a long narrow tube of length L , viscosity of fluid η and radius r of the tube is as:

$$Q = \frac{\Delta P \pi r^4}{8 \eta l}$$

Thus, according to Poiseuille's law, the flow (Q) of a Newtonian fluid through a rigid tube is determined by:

1. Pressure gradient (δP),

i.e. difference in the pressure between the two ends of the tube. In other words, fluid always flows from an area of high pressure (P_1) to one of lower pressure (P_2), and rate of flow (Q) is determined by the pressure gradient ($P_1 - P_2$), i.e. $Q \propto \Delta P$ or ($P_1 - P_2$).

2. Radius of tube.

The flow of fluid varies directly as the fourth power of radius (r^4). Thus, if the radius is halved, the flow will decrease by 16 times and vice versa. Thus, this factor is very important for flow of blood through the blood vessels.

3. Viscosity of fluid (η).

The flow of fluid varies inversely with the viscosity of fluid, i.e. greater the viscosity, lesser the flow and vice versa.

4. Length of the tube (L).

The flow is inversely proportional to the length of the tube. This is easily understandable, as every segment of the tube is offering resistance to the flow; therefore, longer the length, greater will be the total resistance

offered.

Resistance (R).

According to mathematical calculation in principles of physics, resistance (R) is represented by $8 L\eta/\pi r^4$. By replacing $8 L\eta/\pi r^4$ with R in Poiseuille's law, it becomes:

$$Q = \frac{\Delta P}{R}$$

Thus, Poiseuille's law can be considered analogous to Ohm's law of current in which:

$$\text{Current (flow)} = \frac{\text{Voltage (Pressure gradient)}}{\text{Resistance}}$$

Hence, the rate of flow (Q) is inversely proportional to the resistance (R).

The Poiseuille's law is valid for straight rigid tubes with Newtonian fluid flowing through them. Since blood vessels are not rigid and blood is not a Newtonian fluid; therefore, strictly speaking the Poiseuille's law does not apply to flow of blood through the vascular system. Nevertheless, the important principles relating flow, pressure gradient and resistance remain applicable, so they are discussed in relation to blood flow as:

- Blood flow and pressure gradient relationship, and
- Blood flow and resistance relationship.

Blood flow and pressure gradient relationship

According to Poiseuille's law, fluid always moves from an area of higher pressure to one of lower pressure. This downhill movement of blood (i.e. along the pressure gradient) occurs in the vascular system. [Fig. 4.4-3](#) depicts the mean lateral pressure and blood flow in various components of the cardiovascular system (represented as cumulative blood volume in per cent). In systemic circulation, pressure at the beginning of aorta is

about 100 mmHg and near the terminal portion of inferior vena cava it is nearly zero. Therefore, $P_1 - P_2 = (100 - 0) = 100$ mmHg. Note the progressive decrease in pressure from the left ventricle through the systemic circulation until blood enters the right ventricle. It is important to note that the greatest pressure drop occurs in the arterioles, which represent the highest resistance segment of the systemic circulation. Further, according to Poiseuille's law, at constant length and radius of a tube and viscosity of the fluid, the relationship between pressure and flow through a rigid tube is linear, i.e. as pressure increases, flow of fluid also increases (Fig. 4.4-4A). The relationship between flow of blood and pressure in the blood vessels is however not linear:

- In distensible vessels (e.g. aorta), the increase in flow as a result of a rising pressure head is initially less than that occurring in rigid tube, as due to elastic recoil they are slightly collapsed. However, later the flow in such vessels is greater than the rigid tubes (Fig. 4.4-4B), as they distend. At further higher pressure, the flow becomes linear as the vessels cannot distend any more due to the presence of fibrous tissue in the adventitia.
- In resistance vessels, i.e. arterioles, the distension in the absence of other influences, at a given pressure head, would increase their internal radius and would correspondingly cause a raised flow at the pressure. However, in real life, it does not occur so because smooth muscles present in the media of arterioles when distended react actively to stretch by contracting. This myogenic contractile response to stretch offsets the elastic effect and so the flow in these vessels becomes less than the rigid tubes, i.e. the curve becomes concave to the pressure axis (Fig. 4.4-4C).
- In the arterioles where the myogenic contractile response even exceeds the elastic effect of raised pressure, the blood flow is maintained and does not increase with the further increase in the pressure (Fig. 4.4-4D). Thus, as shown in Fig. 4.4-4D, such arterioles serve to stabilize the blood flow over a wide range of pressure (80–200 mmHg). This phenomenon is called *autoregulation*.

FIGURE 4.4-3 Mean lateral pressure in various components of vascular system and cumulative blood volume.

FIGURE 4.4-4 Relationship of pressure to flow: A, in a rigid tube; B, in a distensible blood vessel (aorta); C, in a distensible blood vessel containing active myogenic contractile element, whose contraction affects the distensible effects of raised pressure; and D, in a distensible vessel containing myogenic contractile element, which serves to stabilize flow over a wide range of pressure (80–200 mmHg), such vessels would show autoregulation.

Critical closing pressure

Since the flow–pressure relationship in a rigid tube is linear, the flow will cease only if the pressure is zero (Fig. 4.4-5A). However, in a blood vessel, the flow ceases when the blood pressure is 20 mmHg or even more (Fig. 4.4-5B). The pressure value at which the vessel collapses, its lumen closes and flow ceases is called *critical closing pressure (CCP)*. The blood flow ceases when the blood pressure falls below the CCP because:

- Certain amount of intramural pressure is essentially required to push the RBCs (with average diameter of $7.5\ \mu\text{m}$) through the capillaries (average diameter $5\ \mu\text{m}$).
- Further, the tissue pressure exerted over the vessels also causes their collapse. So, a certain amount of intramural pressure is a must to counteract the tissue pressure and thus to keep the vessels patent and to maintain the blood flow.

FIGURE 4.4-5 Relationship of pressure and flow in a rigid tube (A) and a blood vessel (B) and on sympathetic stimulation (C), depicting critical closing pressure (CCP).

Values of critical closing pressure

- When whole blood is flowing through the vessels, the average value of critical closing pressure (CCP) is 20 mmHg (Fig. 4.4-5B).

- When plasma is flowing, the value of CCP is about 5–10 mmHg.
- On sympathetic stimulation, the value of CCP increases to 60 mmHg (Fig. 4.4-5C)
- On sympathetic inhibition, the value of CCP falls to 0 mmHg.

Equilibrium of factors at critical closing pressure

- In general, vasomotor tone of the blood vessels tries to constrict the vessels. This tone is increased by sympathetic stimulation and decreased by sympathetic inhibition.
- Intramural pressure tries to dilate the blood vessels up to a certain limit. When a point is reached where the intramural pressure (P) is not able to maintain an equilibrium with tension (T) in the vessel wall, at this point the blood vessel closes and the pressure at which it occurs is called critical closing pressure. Laplace law described below helps to explain this equilibrium relationship.

Law of Laplace

Law of Laplace governs relation between the distending pressure and tension in the wall of a distensible viscus including blood vessels (Fig. 4.4-6). According to this law, the distending pressure (P) in a distensible hollow object is equal at equilibrium to the tension in wall (T) divided by the two principal radii of curvature of the object (r_1 and r_2):

$$P = T \left(\frac{1}{r_1} + \frac{1}{r_2} \right), \text{ where}$$

FIGURE 4.4-6 Relationship between distending pressure (P) and wall tension (T) in a hollow viscus.

T is expressed in dynes/cm, r_1 and r_2 are in cm, and so P is expressed in dynes/cm².

- In a sphere, $r_1 = r_2$. Therefore,

$$P = \frac{T}{r}$$

- In a cylinder such as a blood vessel, one radius is infinite. Therefore,

$$P = \frac{T}{r}$$

Physiological applications of law of Laplace.

This law applies to all the hollow viscous structures in the body. Some of its important applications are:

In vascular system.

As described above, for blood vessels, Laplace equation is $P = T/r$. This equation shows that smaller is the radius of a blood vessel, lesser is the tension (T) on the walls of the blood vessel required to balance the distending pressure or force (P). For example,

- In aorta, the tension at normal pressure is 170,000 dynes/cm.
- In inferior vena cava, it is about 21,000 dynes/cm.
- But in the capillaries, it is approximately 16 dynes/cm. This explains why capillaries being so thin walled and delicate are not prone to rupture.

In heart.

Law of Laplace also explains the disadvantage faced by a dilated heart. When the radius of a cardiac chamber is increased, a greater tension must be developed in the myocardium to produce any given pressure; consequently, a dilated heart must do more work than a nondilated heart.

In lungs,

the radii of curvature of the alveoli become smaller during expiration, and these structures would tend to collapse because of the pull of surface tension if the tension were not reduced by the surface tension-lowering agents (surfactants).

In urinary bladder,

for application of law of Laplace, see page 561.

Flow and resistance relationship

From Poiseuille's law, it can be derived that flow is inversely

proportional to the resistance, i.e. $Q \propto 1/R$, and that resistance is represented by $8L\eta/\pi r^4$, i.e. resistance depends upon the length (L) and fourth power of radius (r^4) of the tube and viscosity of the fluid (η). Before discussing the effect of these factors on the blood flow, it will be worthwhile to know about the *peripheral resistance unit* (PRU), i.e. unit of peripheral resistance in vascular system and concept of total peripheral resistance (TPR) in the body.

Peripheral resistance unit (PRU)

As discussed above, Poiseuille's law can be considered analogous to Ohm's law, so:

$$\text{Flow, i.e. } Q(\text{ml/s}) = \frac{P_1 - P_2(\text{mm of Hg})}{\text{Resistance (R)}}$$

$$\text{Thus, } R = \frac{P_1 - P_2 (\text{mm of Hg})}{Q (\text{ml/s})}$$

As flow is in ml/sec, therefore, in vascular system, *peripheral resistance unit* (PRU) is mm of Hg/mL/s.

Total peripheral resistance (TPR)

At rest, in the systemic circulation, pressure at the beginning of aorta (P_1) is 100 mmHg and near the terminal portion of inferior vena cava (P_2) is 0 mmHg. Therefore, pressure gradient ($P_1 - P_2$) = (100 - 0) = 100 mmHg; and rate of blood flow (Q) through circulatory system is 100 ml/s. Thus at rest, the resistance (R) of the entire systemic circulation is called 'total peripheral resistance' (TPR), which can be calculated from the formula:

$$R = \frac{P_1 - P_2 (\text{mm of Hg})}{\text{Flow (ml/s)}}$$

$$\text{TPR at rest} = \frac{100 \text{ mmHg}}{100 \text{ ml/s}} = 1 \text{ mm of Hg/ml/s} = 1 \text{ PRU,}$$

- TPR during maximum vasoconstriction may increase to 4 PRU, and

- TPR during maximum vasodilation may decrease to 0.2 PRU.
- Pulmonary vascular resistance is about 0.1–0.2 PRU.

Factors that affect resistance to blood flow

According to Poiseuille's law, resistance (R) depends upon the length of tube (L), fourth power of radius of tube (r^4) and viscosity of the fluid (η). Since in an intact body the length of the blood vessels does not change, i.e. remains constant, the major factors that determine the resistance to blood flow are:

- I. The viscosity of blood and
- II. The radius of vessels.

Blood viscosity and resistance.

Resistance (R) to blood flow is directly proportional to viscosity (η) of blood.

Definition and unit of viscosity.

Viscosity was described by Isaac Newton in 1713 as internal friction to flow in a fluid or lack of slipperiness. These terms emphasize that when a fluid moves along a tube, laminae in the fluid slip on one another and move at different speeds thereby causing a velocity gradient in a direction perpendicular to the wall of the tube. This velocity gradient is called the *rate of shear*. A simple viscous fluid known as *Newtonian fluid* is defined as one whose viscosity does not vary with the rate of shear and remains constant at different rates of laminar flow. Therefore, resistance met by the fluid moving through a tube in a streamlined flow is due to the friction between adjacent laminae and not due to the friction between vessel wall and fluid. Thus, greater the internal friction, greater is the difference in velocity (shear rate) between two laminae and greater the coefficient of viscosity.

- **Unit of viscosity** is *Poise* (after Poiseuille). A fluid of 1 poise viscosity has a force of 1 dyne/cm² of contact between layers when flowing with a velocity gradient of 1 cm/s. 1 Poise is considered to be consisting of 100 centipoise (CP). *Viscosity of water* at 21°C is 0.01 poise or 1 centipoise.
- **Relative viscosity** is a more often used term, and refers to the viscosity

of a fluid relative to the viscosity of water at body temperature (37°C).

- Water has a viscosity of 0.695 centipoise at body temperature.
- Plasma, which has a viscosity of 1.2 CP at 37°C, thus has a relative viscosity of 1.7.
- Blood (plasma plus cells), which has a viscosity of 2.8–3 CP at 37°C, thus has a relative viscosity of about 4–5.

Factors affecting blood viscosity

1. *Shear rate or velocity gradient.* Viscosity of the blood decreases as the shear rate or velocity gradient increases and vice versa.

- *At high shear rate*, the RBCs occupy the central axis of the tube and move with their long axis parallel to the direction of flow where the flow rate is fastest, leaving the cell-free zone of plasma at periphery. This process is called *plasma skimming* (Fig. 4.4-7A). This causes least friction between the cells and plasma and thus viscosity decreases. At high rates of flow, blood behaves almost like a Newtonian fluid with constant viscosity (Fig. 4.4-8).

Note. The phenomenon of plasma skimming is responsible for low value of haematocrit in capillary blood. The haematocrit of capillary blood is about 25% lower than that of venous blood.

- *When shear rate is low* (at low flow rate), tendency of RBCs to occupy central axis decreases (Fig. 4.4-7B). The suspended RBCs in plasma increase internal friction due

to collision among these suspended particles. So, with slow shear rate the viscosity increases.

2. **Haematocrit.** In general, variation in the haematocrit is the major factor that changes the viscosity of blood. An increase in haematocrit tends to reduce flow rate because of increased viscosity. The normal haematocrit for men is 40–45%, whereas the normal value for premenopausal women is 35–40%. Viscosity of blood with a haematocrit of 40% is approximately three times that of water.

- *In vitro*, the relative viscosity of blood increases proportionally with increase in haematocrit (above 45%).
- *In vivo*, the effect of increased haematocrit on viscosity is affected by the diameter of the vessels as discussed:
 - In large vessels, increase in haematocrit causes appreciable increase in the viscosity. However, in small vessels (<10 μm diameter), i.e. arterioles, capillaries and venules, change in viscosity per unit change in haematocrit is much less compared with large vessels (Fig. 4.4-9). How it happens, is explained here.

3. **Diameter of blood vessels.** The relationship between viscosity and diameter of the vessels is expressed as *Fahraeus–Lindquist effect* after the name of the workers. According to their experimental observations, the viscosity of blood in vessels with diameter less than 300 μm is less than the viscosity of blood in larger diameter vessels. These workers reported that in a tube of 40 μm diameter, the relative viscosity of blood was only 70% of that through a tube of 150 μm . Further, studies have also shown that in a tube of 14 μm diameter the, viscosity was only 47% of that through a tube of 150 μm .

Explanation for Fahraeus–Lindquist effect. This effect was observed only when the experiments were performed using blood and not when studied with water and plasma. Factors responsible for this effect are:

- The RBCs present in the blood are deformable in nature, so that apparent viscosity of blood does not change while passing through a tube of smaller diameter.
- Due to the phenomenon of plasma skimming in large- and moderate-sized vessels, blood that enters the small vessels such as capillaries is of lesser haematocrit (25% less than the whole blood haematocrit). The width of cell-free zone at the periphery is constant whatever may be the tube diameter and correspondingly occupies a bigger proportion in narrow tubes. As a result, the total relative viscosity is less in smaller diameter vessels. Because of this effect, a satisfactory flow rate exists even in the blood vessels whose diameters are small.
- In addition, there is a suggestion that capillary endothelial cells secrete a substance (mucopolysaccharide) which further helps to lower the viscosity of the blood in the capillaries.

Applied aspect of Fahraeus–Lindquist effect. Because of this effect, haematocrit changes have relatively little effect on the *resistance* except when the changes are large.

4. *Temperature.* Cooling increases the viscosity of blood. In an intact body, though there is no variation in the body temperature normally, the cutaneous and subcutaneous vessels and even those of deeper regions in the limbs are subjected to considerable alteration of temperature due to atmospheric temperature. Thus, when the hand is kept in ice water, regional viscosity of the blood shows a threefold increase.

Pathological conditions associated with high blood viscosity are:

- Severe polycythaemia,

- Abnormal shaped RBCs (congenital spherocytosis),
- Abnormally high immunoglobulin level and
- Lowered body temperature (in frost bite).

To summarize. Viscosity of blood is *inversely proportional to*:

- Flow rate (shear rate) and
- Temperature within limit.

Directly proportional to:

- Haematocrit, i.e. packed cell volume (PCV),
- Concentration of plasma proteins, especially immunoglobulins and
- Diameter of vessel wall.

FIGURE 4.4-7 Features of streamlined flow at high flow rate (A) and at slow flow rate (B).

FIGURE 4.4-8 Effect of shear rate on relative viscosity of blood. Note, at higher shear rate, the viscosity of blood becomes constant and it behaves like a Newtonian fluid such as plasma or saline.

FIGURE 4.4-9 Relationship between the haematocrit and relative viscosity when blood flows through a tube of diameter 200, 60 and 6 μ m.

Radius of blood vessels and resistance.

As mentioned earlier, the rate of flow is proportional to the fourth power of the radius (r^4) of the blood vessels. Thus, even a small change in the calibre of the blood vessels will produce a marked change in blood flow. For example, at a pressure head of 100 mmHg, the change in flow rate with change in the radius is:

Radius	Flow rate
1 mm	1 ml/min
2 mm	16 ml/min
4 mm	256 ml/min.

Among the blood vessels, in aorta and large arteries, there is little resistance. Arterioles are the major seat of vascular resistance because of the following facts:

- These are small bored vessels (30 μ m in diameter).
- Presence of large amount of smooth muscles in their wall. Thus, constriction of arterioles increases the resistance and decreases blood

flow while dilation of arterioles decreases the resistance and increases the blood flow.

Control of blood flow to organs or tissues is thus regulated primarily by altering the radius of the arterioles. Because the arterioles control the flow to various vascular beds, they are considered the *stopcocks* of the circulation. In our body, arterioles are in large bulk in splanchnic region and skeletal muscles, and constitute the major site of peripheral resistance. Because of their characteristics, arterioles play an important role in the following functions:

- Control of blood flow during alteration in arterial blood pressure, i.e. autoregulation (see page 315),
- Control of blood flow following occlusive ischaemia, i.e. reactive hyperaemia (see page 315),
- Control of blood flow during exercise (see page 315) and
- Conversion of pulsatile flow from heart to a steady flow, in association with elastic vessels (see page 314).

Velocity of blood flow

The velocity of blood flow refers to displacement of blood per unit time, i.e. cm/s, while the rate of blood flow is the amount of blood flowing per unit time, i.e. cm³/s. The physiologically important aspects to be considered in relation to velocity of blood flow are:

- Velocity and cross-sectional area relationship, and
- Velocity–pressure relationship.

Velocity and cross-sectional area relationship

- The relationship between velocity (V), quantity of blood flow (Q) and cross-sectional area (A) of the blood vessel is:

$$V = \frac{Q}{A}$$

- Thus, if quantity of blood flow (Q) remains constant and the cross-sectional area (A) increases, then the velocity of blood flow will decrease.
- Since cross-sectional area of capillaries is 1000 times as that of aorta, the velocity of blood flow in capillaries is approximately 1 mm/s as compared to 40 cm/s in aorta.
- The total cross-sectional area of various types of blood vessels, the velocity of blood flow and pressure in the various segments of the cardiovascular system plotted as a function of the cumulative blood volume are shown in Fig. 4.4-10 and Table 4.4-1.

FIGURE 4.4-10 Relationship between cross-sectional area, velocity of blood flow and pressure as a function of cumulative blood volume.

Thus, Fig. 4.4-10 depicts that to keep the flow rate equal, the velocity of flow must vary inversely with the cross-sectional area of each vascular

segment. This is in accordance with the continuity principle, according to which in any system arranged in series, the flow through each vascular segment must be equal to the flow through every other, unless one segment becomes progressively distended.

Velocity–pressure relationship

To understand the effect of velocity of blood flow on pressure, it is important to understand the concept of total energy (total pressure), potential energy and kinetic energy put forward by Burton in 1965.

Total energy (total pressure) of a fluid in a tube at any point equals the sum of the potential energy and kinetic energy.

Potential energy of a fluid in a tube comprises hydrostatic pressure and lateral (static) pressure.

1. Hydrostatic pressure (pH)

results from a difference in vertical height in a fluid-filled system. Because of gravity, fluid has weight that generates force, which is proportional to its vertical height:

$$Ph = \delta \cdot h \cdot g,$$

where δ = fluid density, h = height of fluid column above or below a reference level and g = gravitational constant.

Some facts about effects of hydrostatic pressure on human vascular system are:

- The zero reference level is at the right atrium, so vascular segments higher than reference point will have negative gravity effect and vascular segments below reference point will have positive gravitational effect.
- Both arteries and veins at any given horizontal level are affected by the same hydrostatic pressure of blood so that the pressure gradient between arteries and veins is same (about 100 mmHg), i.e. it is not altered (Fig. 4.4-11).
- As shown in Fig. 4.4-11, in an upright person, assuming that foot is 100 cm below the heart, the pressure in the vessels (arteries as well as veins) of foot is 100 cm H₂O (77 mmHg) higher than the pressure at the

root of aorta.

- In a supine position, the hydrostatic effect is eliminated because the entire cardiovascular system is essentially at the same horizontal level.

FIGURE 4.4-11 Effect of hydrostatic pressure of blood on arterial and venous pressure in an upright position.

2. Lateral (static) pressure

represents the pressure in the cardiovascular system that is usually measured with a strain gauge or transducer after eliminating the hydrostatic pressure effect. To eliminate hydrostatic pressure effect, it is essential to place the gauge or the sphygmomanometer cuff at the *zero reference* (phlebostatic) level, which is equivalent to the level of right atrium.

Kinetic energy is the momentum that blood gains because of its mass and

velocity:

$$\text{Kinetic energy} = \frac{mV^2}{2}$$

where m = mass and V = velocity.

Thus, when velocity of flow is very low, kinetic energy is negligible.

Total energy (total pressure), as stated above according to Burton, at any point equals the sum of potential energy and the kinetic energy.

Therefore, when velocity of flow is very low (i.e. with negligible kinetic energy), the magnitude of total energy (i.e. total pressure or perfusion pressure) is almost equal to the lateral pressure. However, when the velocity of flow is high, the lateral pressure exerted by the flowing fluid is much less than the total pressure exerted. This is because of the fact that at high velocity of flow some potential energy is *converted into kinetic energy*. The effect of velocity of flow on total pressure exerted is expressed mathematically by:

Bernoulli's principle

which states that in a supine position (i.e. when the effect of gravity or hydrostatic pressure effect is removed), the total energy or pressure (E) of flowing blood in a vessel is:

$$E = P + \frac{1}{2}\rho V^2, \text{ where}$$

P = lateral pressure, ρ (Rho) = the density of blood and

V = Velocity of blood in the vessel.

Experimental demonstration of velocity–pressure relationship.

The velocity–pressure relationship expressed above in *Bernoulli's principle* can be demonstrated experimentally by a system of pilot tubes (Fig. 4.4-12) as:

- AB is a tube through which fluid is flowing from direction A to B.
- The tube AB has central narrow segment S_2 where velocity of flow is

higher. On each side of the narrow segment are wide segments S_1 and S_3 , where velocity of flow is low. The length of arrows represents relative velocity of flow.

- Six tubes (a_1 , a_2 , a_3 , b_1 , b_2 and b_3) are inserted in the tube AB. Lower ends of tubes a_1 , a_2 and a_3 are so constructed that they face upstream and hence record the total energy (total pressure), while tubes b_1 , b_2 and b_3 record lateral pressure only.
- *In segment S_1 of the tube AB*, where velocity of the flow is low (because the diameter is big), there is little difference in the height of fluid level in a_1 (representing total energy) and b_1 (representing lateral pressure).
- *In segment S_2 of the tube AB*, where velocity of the flow is very high (due to smaller diameter), there is marked difference in the height of fluid level in a_2 (representing total energy) and b_2 (representing lateral pressure). This shows that when velocity of flow is high, potential energy is converted into kinetic energy and the potential energy (lateral pressure) becomes much less than the total pressure (potential energy plus kinetic energy).
- *In segment S_3 of the tube AB*, where velocity of the flow slows again (due to bigger diameter), part of the kinetic energy is transformed into potential energy and consequently lateral pressure is increased, and the difference between the height of fluid level in a_3 (representing total energy) and b_3 (representing lateral pressure) decreases.

FIGURE 4.4-12 Experimental set-up demonstrating the effect of velocity on pressure and also effect of resistance on pressure (for explanation see text).

Conversion of energy and loss of energy.

Considering the values of total pressure (E), lateral pressure (P) and kinetic energy (KE) in tubes a_1, a_2, a_3 and b_1, b_2, b_3 , the following conclusions can be drawn:

- *Energy can be converted* between potential and kinetic energy ($P \leftrightarrow KE$); as:
- In segment S_1 , P is 100 and KE is 1;
- In segment S_2 , P falls to 50 and KE increases to 36 and
- In segment S_3 , P increases to 80 and KE falls to 1.
- *Energy in a moving fluid is progressively lost* due to resistance offered by the walls of the tubes as E which in segments S_1 is 101, falls to 86 in S_2

and in S_3 is 81. Further, the energy loss (pressure drops) occurs more where the resistance is high (narrow S_2 segment).

Physiological significance of velocity–pressure relationship

The values of E , P and KE in Fig. 4.4-12 clearly reveal that flow is a down gradient of total energy, and not of lateral pressure. Therefore, Burton pointed out that the kinetic energy factor has to be borne in mind when pressures are measured by catheterizing blood vessels (discussed below). The relative importance of kinetic energy factor in various segments of the vascular system is:

- In the arterial system, the kinetic energy factor is negligible, except in the aorta in heavy exercise.
- In the vena cava, kinetic energy is important only during exercise.
- In the atria and pulmonary artery, kinetic energy is not inconsiderable at rest and is very important when the cardiac output is increased.
- It has been calculated (Burton, 1965) that the kinetic energy factor is 50–55% of the total energy in the vena cavae, atria and pulmonary artery.
- Thus, in the circulation at rest, the kinetic energy factor is of little importance on the systemic arterial side and of only moderate significance in the systemic veins. Flow, therefore can be regarded as occurring between the root of aorta and the right atrium by virtue of a pressure gradient ($P_1 - P_2$).

Significance of kinetic energy factor while measuring pressure by catheterizing blood vessels

- When measuring pressure, unless the top of the catheter has its opening at right angles to the stream (Fig. 4.4-13A) (measuring ‘side pressure’), the pressure recorded is not accurate at that point. If the catheter faces the oncoming bloodstream or if an end cannula is tied into the artery, the flow of blood is prevented and the manometer registers a pressure higher than that by the factor $\frac{1}{2}\rho V^2$ (Fig. 4.4-13B).
- If the catheter opening faces downstream (Fig. 4.4-13C), the pressure recorded is lower than the pressure in the fluid by slightly less by the factor $\frac{1}{2}\rho V^2$ (flow is distorted by streaming round the catheter tip and

this reduces the correction required). Such a catheter placement is the accepted technique for recording of pulmonary arterial pressure.

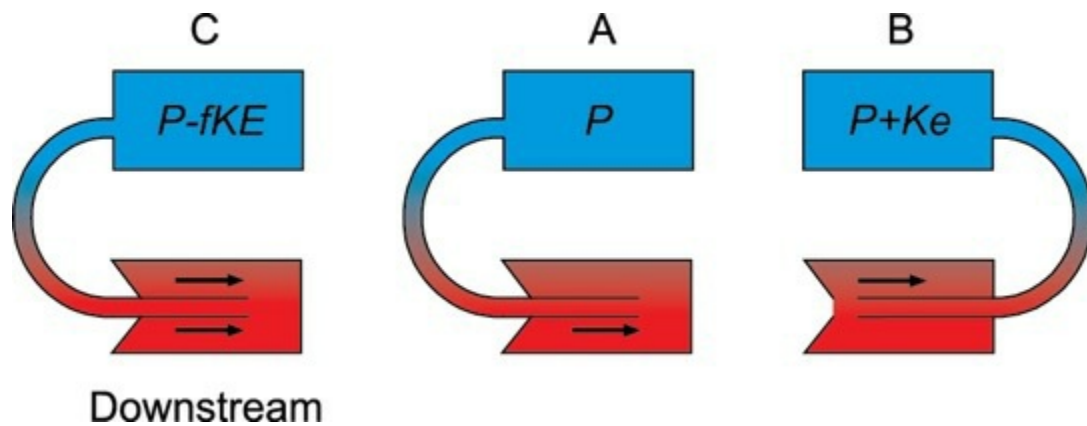

FIGURE 4.4-13 Experimental set-up demonstrating significance of kinetic energy factor while measuring pressure by catheterizing a blood vessel.

Circulation time

Circulation time refers to the time taken by the particles in blood in reaching from one point to another. It measures average linear velocity of blood. Calculation of circulation time in different regions of the body has clinical importance in circulation disorders of that particular region. The circulation time between two points can be estimated by injecting a substance into one segment of the circulation and of noting the time lapse when it can be detected at another point. Example of estimation of circulation time in certain regions is:

- *Arm to retina circulation time* is estimated by injecting fluorescein dye in the vein of arm and detecting its appearance with the fundus camera on retina (procedure is called fundus fluorescein angiography).
- *Arm to tongue circulation time* can be estimated by injection of bile salts in the vein of arm and appearance of bitter taste of bile salts. Average normal arm to tongue circulation time is 15 s.
- *Arm to face circulation time* is estimated by injecting histamine in the arm vein and noting the time taken for causing flushing of face. Average arm to face time is 24 s.
- *Arm to lung circulation time* can be estimated by noting the interval

between the injection of a bolus of ether into the vein of arm and the appearance of coughing produced by its arrival in the lungs. Average arm to lung time is 6 s.

- **Foot to foot circulation time.** A dye injected into the vein of a foot reaches the other foot after circulation through the heart within 80 s. It indicates total circulation time.
- **Factors affecting circulation time** are:
 - Increased cardiac output,
 - Exercise,
 - Excitement,
 - Adrenaline and
 - Basal metabolic rate.

Blood flow: Types, measurement and distribution

Types of blood flow

Blood flow in the vascular system is of two types:

- Laminar blood flow and
- Turbulent blood flow.

Laminar blood flow

Blood flow in the blood vessels is normally in streamline, like the flow of liquids in narrow rigid tubes. Such a blood flow is called laminar blood flow and is considered to consist of a series of thin laminae slipping over one another.

- The outermost lamina, i.e. an infinitely thin layer of blood in contact with the wall of the blood vessel, does not move and the next lamina

has some velocity. The subsequent inner layers have progressively increasing velocity, and thus the innermost lamina, i.e. the core of the bloodstream, has the maximum velocity (Fig. 4.4-14).

- The laminar blood flow being streamlined is noiseless and within physiological limits shows a linear relationship with pressure.

FIGURE 4.4-14 Laminar blood flow showing different velocities of the different laminae resulting in parabolic distribution of velocities. Note the central core of bloodstream has greatest velocity.

Turbulent blood flow

The above-described laminar blood flow occurs up to a certain velocity, at or above which the blood flow becomes turbulent. The velocity of flow at which blood flow becomes turbulent is called critical velocity.

- In turbulent blood flow, the blood moves in irregular varying paths continuously mixing within the vessel and colliding with the vessel wall. This causes a greater energy loss compared with laminar flow.
- Turbulent blood flow is noisy and does not show a typical linear

relationship with the pressure.

- Normally, none of the small vessels show turbulent flow. In humans, the critical velocity sometimes exceeds in the aorta at the peak of systole.

Probability of turbulence.

The chances of blood flow becoming turbulent are determined by the *probability of turbulence*, which is denoted as Re (Reynolds number), named for the man who described it. According to Reynold, the probability of turbulence (Re) is:

- Directly proportional to the:
 - Density of blood (ρ) equal to 1,
 - Diameter of the vessel (D) in cm,
 - Velocity of blood flow (V) in cm/s and is
- Indirectly proportional to:
 - Viscosity of the blood (η) in poises.

$$\text{thus } Re = \frac{\rho DV}{\eta}$$

- Blood flow is usually not turbulent when Re is less than 2000.
- Chances of blood flow becoming turbulent are increased when Re exceeds 2000.

When Re is more than 3000, turbulence is almost always present.

Conditions associated with turbulent blood flow

- *Constriction of the artery* by an atherosclerotic plaque (Fig. 4.4-15) or by any other cause, e.g. application of external pressure while

measuring the blood pressure with sphygmomanometer, is associated with a blood flow velocity which exceeds critical velocity and thus causes the turbulent blood flow. The turbulent flow generates vibrations (sounds) which can be heard over the artery by a stethoscope, e.g. *Korotkoff sounds* heard while recording the blood pressure or the *murmur* heard over a constricted artery.

- **Anaemia** is frequently associated with turbulence, because of *lowered blood viscosity*. This may be the explanation of the systolic murmurs that are common in anaemia.
- **Large diameter vessels**, e.g. ascending aorta, as mentioned above, may have turbulent flow at the peak of systolic ejection which may cause *ejection systolic murmur*.

FIGURE 4.4-15 Turbulent blood flow caused by constriction of the lumen of blood vessel.

Measurement of blood flow

Following methods are known for measurement of blood flow in various parts of the body:

1. Methods based on Fick's principle

Methods based on Fick's principle can be used to measure blood flow through some of the organs like the lungs, the heart and the brain. The methods are similar to those described for measurement of cardiac output (page 285).

2. Para-amino-hippuric (PAH) acid clearance method

Para-amino-hippuric acid clearance method is used to determine the renal blood flow and thus study the renal physiology (see page 553).

3. Venous occlusion plethysmography

Venous occlusion plethysmography is a simple but crude method of measuring blood flow through the limbs.

Principle.

It is based on the principle that if venous return of a region (part) is suddenly obstructed, that part increases in size due to arterial flow. The increase in size is equivalent to the blood flow to that part.

Procedure.

To measure blood flow through a limb (say a forearm), the part is enclosed in a watertight chamber (plethysmograph) connected to a volume recorder. The venous drainage from the limb is occluded for a few seconds by inflating the sphygmomanometer cuff to 60 mmHg. The increase in the size of the arm will displace the water in the plethysmograph, which will be recorded with a volume recorder (Fig. 4.4-16). The displacement is equal to the blood flow to the part during that period.

FIGURE 4.4-16 Plethysmography showing measurement of blood flow in forearm.

4. Electromagnetic flowmeter

The electromagnetic flowmeter is based on the principle that when a vessel containing blood (a conductor) is placed between the two poles of a magnet, voltage is generated in the blood flowing through the magnetic field. The magnitude of the voltage is proportionate to the volume of flow and can be measured with an appropriately placed electrode on the surface of the vessel (Fig. 4.4-17).

FIGURE 4.4-17 Principle of electromagnetic flowmeter.

5. Doppler flowmeter (ultrasonic flowmeter)

Ultrasonic flowmeter is based on the principle of Doppler effect. In this instrument, ultrasonic waves are sent into a vessel diagonally from one crystal, and the waves reflected from the red and white blood cells are picked up by a second downstream crystal (Fig. 4.4-18). The frequency of the reflected waves is higher by an amount that is proportionate to the rate of flow toward the second crystal because of the Doppler effect.

FIGURE 4.4-18 Principle of ultrasonic flowmeter.

Distribution of blood flow to various regions of the body

At rest, about 5 L of blood enters aorta per minute. In terms of tissue weight, blood flow to liver, brain and heart is very high. Kidney has high blood flow because it is related to excretory function rather than metabolic requirement. The distribution of blood flow to various organs and regions of the body during resting conditions and during maximum activity conditions is shown in [Table 4.4-2](#).

- At rest, at least 50% of the circulating blood volume is in the systemic veins, 12% is in the heart cavities, and 18% in the lower pressure pulmonary circulation; only 2% is in the aorta, 8% in the arteries, 1% in the arterioles and 5% in the capillaries.
- When extra blood is administered by transfusion, less than 1% of it is distributed in the arterial system (the high pressure system) and all the rest in the systemic veins, pulmonary circulation and heart chambers other than the left ventricle (the 'low-pressure system').

TABLE 4.4-2

Distribution of Blood Flow to Various Organs of the Body

Organs	Blood flow per organ ml/min		Blood flow ml/100 g/min	
	At rest	During maximum activity	At rest	During maximum activity
Heart	250	1200	80	400
Brain	750	2100	55	150
Liver	1500	3000	58	120
Skeletal muscles	150	1800	04	70
Kidney	1200	1400	400	450
Skin	200	3500	08	150

Pressure and flow in various functional segments of systemic vascular tree

Pressure and velocity of flow of blood in the various parts of systemic circulation along with the pulmonary circulation summarized in [Table 4.4-1](#) and [Fig. 4.4-19](#) show that:

- **Pressure** in the left ventricle, aorta and large arteries is *pulsatile* (i.e. rises to a peak value during systole and decreases to minimum during diastole) and becomes continuous in the capillaries. Based on the pressure changes, the whole of the vascular system is broadly divided into:
 - *High-pressure system* which includes left ventricle, arteries and arterioles. This system controls the blood pressure and blood flow in the body.
 - *Low-pressure system* includes capillaries, venules, veins, right atrium, pulmonary vessels and left atrium. The low-pressure system is responsible for the control of blood volume and venous return.
- **Velocity** of blood flow in proximal part of aorta averages 40 cm/s. However, the flow in aorta is phasic, and velocity ranges from 120 cm/s during systole to even a negative value at the time of transient

backflow before the aortic valve closes in diastole.

- **Total cross-sectional area (TA)** of the vessels increases from 4.5 cm² in the aorta to 4500 cm² in the capillaries.
- **Relative resistance (RR)** is highest in the arterioles. As mentioned in the beginning of chapter, from functional point of view, the systemic vascular tree has been divided into various functional segments. Pressure and flow functions of the following functional segments of systemic vascular tree are:
 - Elastic arteries,
 - Muscular arteries,
 - Arterioles,
 - Microcirculation,
 - Venous circulation and
 - Lymphatic circulation.

FIGURE 4.4-19 Diagram showing pressure changes, velocity of blood flow through systemic circulation, total cross-sectional area of the blood vessels and relative resistance in the vessels (which is highest in the arterioles).

Pressure and flow functions of elastic arteries

The large elastic arteries (Windkessel vessels) include aorta and its main branches such as carotid, iliac and axillary arteries. These vessels contain elastic tissue in their walls in abundance which provides them two properties of distensibility and elastic recoil. The effect of these two properties of the elastic arteries on pressure and flow of blood is distensibility and elastic recoil.

Distensibility

As we know, the heart acts as a pump and ejects about 70 ml of blood into the aorta with each systole. The distensibility (compliance) of the elastic arteries allows them to accommodate the stroke volume of heart with only a moderate increase in pressure (from 80 to 120 mmHg) (Fig. 4.4-20A). Due to distension of these vessels, a part of energy released from the heart is stored as potential energy in the wall of aorta.

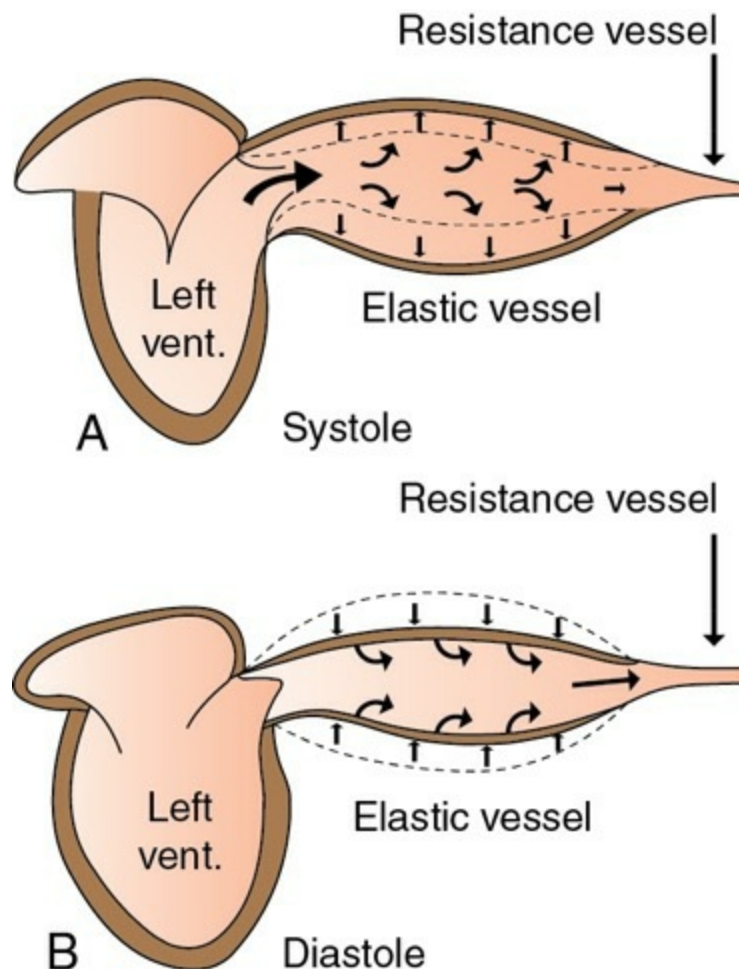

FIGURE 4.4-20 Distensibility (A) and elastic recoil (B) seen in aorta and its main branches maintain arterial pressure and flow during diastole.

Elastic recoil

During diastole, the stretched elastic wall of the aorta recoils and the potential energy stored in the wall is released onto the blood. This causes the blood to flow during diastole also; in this way, the pressure in the aorta does not fall below 80 mmHg (Fig. 4.4-20B). In other words, the elastic recoil of big arteries acts as a subsidiary pump for a continuous blood flow. This recoil effect is called *Windkessel effect*. *Windkessel* is a German word meaning elastic reservoir.

Functions of elastic vessels

1. They reduce velocity of blood flow to some extent during ventricular contraction (systole) due to property of distensibility.
2. They cause increase in velocity of blood flow to some extent during

ventricular diastole by elastic recoil. Thus, the Windkessel effect reduces the energy expenditure of heart.

3. Pumping action of the heart along with elastic recoil of aorta together constitutes a driving force for blood to move forward (towards periphery). This force is called *vis-a-tergo force*, and is an important determinant for venous return (see page 288).

4. Conversion of pulsatile blood flow from heart to a steady continuous flow. Since the heart contracts intermittently, therefore, the pressure and flow from the heart into large arteries is pulsatile. The elastic vessels act together with arterioles (resistance vessels) to convert this pulsatile flow into a steady continuous flow in the tissue capillaries, which allows maximum exchange between the blood and tissues. This role of elastic vessels and the arterioles can be explained by a simple experiment performed by Borelli.

Borelli's experiment.

In this experiment, one end of a rubber bulb having a one-way valve is dipped into a beaker of pure water and its other end is attached to a tube (Fig. 4.4-21). When the bulb is squeezed repeatedly, the water flow in different situations is as follows:

- **Intermittent flow** is seen when the tube is rigid whether without (Fig. 4.4-21A) or with (Fig. 4.4-21B) a narrow nipple attached to the outlet (open end), and also when the tube is elastic but without a narrow nipple attached (Fig. 4.4-21C).
- **Continuous flow** is, however, seen when a narrow nipple is attached to the outlet of an elastic tube (Fig. 4.4-21D). This set-up can be compared to combined effect of the aorta (elastic tubes and arterioles (narrow nipples producing resistance) which produce a continuous and streamlined flow of blood.

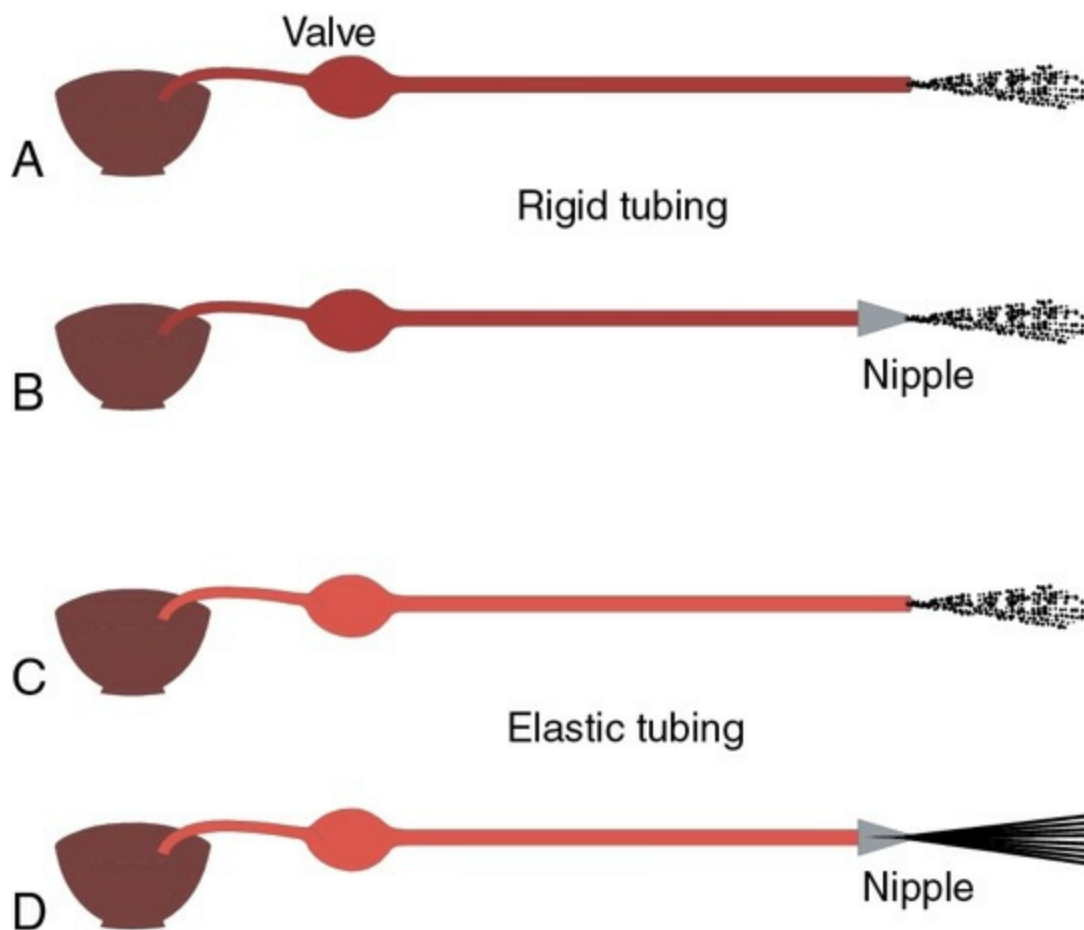

FIGURE 4.4-21 The Borelli's experiment showing intermittent flow of fluid in a rigid tube without nipple at the open end (A), in a rigid tube with nipple at the open end (B), in an elastic tube without nipple at the open end (C) and continuous flow in an elastic tube with nipple at the open end (D).

Clinically applied aspects

1. Due to age-related degenerative changes,

the elasticity of large vessels is decreased and so is the Windkessel effect. Therefore, in old age, systolic blood pressure increases due to loss of distensibility and diastolic blood pressure decreases (due to loss of elastic recoil). Thus, in a normal healthy individual aged about 70 years, typical blood pressure is 160/70 mmHg. That is, there occurs *systolic hypertension* with *increased pulse pressure* (SBP – DBP).

2. Atherosclerotic changes in small blood vessels

are also common in old age. These produce *essential hypertension*, i.e. an increase in systolic as well as diastolic blood pressure.

Pressure and flow functions of muscular arteries

The muscular arteries comprise most of the named arteries in the body such as radial artery, facial artery, ophthalmic artery and so on. These arteries serve as the *distributing channels* to the organs. Their relatively large lumen minimizes the pressure drop that occurs as a result of resistance.

Pressure and flow functions of arterioles

Structural characteristics

Each arteriole is only a few millimetre long and branches many a times to supply about 10–100 capillaries. The characteristic features of arterioles are:

- A thick muscular wall having profuse vasomotor (sympathetic) innervation; and
- A relatively narrow lumen (30 μm), because of which these vessels are considered the major site of peripheral resistance. The arterial pressure drops by about 50 mmHg while passing through few millimetre long arterioles (Fig. 4.4-19).

Functions of arterioles

1. Control of blood flow to the organs

The arterioles play a major role in the control of blood flow to organs or tissues. So, they are considered *stopcocks (valves) of circulation*. The constriction of arterioles increases the resistance and decreases the blood flow while dilation of arterioles decreases the resistance and increases the blood flow. Thus, blood flow is primarily regulated by altering the radius of arterioles, since according to Poiseuille's law rate of flow, it is proportional to the fourth power of the radius, i.e. r^4 (see page 302). The arterioles control blood flow to organs by the following two mechanisms:

Control of blood flow during alterations in blood pressure (autoregulation)

Autoregulation.

It is the ability of an organ or tissue to adjust its vascular resistance and

maintain a relatively constant blood flow over a wide range of arterial pressure (Fig. 4.4-22). This is accomplished by a change in the resistance (due to change in lumen as above) proportionate to change in the arterial pressure. Autoregulation is well developed in the kidney, brain, heart, skeletal muscle and mesentery. Two theories have been put forward to explain the phenomenon of autoregulation.

- **Metabolic theory** proposed that an increased arterial blood pressure initially increases blood flow to a tissue or organ. This increased blood flow washes out the vasodilator substances such as CO₂, H⁺, nitric oxide, adenosine, prostaglandins, K⁺, phosphate ions and low oxygen levels in the area. As a result, the arterioles constrict, vascular resistance increases and blood flow returns to normal. However, it has been reported that changes in the concentration of any of the above-mentioned substances cannot explain autoregulation.
- **Myogenic theory.** According to this theory, the vascular smooth muscle (VSM) responds to wall tension, which is a function of pressure and wall radius according to the law of Laplace (see page 304). An increase in arterial pressure initially stretches the smooth muscle fibres, in response to which the VSM contracts and returns the wall tension to control levels that can only be achieved with vessels of smaller radius. The narrowed lumen increases the resistance and compensates for the higher arterial pressure, returning the blood flow to control levels.

FIGURE 4.4-22 Autoregulation of blood flow. Note the blood flow remains relatively constant over a wide range of arterial pressure. This is accomplished by change in resistance proportionate to change in arterial pressure.

Control of blood flow after occlusive ischaemia (reactive hyperaemia).

Reactive hyperaemia is a phenomenon by which the vessels control blood flow to the organ after a period of ischaemia following occlusion of the artery to an organ or tissue. Due to this phenomenon, the blood flow exceeds the control level when the occlusion is resolved. The magnitude and duration of reactive hyperaemia depends on the duration of occlusion (Fig. 4.4-23). It has been proposed that reactive hyperaemia occurs due to a metabolic mechanism that controls blood flow to tissues.

FIGURE 4.4-23 Phenomenon of reactive hyperaemia, which increases blood flow after a period of ischaemia.

Control of blood flow during exercise.

The arteriolar smooth muscles respond not only to sympathetic discharge, but also to products of local metabolism. So, by these two mechanisms, regional blood flow is controlled in such a way that it is almost exactly proportional to the metabolic requirements of the tissues. For example, during muscular exercise, strong sympathetic discharge causes constriction of arterioles of the splanchnic region (where blood is not immediately required). Also, in the skeletal muscles, metabolites like CO_2 , H^+ , lactic acid, etc. cause marked arteriolar dilation and consequently blood flow is diverted from the splanchnic region to the skeletal muscles and heart to meet the elevated demand due to metabolic activity.

2. Conversion of pulsatile flow from heart to a steady continuous flow

As described in function of the elastic vessels, the arterioles along with the elastic vessels convert the pulsatile flow in the arteries to a steady flow in capillaries. For explanation, see Borelli's experiment (see [page 324](#)).

Microcirculation

Architecture of microcirculation

The microcirculation involves a meshwork of vessels less than 100 μm in diameter. These include small arterioles, meta-arterioles, capillaries, postcapillary venules and arteriovenous shunts (Fig. 4.4-24):

- **Meta-arterioles.** The arterioles divide into smaller muscle walled vessels, sometimes called meta-arterioles and these in turn feed into capillaries.
- **Precapillary sphincters** refer to a cuff of smooth muscle cells that surround the origin of capillaries. These determine the size of capillary exchange area at one particular moment in the tissue. For example, increase in the sphincter patency increases number of open capillaries. It is unsettled whether the meta-arterioles are innervated, and it appears that the precapillary sphincters are not. However, they can of course respond to local or circulating vasoconstrictor substances.
- **Capillaries** arise directly from arterioles or meta-arterioles. These vessels allow easy exchange of gases and nutritive substances across them and so are also called as *exchange vessels*. Capillaries constitute the most important segment of the circulatory system. Their structure and functions will be discussed in detail.
- **Postcapillary venules**, which measure 20-60 μm in diameter, are the *most permeable part* of the microcirculation.
- **Arteriovenous anastomosis (shunt or thoroughfare vessels).** These are short, low-resistance connections between the arterioles and veins, bypassing the capillaries. These are abundantly innervated by vasomotor sympathetic fibres. These vessels are especially found in the skin of fingers, toes and earlobes, where they are involved in the regulation of body temperature.

FIGURE 4.4-24 Architecture of microcirculation.

Structural characteristics of capillaries

Each capillary has an average diameter of $5\ \mu\text{m}$, length of $50\ \mu\text{m}$, wall thickness of $1\ \mu\text{m}$ and cross-sectional area of $40\ \mu\text{m}^2$.

The capillary wall essentially consists of a single layer of endothelial cells which are lined on the outside by a basal lamina (glycoprotein); overlying the basal lamina there may be isolated branching perivascular cells called *pericytes*.

The endothelial structure of capillaries varies in different organs depending on the function of the particular tissue. Under electron microscope, three types of capillaries have been identified: continuous or nonfenestrated capillaries, fenestrated capillaries and discontinuous capillaries or sinusoids.

1. Continuous capillaries

are characterized by a single layer of endothelial cells which are almost continuous, except for small clefts of $6\text{--}7\ \text{nm}$ in size in between the cells. It is believed that most of water-soluble ions (Fig. 4.4.25A) and molecules pass across the capillary through these clefts (or *slit pores*). These are the most common type of capillaries and are found in most of the body tissues viz. skeletal muscle, adipose tissue, connective tissue, pulmonary circulation and so on.

The junction between endothelial cells of capillaries of the brain and retina are tight and possess a complete basement membrane that retards or prevents the transfer of many substances and constitutes the so-called *blood–brain barrier and blood–retinal barrier*, respectively.

2. Fenestrated capillaries

consist of thin endothelial cells with large fenestrations (20–100 nm in diameter) in between which are bridged by a thin basement membrane which surrounds the endothelial cells (Fig. 4.4-25B). The fenestrations permit the passage of relatively large molecules and make the capillaries porous. Fenestrated capillaries are found in organs where transport of fluid is paramount, e.g. renal glomeruli, intestinal villi, most endocrinal glands, ciliary processes in the eye, choroid plexus and so on.

FIGURE 4.4-25 Structure of different types of capillaries: **A**, continuous; **B**, fenestrated; and **C**, discontinuous.

3. Discontinuous capillaries

are characterized by large gaps (600–3000 nm in diameter) between endothelial cells that are not closed by basement membrane (Fig. 4.4-25C). Through these gaps, even formed elements of blood can pass freely. Such capillaries are also called sinusoids and are found in bone marrow, liver and spleen.

Functional characteristics of capillaries

The primary function of circulation is to transport nutrients to the tissues and remove waste products—occurs in the capillaries. About 10 billion capillaries, which have a total surface area of 500–700 m², provide this function for the body. The cross-sectional area of capillary bed when fully patent is 2800 times that of aorta.

Active and inactive capillaries

- **In resting tissues,**

most of the capillaries (75%) are collapsed (inactive capillaries) and blood bypasses them to flow through the *thoroughfare vessels* connecting arterioles to the venules.

- **In active tissues,**

the meta-arterioles and the precapillary sphincters dilate. The intracapillary pressure rises, overcoming the critical closing pressure and blood flows through all the capillaries (active capillaries).

The opening and closing of the precapillary sphincters is controlled mostly by the local metabolic vasodilators and possibly also through sympathetic innervation.

Capillary pressure and flow

Capillary pressure

varies considerably; therefore, it is difficult to describe a generalized picture of capillary pressure and flow. However, typical values in human nail bed capillaries are 35 mmHg at the arteriolar end and 15 mmHg at the venous end, and thus vary over the length of capillary (average being

25 mmHg). The pulse pressure is approximately 5 mmHg at the arteriolar end and 0 at the venous end. Average capillary pressure is less than 10 mmHg in pulmonary capillaries and hepatic sinusoids.

Blood flow velocity.

The capillaries are short, but blood moves slowly (average velocity being 0.3–0.4 mm/s) because of a large cross-sectional area. The velocity varies widely – within short periods of time; it can range from 0–1 mm/s within the same capillary. The transit time of blood between the arteriolar end to the venular end of an average-sized capillary is 1–2 s.

Blood flows

into the capillaries intermittently because of the phenomenon of vasomotion, i.e. intermittent contraction of meta-arterioles and precapillary sphincters. This in turn is mainly controlled by concentration of oxygen and waste products of tissue metabolism.

Transcapillary exchange

The capillary blood brings oxygen, electrolytes and nutrients to the tissues and removes the waste products of cellular metabolism. The exchange of these substances occurs across the thin membrane formed by the endothelial cells. Before discussing the chief mechanism of transcapillary exchange, it will be worthwhile to know about interstitium and interstitial fluid.

Interstitium and interstitial fluid

Spaces between the cells in the body are collectively known as *interstitium*, which constitutes about one-sixth of the body. The fluid present in the interstitium is called *interstitial fluid*. The interstitium also contains two major types of solid structures: collagen fibre bundles and proteoglycan filaments. *Collagen fibres* are strong and therefore they provide most of the tensional strength to the tissues. *Proteoglycan filaments* consist of 98% hyaluronic acid and 2% protein, and form fine reticular filaments described as *brush file*. Most of the interstitial fluid is entrapped in the proteoglycan filaments and the two combinedly constitute the *tissue gel*. Rest of the interstitial fluid (<1%) forms the *free fluid*. Free fluid and gel are continuously interchanging with each other. Fluid can pass through the tissue gel very slowly but diffusion can occur through it as rapidly as in free fluid. Gases, nutrients and cellular waste products diffuse through the tissue gel very freely. *Oedema* results due to

increased free fluid in the tissues.

Mechanisms of transcapillary exchange

Exchange of substances occurs primarily in the capillaries and postcapillary venules. The major mechanisms of exchange are diffusion and filtration (bulk flow). Some substances also pass through the cells by *vesicular transport*.

Diffusion across microvascular endothelium.

Diffusion is the principal mechanism of microvascular exchange of materials between the plasma and the interstitial fluid against their concentration gradient.

- *Lipid-soluble substances* like O₂ and CO₂ diffuse most freely across the cell membrane.
- *Water and water-soluble micromolecules* (molecular weight less than 69,000) like Na⁺, Cl⁻, K⁺, glucose, urea, etc. diffuse almost freely through the intercellular clefts and intracellular pores in the capillary membrane.
- *Large molecules* (molecular weight more than 69,000) such as albumin and other plasma proteins cannot cross the endothelial barrier. However, some amount of albumin does enter the interstitial fluid.

Factors affecting rate of diffusion

across the capillary wall thus are pore size of the capillary, molecular size of the diffusing substance and the concentration difference of the substances between two sides of the membrane.

For details about the 'diffusion', see page 23.

Filtration and reabsorption across microvascular endothelium.

The backflow or ultrafiltration of protein free plasma determines the distribution of fluid across the capillaries. The rate of filtration and absorption at any point along the capillary wall depends on the balance of forces known as *Starling forces*. According to Starling's hypothesis, the filtration absorption is expressed as:

$$K(P_c + \pi_i) - (P_i + \pi_c)$$

K = the permeability-surface area coefficient

P_c = the hydrostatic capillary pressure,

P_i = the hydrostatic interstitial pressure,

π_c = oncotic pressure of blood and

π_i = oncotic pressure of the interstitium.

Thus, $P_c - P_i$, represents the hydrostatic pressure gradient, and $\pi_c - \pi_i$ represents the oncotic pressure gradient.

Starling forces are defined:

1. Hydrostatic capillary pressure (P_c)

tends to force the fluid out through the capillary membrane. The values of hydrostatic capillary pressure in most of the tissues are:

- At the arterial end = 30–40 mmHg,
- At the venous end = 10–15 mmHg and
- In the middle = 25 mmHg.

It is important to note that in the kidneys, the glomerular capillary pressure is 50–60 mmHg (see page 492). The hydrostatic capillary pressure depends on:

- The arterial blood pressure,
- Pre- and postcapillary resistance and
- Venous pressure (most important).

2. Hydrostatic interstitial pressure (P_i)

tends to force fluid inward through the capillary membrane. It is about –2 mmHg in subcutaneous tissue but is positive in the liver and kidneys, and as high as +6 mmHg in the brain.

3. Oncotic pressure of blood or plasma colloid osmotic pressure

(π_c)

results from the osmotic pressure of plasma proteins. It tends to pull fluid inward through the capillary membrane. It is about 25–27 mmHg.

4. Oncotic pressure of the interstitium (π_i)

is due to the presence of proteins in the interstitial space. It tends to pull fluid out of the capillary membrane. The effective oncotic pressure in the interstitium is estimated to range between 5 and 10 mmHg (average 8 mmHg).

Calculation of net filtration at the capillaries

From the above description, the net forces acting on the fluid at the arteriolar and venous end of a typical muscle *capillary* can be calculated (Table 4.4-3):

- Thus, at arteriolar end, the filtering force of 15 mmHg moves the fluid out of capillary (filtration) into the interstitium, while at venous end the filtering force of -10 mmHg moves the fluid into the capillary (reabsorption) from the interstitium.
- The net filtering force for the whole capillary is 5 mmHg.

TABLE 4.4-3

Calculation of Net Filtration Force at the Capillaries

	At the arteriolar end (mmHg)	At the venous end (mmHg)
• Forces tending to move fluid outward	35	10
• Capillary hydrostatic pressure (P_c)	3	3
• Interstitial oncotic pressure (π_i)		
<i>Total outward force ($P_c + \pi_i$)</i>	38	13
• Forces tending to move fluid inward	25	25
• Oncotic pressure of blood (π_c)	-2	-2
• Interstitial hydrostatic pressure (P_i)		
<i>Total inward force ($\pi_c + P_i$)</i>	23	23
• Filtering force	38-23 =15	13-23 =-10
• Net filtering force of the whole capillary	= (15 - 10) = 5	

In the example given above, we have studied the balance of Starling forces at the arteriolar and venous end of the capillary only. However, over the length of the capillary, the hydrostatic pressure gradually declines to zero near the middle of capillary. From here, the inward forces become dominant and reabsorption process starts to reach its maximum at the venular end (Fig. 4.4-26).

FIGURE 4.4-26 Filtration and reabsorption in a capillary due to balance of Starling forces.

Capillary filtration and reabsorption in different tissues

In above example, we have calculated *net filtration forces*. However, the net filtration in the capillaries varies in the different tissues not only on the balance of Starling forces (net filtration force), but also by the capillary filtration coefficient (K).

Capillary filtration coefficient

or the so-called permeability–surface area coefficient (K) of a tissue depends on the number of capillaries receiving blood flow and the permeability of capillaries (i.e. type of capillaries). Because of the extreme difference in the permeabilities and surface areas of the capillary systems in different tissues, the capillary filtration coefficient (K) may vary more than 100-fold among the different tissues. For example,

- In subcutaneous tissues, ' K ' is -0.01 ml/min/mmHg/100 g tissue and
- In kidney, ' K ' is -4.2 ml/min/mmHg/100 g tissues, which is almost 400 times as great as ' K ' of many other tissues. This obviously causes a much greater rate of filtration in the glomerular capillaries of the kidney.

Thus, depending upon the balance of Starling forces and capillary filtration coefficient (K), the capillary exchange in some important tissues is:

- *In renal glomerular capillaries*, fluid moves out of almost the entire length of the capillaries.
- *In interstitial capillaries*, fluid moves out of the capillaries from the arteriolar end up to the middle part and then moves into the capillaries.
- *In pulmonary capillaries*, filtration does not occur at all.

Flow-limited and diffusion-limited capillary exchange

Flow-limited exchange.

It is worth noting that small molecules often equilibrate with the interstitial fluid of the tissues near the arteriolar end of each capillary. In such situations, the total diffusion can be increased by increasing the blood flow. Therefore, exchange of such substances is called flow limited (Fig. 4.4-27).

FIGURE 4.4-27 Flow-limited (X) and diffusion-limited (Y) capillary exchange. A and B indicate arteriolar and venous ends of the capillary.

Diffusion-limited exchange.

The transfer of substances that do not reach equilibrium with the tissues during their passage through the capillaries is called diffusion-limited exchange (Fig. 4.4-27). Therefore, exchange of such substances cannot be increased by increasing the blood flow.

Exudate versus transudate

Exudate

refers to the protein-rich fluid that comes out of the capillaries with marked increase in their permeability under conditions of inflammation due to any cause.

Transudate

refers to the fluid that enters the interstitial fluid through normal capillaries. It does not have appreciable amount of proteins.

Total capillary exchange in the body

It has been observed that in the whole body (leaving aside the

glomerular capillary filtration), approximately 24 L of fluid is transferred per day from the capillaries to the interstitial spaces of the body. Of this, about 85–90% is reabsorbed back to the capillaries and the rest is returned to the circulation via the lymphatics. Since the capillaries are said to be impermeable to plasma proteins, the filtered fluid should contain all the constituents of plasma except proteins. However, a small amount of albumin does pass out of the capillary membrane. And practically whole of it is returned to the circulation through the lymphatics.

Lymphatic circulation

Lymph: Formation and composition

Formation.

As discussed in capillary exchange, most (90%) of the fluid filtered at arterial end of the capillary is reabsorbed at its venous end, and the remaining 10% enters the circulation through lymphatics and is called lymph. Thus, the lymph is a transudate formed from blood in the tissue spaces, i.e. it is derived from the interstitial fluid.

Composition

of lymph is similar to plasma except that its protein content is usually lower than that of plasma.

- **Protein content** of the lymph varies with the region it drains:
- In most of the tissues, protein concentration of the interstitial fluid is 2 g/100 ml, so lymph also has the same content of protein.
- Lymph from liver has protein concentration of 6 g/100 ml and that from the intestine 3–4 g/100 ml.
- Since about two-third of the lymph is derived from liver and intestine, the thoracic duct lymph (mixture of lymph from different areas) has usually a protein

content of 3–5 g/100 ml.

- **Fat content.** Since the lymphatic system also provides a route of absorption of long-chained fatty acids and cholesterol from the intestine (in the form of *chylomicrons*), the lymph from the intestine contains these large molecules of fat. After a fatty meal, these fat globules may be so numerous that the lymph becomes milky and is then called *chyle*.
- **Cellular content.** Suspended in the lymph are cells that are chiefly lymphocytes. Most of these lymphocytes are added to the lymph as it passes through lymph nodes, but some are derived from the tissues drained by the nodes.

Lymphatic vessels

The lymphatic system constitutes an accessory route for the removal of interstitial fluid. The small lymph vessels are called lymph capillaries and the large lymph vessels are called lymphatic trunks and the largest lymph vessel is thoracic duct.

Lymph capillaries

The lymph capillaries are *present* in most tissues of the body except brain, cartilage, splenic pulp, bone marrow and avascular structures (e.g. cornea and nails).

The lymph capillaries *originate* as closed endothelial tubes that are permeable to fluid and high molecular weight compounds.

The *structure* of lymph capillaries (Fig. 4.4-28) is basically similar to that of blood capillaries with the following differences:

- The basal lamina around the endothelial cells is absent or poorly developed.
- Pericytes or connective tissue is not present around the lymph capillaries.
- There are no visible fenestrations in the endothelium.
- The junctions between endothelial cells are open, with no tight intercellular connections. In fact, the edges of the endothelial cells overlap in such a way that they form minute flap valves. So, through the lymph capillary, the substances that can pass are larger molecules

such as proteins, fat droplets and particulate matter like bacteria. But once inside, the fluid particles cannot move out of capillary wall, since the tendency to backflow closes the flap valve (Fig. 4.4-28).

FIGURE 4.4-28 Structure of lymphatic capillary.

Larger lymph vessels

The lymphatic capillaries join to form larger lymph vessels which ultimately form lymphatic trunks and lymphatic ducts as:

- **Thoracic duct** is the largest lymph vessel in the body. It carries lymph from both sides of the body below the diaphragm and from the left side above the diaphragm. Near its termination, it receives the *left subclavian lymphatic trunks* carrying lymph from left upper limb, the *left jugular lymphatic trunk* carrying lymph from left half of head and neck, and sometimes the *left bronchomediastinal lymphatic trunk* carrying lymph from left half of thorax (usually this trunk enters the subclavian vein independently).

The thoracic duct ends by opening into the junction of the

left subclavian vein and the internal jugular vein.

- **Right lymphatic duct** drains lymph from the right half of the body above the diaphragm. It is formed by the *right bronchomediastinal trunk* carrying lymph from the right half of thorax, *right jugular trunk* draining lymph from the right half of head and neck, and *right subclavian trunk* carrying lymph from the right upper limb. The right lymphatic duct ends by opening into the right subclavian vein.

Structure of larger lymph vessels

is similar to that of veins:

- *Three coats*, i.e. tunica intima, tunica media and tunica adventitia, can be distinguished.
- *Valves* similar to those in veins are present in abundance in small as well as large lymphatic vessels. The valves often give lymph vessels a beaded appearance.

Lymph flow

Functions of lymph flow

1. Returns proteins from tissue spaces to blood.

Lymph flow represents the only mechanism for returning albumin and other interstitial macromolecules to the circulatory system. The lymphatic system recovers approximately 200 g of protein daily that has been lost from the microcirculation. In addition, excess fluid is removed from the interstitium to maintain a gel state.

2. Absorption of nutrients,

especially fats from the gastrointestinal tract.

3. Acts a transport mechanism

to remove red blood cells that have lost into the tissues as a result of haemorrhage.

4. Supplies nutrients and oxygen

to those parts where blood cannot reach.

5. Role in defence mechanism.

Lymph nodes associated with lymphatic system act as efficient filters. They have sinuses lined with phagocytic cells that engulf bacteria, red cells and other particulate material.

Mechanism of lymph flow

1. Intrinsic lymphatic pump.

Lymph is pumped out of the tissues by the lymphatic vessels which have valves and smooth muscles in their walls. They contract in a peristaltic fashion, propelling the lymph along the vessels. The extensive system of one-way valves present in the lymphatics maintains lymph flow towards the heart.

2. Pumping by external compression of the lymphatics.

Though the contractions of lymphatics are the principal factor propelling the lymph, the lymph is also pumped by the external compression of the lymphatics by:

- Contraction of the skeletal muscles,
- Movements of different body parts,
- Arterial pulsations and
- Compression of tissue by objects outside the body.

3. Negative intrathoracic pressure

during inspiration increases the rate of lymph flow.

4. Suction effect of high-velocity blood flow

in the veins in which the lymphatics terminate also promotes lymph flow.

5. Interstitial fluid pressure.

An increase in the interstitial fluid pressure increases the lymph flow up to a certain limit.

6. Increase in capillary surface area

by capillary distension is associated with increased lymph flow under the following conditions:

- Increased capillary pressure,
- Increase in local temperature and
- Infusion of fluid.

7. Increase in capillary permeability

under the following conditions is also associated with increased lymph flow:

- Increase in temperature,
- Effect of toxins and
- Decreased oxygen (hypoxia).

8. Increase in functional activity of the tissue

also increases the lymph flow.

Normal lymph flow

• Normal lymph flow

is 2–4 L/day (80–150 ml/h) for the entire body.

• Rate of lymph flow

varies in different organs and is highest in the gastrointestinal tract and the liver.

• In lymphatics,

rate of lymph flow is 100 ml/h through thoracic duct and about 20 ml/h through other lymphatic channels.

Rate of formation of lymph is somewhat accelerated by regional venous obstruction (which leads to decreased absorption of tissue fluids into blood capillaries) and also by arteriolar dilations (which leads to increased tissue fluid formation).

Venous circulation

Structural characteristics of veins

Walls

of veins, compared with arteries, at equivalent levels in the vascular tree are thin walled and contain small amount of elastic tissue and smooth muscle, and have larger lumen. Because of their structural characteristics, they are more distensible and collapsible.

Lumen

of the veins is larger than the equivalent arteries. In comparable vessels, the veins provide a larger cross-sectional area than do the arteries.

Valves

are present in the veins of the dependent parts of the body (Fig. 4.3-15) that prevent the backflow of venous blood. The valves also support the column of blood so that increase in capillary pressure in the dependent parts of the body (caused by hydrostatic pressure) is minimized.

Functions of the veins

1. Blood reservoirs

Because of their feature of *distensibility and collapsibility*, the veins serve as blood reservoirs. About 60–70% of the circulating blood is present in the venous system. When their blood content decreases, the veins assume an elliptical profile because of their *collapsibility*. As the venous blood content increases, they assume more and more circular profile to accommodate progressively greater amount of blood per unit length. Further increase in the volume of blood is accommodated by distension of the walls without any significant increase in venous pressure. In other words, small changes in pressure can cause large changes in volume (Fig. 4.4-29). Due to this property, veins are also called *capacitance vessels*.

FIGURE 4.4-29 Pressure–volume relationship of arteries and veins. The slope of each line at any point represents compliance (distensibility). Note that the veins are much more compliant than the arteries at low pressure because veins are not completely distended at these pressures.

Certain portions of the circulatory system are highly compliant and are especially important as blood reservoirs. These include:

- *Spleen* can sometimes decrease in size and release as much as 100 ml of blood into the reservoir of circulation.
- *Liver* sinuses can also release several hundred millilitres of blood into the rest of circulation.
- *Large abdominal veins* can contribute as much as 300 ml.

- *Venous plexuses beneath the skin* can also contribute several hundred millilitres of blood.

2. Conduits

The systemic veins carry blood from the tissues to the right atrium, and the pulmonary veins collect blood from the lungs and return it to the left atrium.

3. Maintenance of cardiac output

Veins help to maintain the cardiac output whenever there is loss of blood. After blood loss from an external or internal injury, reflex increase in sympathetic discharge produces contraction of the smooth muscles in the walls of the veins. As a result of venular contraction, there occurs a decrease in their capacity leading to increased venous return to heart. In this way, veins help to maintain cardiac output by maintaining normal venous return in spite of blood loss.

Venous pressure and flow

The venous system is a low-resistance, low-pressure and highly distensible part of the vascular system. At normal pressures, the veins are approximately 20 times more compliant than the arteries.

Central venous pressure

Central venous pressure refers to the pressure in the right atrium because all the systemic veins open into the right atrium. The normal right atrial pressure is about 0 mmHg (i.e. equal to atmospheric pressure), but it can rise to as high as 20–30 mmHg under abnormal conditions such as heart failure and massive blood transfusion. The right atrial pressure can decrease to as low as –3 to –5 mmHg when the heart (right atrium) is pumping with vigour or when venous return is greatly depressed.

Peripheral venous pressure

The pressure in the venules is about 10 mmHg. As the veins approach the heart, there is a gradual decrease in the venous pressure. In the great veins, near the heart, venous pressure is approximately 5 mmHg. Large veins do not offer any resistance when they are distended. However, many of the large veins entering the thorax are compressed by the surrounding tissues, so they are at least partially collapsed or collapsed to an ovoid state. This impedes the blood flow. Therefore, large veins do offer considerable resistance to blood flow and thus pressure in the

peripheral veins is usually greater (4–7 mmHg) than that of the right atrial pressure. This produces a pressure gradient which propels the venous blood towards the heart (venous return).

Factors affecting peripheral venous pressure

1. Effect of gravitational pressure.

Gravitational *hydrostatic pressure* occurs in the vascular system because of the weight of the blood in the vessels. Peripheral venous pressure, like arterial pressure, is affected by this gravitational hydrostatic pressure. When an adult person stands absolutely still, the pressure in the body veins because of the effect of hydrostatic pressure is (Fig. 4.4-11):

- At the level of heart, it is 0 mmHg.
- At the level of ankles, it is approximately +80 mmHg.
- At other levels in the body, from heart to feet, the venous pressure varies between 0 and 80 mmHg. It increases by 0.77 mmHg for each centimetre below the right atrium. Therefore, if the venous valves are incompetent, as in *varicose veins*, it results in venous pooling, i.e. accumulation of blood in the lower parts of the body.
- Pressure in the veins above the right atrium decreases by 0.77 mmHg for each centimetre. Therefore, *neck veins* completely collapse due to atmospheric pressure on the outside of neck, and pressure inside the vein almost remains zero.
- *Subdural venous sinuses in the skull* cannot collapse because of the tough noncollapsible nature of dura mater; therefore, a negative hydrostatic pressure (–10 mmHg) exists in them. Because of this reason, if a dural sinus is opened during a neurosurgical procedure with the patient seated, air is sucked into the sinus, resulting in *air embolism*.

2. Effect of venous resistance.

Increased venous resistance can raise peripheral venous pressure to some extent. Like arterioles, myogenic tone of the veins induced by sympathetic constrictor nerves helps to adjust the capacity of vascular system. This is especially useful in postural changes. For example, sudden change of posture from lying down to standing position results in peripheral pooling of the blood in veins of legs and feet due to effect of

gravity. Therefore, venous return to heart decreases, systemic blood pressure falls and may cause dizziness. However, normally, the compensatory mechanism operated via baroreceptor reflex prevents any fall in blood pressure (see page 335). Increase in venous resistance due to compression of peripheral veins within or without causes an increase in peripheral venous pressure.

3. Effect of central venous pressure.

Peripheral venous pressure, to a great extent, depends upon the central venous pressure. Therefore, any factor that increases central venous pressure (i.e. right atrial pressure) will also increase the peripheral venous pressure. Common causes associated with rise in right atrial pressure are:

- Increased blood volume (massive blood transfusion,
- Heart failure and
- Arteriolar dilation decreases peripheral resistance causing rapid flow of blood from arterioles thus increasing the central venous pressure.

4. Effect of venous valves and venous pump.

The venous pressure in feet is approximately +90 mmHg in a standing position because of hydrostatic pressure effect. However, movements of legs and muscle contractions (*muscle pump or venous pump*) squeeze the blood out of veins; the *valves* in the veins are arranged in such a way that the direction of blood can only be towards the heart. Thus, lowers the pressure in the veins. Therefore, in walking adults, venous pressure remains less than 25 mmHg due to combined effect of 'venous pump' and venous valves.

Measurement of peripheral and central venous pressure

- *Clinical assessment of venous pressure* is made by observing the degree of distension of neck veins. When right atrial pressure is increased up to 10 mmHg, the lower neck veins begin to protrude in sitting position (in normal person, in this position, the neck veins are never distended).
- *Peripheral venous pressure measurement with a manometer* can be made easily by connecting it to cannula inserted into a superficial vein.

- *Central venous pressure measurement using a cardiac catheter* whose tip is led up to superior vena cava through a superficial vein can be made accurately. The other end of the catheter is connected to a pressure transducer.

Venous flow and venous return

As we know, the blood flows in the veins towards the heart due to a pressure gradient which exists between the right atrial pressure (0 mmHg) and the peripheral veins (6–7 mmHg). The *velocity of blood flow* in the veins increases with increase in the size of vein. In inferior vena cava, the average velocity of blood flow is 10 cm/s.

Venous return has been discussed in detail on page 288.

Blood pressure

Definitions (terminology)

Blood pressure

Blood pressure is the lateral pressure exerted by the flowing blood on the walls of the vessels. It is usually measured in mmHg. Without any further qualification, the term blood pressure denotes the *arterial pressure*. While describing the pressure exerted by the blood column in other types of blood vessels, the type of vessels is also mentioned, e.g. *capillary pressure* and *venous pressure*.

As described in *Bernoulli's experiment* (page 309), the lateral pressure exerted on the vessel wall by the flowing blood represents the *potential energy* (PE) and the *end on pressure* (perfusion pressure) represents the total energy, i.e. kinetic energy (KE) plus potential energy (PE). Kinetic energy (KE) depends on the velocity of blood flow. Therefore, with velocity of flowing blood remaining constant, a rise in lateral pressure (potential energy) indicates a rise in perfusion pressure (total energy) and vice versa.

Systolic blood pressure

- The arterial pressure varies with phases of cardiac cycle. The maximum arterial pressure during systole is called *systolic blood pressure*, and occurs during ventricular ejection.

- The systolic blood pressure is a function of the cardiac output (CO), i.e. it represents the extent of work done by the heart.
- Normal systolic blood pressure in a young adult is 120 mmHg (range: 105–135 mmHg).
- Systolic blood pressure undergoes considerable fluctuations, e.g. it is increased during excitement, exercise and meals, and is decreased during sleep and rest.

Diastolic blood pressure

- Diastolic blood pressure refers to the minimum arterial pressure during diastole and occurs just before the onset of ventricular ejection.
- Normal diastolic blood pressure in a young adult is 80 mmHg (range 60–90 mmHg).
- The diastolic pressure is the function of total peripheral resistance (TPR) and indicates the constant load against which the heart has to work. It undergoes much less fluctuations.

Conventional expression of blood pressure

Conventionally, systolic and diastolic blood pressures are denoted as numerator and denominator, respectively. For example, blood pressure of a normal person is written as 120/80 mmHg.

Pulse pressure

- Pulse pressure is the arithmetic difference between systolic and diastolic blood pressures.
- Normally, average pulse pressure is 40 mmHg.
- It determines the pulse volume.
- It depends upon three factors: arterial volume, stroke volume and arterial elastic constant. Thus, according to Young's elastic modulus, the pulse

$$\text{pressure (PP)} = \frac{\Delta V}{V} - \frac{1}{K_a}, \text{ where}$$

- ΔV is arterial uptake volume (approximately equal to but not less than the stroke volume),
- V is arterial volume (proportional to the mean arterial pressure) and
- K_a is arterial elastic constant.
- The high pulse pressure is indicative of systolic hypertension and indirectly determines decrease in elasticity of blood vessels.

Mean arterial pressure

- Mean arterial pressure (MAP) is the average of all pressure measured millisecond by millisecond throughout the cardiac cycle.
- Since the duration of cardiac systole is shorter than the duration of diastole, the MAP is not equal to the algebraic mean of the systolic and diastolic blood pressures, i.e. it is not equal to (systolic pressure + diastolic pressure).^{1/2}
- A mathematically precise method for finding out MAP is to find the area under the arterial pressure curve and divide it by the duration of curve (Fig. 4.4-30). However, it is a time-consuming and cumbersome method.
- Practically, MAP is roughly equal to diastolic pressure (DP) plus one-third of pulse pressure (PP), i.e.

$$DP + \frac{1}{3} pp$$

- MAP, in fact equals total peripheral resistance (TPR) divided by cardiac output (CO), i.e.

$$\text{MAP} = \frac{\text{TPR}}{\text{CO}}$$

- MAP is same for each organ and determines the pressure head. Thus, regional blood flow through an organ depends on it.
- All cardiovascular reflexes are sensitive to mean arterial pressure.
- Normal value of MAP is 93 mmHg (range: 90–100 mmHg).

FIGURE 4.4-30 Arterial pressure curve. The line for MAP is drawn in such a way indicating that area (1 + 2) = area 3.

Determinants of (factors affecting) arterial blood pressure

- The arterial blood pressure (BP) is a function of the product of cardiac output (CO) and total peripheral resistance (PR), i.e.

$$\text{Arterial BP} = \text{CO} \times \text{PR}$$

- Therefore, arterial blood pressure is affected by conditions that affect either cardiac output or peripheral resistance.

- Changes in cardiac output affect the systolic pressure more than diastolic pressure, while changes in peripheral resistance affect diastolic pressure more than the systolic pressure.
- As discussed in the section on cardiac output (page 284), the cardiac output is a function of *heart rate* and *stroke volume*, so these two are important determinants of the blood pressure.
- The peripheral resistance (page 305) depends upon the viscosity of blood, elasticity of the vessel wall and velocity of the blood flow. Thus, these factors are also important determinants of the blood pressure.

Effect of some of the important determinants of the blood pressure is shown in [Fig. 4.3-13](#) and described here briefly:

1. Heart rate.

An increase in heart rate usually increases the cardiac output and decreases the duration of cardiac cycle and thus raises the blood pressure. The increase in cardiac output due to increase in heart rate increases diastolic pressure more than the systolic pressure (because increased heart rate duration of diastole decreases more than systole and the tendency of fall in pressure during diastole decreases).

After an increase in heart rate, the arterial pressure rises, increasing the driving pressure for flow, until the amount of blood exiting the arterial system equals the amount entering. At this time, the transfer of blood from the venous to the arterial system has raised the arterial pressure and lowered the venous pressure.

Conversely, reduction in heart rate decreases the arterial blood pressure.

2. Stroke volume.

An increase in stroke volume increases the cardiac output and raises the arterial pressure, and the reverse effect occurs due to decrease in the stroke volume. When increase in cardiac output is primarily due to increase in stroke volume, it mainly increases systolic blood pressure. While an increase in cardiac output due to increase in both the stroke volume and heart rate increases systolic as well as diastolic pressure.

3. Arterial elastic constant.

It refers to stiffness of the arterial system which progressively increases from birth until death ([Fig. 4.4-31](#)). An increase in arterial elastic constant

(or loss of elasticity of vessel wall) with advancing age results in decreased stretching of the elastic vessels during systole. This results in increased pressure during systole (*systolic hypertension*) with normal diastolic blood pressure. It is characterized by high pulse pressure. When stiffness occurs in small vessels, the diastolic blood pressure is also increased.

FIGURE 4.4-31 The average pressure–volume relationship of arterial system in 20-, 30-, 40-year-old individuals. Note the increasing elastance (decreased distensibility) that occurs with aging. V = volume change, V_0 = unstressed arterial volume.

4. Arterial blood volume.

An increase in total blood volume increases both systolic and diastolic blood pressures by increased quantity of blood in the arterial system and greater stretching of the vessel wall.

Conversely, *haemorrhage* and *blood pooling* reduces the arterial pressure by reducing the circulating blood volume. Gravity or marked vasodilation by neural, chemical or mechanical factors may lead to blood pooling in dependent portions of the body and decrease circulating blood volume.

5. Peripheral resistance (Pr).

Peripheral resistance is an important determinant of arterial pressure. An increase in PR increases and a decrease in PR decreases the arterial pressure. Increased PR raises the arterial pressure by raising the arterial volume due to reduction in the amount of blood that leaves the arterial system. The arterial pressure rises until the new pressure is sufficient to overcome the additional resistance to flow, and arterial outflow again equals inflow.

Peripheral resistance in turn is determined by radius of vessels (arterioles), velocity of blood flow and viscosity of blood. For details, see page 305.

Variations in blood pressure

Physiological factors affecting blood pressure

1. Age.

In healthy humans, both systolic and diastolic pressures rise with age.

- *At birth*, systolic blood pressure is 40 mmHg (range: 20–60 mmHg). It then rises rapidly up to 1 month of age.
- *At 1 month* of age, the systolic blood pressure becomes about 80 mmHg and then rises slowly.
- *At about 17 years* of age, normal adult level of blood pressure 120/80 mmHg is reached, which remains almost constant up to 40 years of age and then very slowly rises.
- *At about 70 years of age*, the normal value of blood pressure is 160/90 mmHg. The increase in blood pressure associated with advancing age is due to increase in rigidity of vessel wall owing to arteriosclerotic changes.
- *A convenient empirical formula* as to what should be considered as normal blood pressure at various ages (after 10 years of age) is:
 - Systolic blood pressure: $110 + \frac{3}{5}$ of age in years.
 - Diastolic blood pressure: $70 + \frac{2}{5}$ of age in years.

2. Sex.

Before menopause, females have little lower (4–6 mmHg) systolic blood pressure than males of corresponding age. This may be because of effect of oestrogen, while *after menopause*, systolic blood pressure in females is little higher (4–6 mmHg) than males of same age group.

3. Effect of meals.

Systolic blood pressure increases by 4–6 mmHg after meals and this effect lasts for about 1 h. This occurs due to two reasons:

- *Increase in heart rate* due to pressure over the heart by distended abdomen and
- *Increased epinephrine release* from adrenal medulla.

Diastolic blood pressure either remains unchanged or decreases slightly due to vasodilation in splanchnic vessels.

4. Emotions.

Increased sympathetic activity during emotional situations such as excitement, fear and worry leads to increase in systolic blood pressure due to increase in the cardiac output.

5. Climatic temperature.

Exposure to cold produces rise in the blood pressure by increase in peripheral resistance due to cutaneous vasoconstriction through hypothalamic stimulation. Conversely, *exposure to hot temperature* lowers the blood pressure by decreasing peripheral resistance due to cutaneous vasodilation, again through hypothalamic pathway.

6. Diurnal variation.

Systolic blood pressure shows a diurnal variation of about 6–10 mmHg, the values being lower in the morning and higher in the afternoon. In night workers, however, a reverse rhythm is observed.

7. Exercise.

In muscular exercise, generally systolic blood pressure rises and diastolic blood pressure falls. However, the effect of exercise is different in trained individuals (regular exerciser) than the untrained individuals (occasional exerciser). Further, the effect also varies depending upon the severity of

exercise, whether mild, moderate or severe. However, blood pressure returns to normal levels within 5 min of stoppage of exercise due to sudden relaxation of muscles which produces vasodilation (for details, see page 1213).

8. Effect of gravity.

In standing position, due to hydrostatic (gravitational) effect of the blood column, the pressure in the vessels below heart level is increased and in the vessels above heart level, it is decreased (Fig. 4.4-11). For every centimetre below or above the heart level, the pressure increases or decreases by 0.77 mmHg, respectively. Therefore, in an individual having 120/80 mmHg blood pressure in brachial artery, the blood pressure in the dorsalis pedis artery (which is about 100 cm below heart level) will be about 200/160 mmHg, i.e. about 80 mmHg more ($0.77 \times 100 = 77 \text{ mmHg} = \text{about } 80 \text{ mmHg}$). Therefore, for clinical recording, blood pressure should always be checked at the heart level.

9. Effect of change in posture.

Sudden change in posture from lying down to standing initiates some momentary changes in blood pressure which in normal humans are immediately rectified by baroreceptor reflexes, and practically such changes are not experienced. However, in patients with autonomic disturbances, these changes become symptomatic. A chain of physiological changes in blood pressure during change of posture is:

- Immediately on standing, there occurs peripheral pooling of blood in dependent parts leading to decreased venous return and decreased cardiac output, and momentary fall in systolic blood pressure. Fall in systolic pressure immediately decreases baroreceptor discharge via vasomotor centre leading to increased *diastolic blood pressure*. On standing, there also occurs an increase in peripheral resistance and momentary increase in diastolic blood pressure.

Thus, immediately after standing from lying down posture, a rise in diastolic blood pressure can be recorded for about 30–60 s. Later on, due to decrease in baroreceptor discharge, blood pressure comes back to normal and no symptoms are experienced by the normal individuals.

10. Sleep.

In complete relaxed state, during early hours of sleep, there occurs

general vasodilation leading to fall in blood pressure up to 15–20 mmHg. However, in disturbed sleep, blood pressure increases due to increased sympathetic discharge.

11. Body built.

Systolic blood pressure is slightly higher in obese individuals compared with thin-built individuals. Further, falsely higher values are obtained in obese individuals while testing brachial artery blood pressure using standard arm cuff. This occurs because there is more tissue between the cuff and artery and so, some of the cuff pressure is dissipated. Therefore, use of a cuff that is wider than the standard arm cuff is recommended for accurate record of blood pressure in obese individuals.

Measurement of blood pressure

Direct method

Direct method of measuring blood pressure is used in experimental studies. In it, a cannula or T-tube is inserted into an artery and connected to either:

- *Mercury manometer* and pressure is recorded on the kymograph or
- *Pressure transducer* (strain gauge) which in turn is connected to Polyrite for recording.

The record will show fluctuations as depicted in Fig. 4.4-32, upper level of which indicates systolic blood pressure and lower level indicates diastolic blood pressure.

FIGURE 4.4-32 Record of arterial blood pressure obtained by direct arterial cannulation method.

Indirect method

In humans, blood pressure is measured indirectly by using a

sphygmomanometer.

Sphygmomanometer

Commonly called blood pressure apparatus, a sphygmomanometer is the instrument used to measure blood pressure. It consists of the following parts:

1. Manometer.

Two types of manometers are used:

- *Aneroid manometer* (Fig. 4.4-33) in which metal bellows, mechanical rings and a dial replaces the glass tube mercury manometer. It is also very commonly used nowadays. However, it needs calibration against a mercury manometer from time to time.
- *Mercury manometer* is commonly used in a classical sphygmomanometer (Fig. 4.4-34). It consists of a *graduated narrow glass tube* having markings 0–300. Upper end of the tube is closed and lower end is connected to lower end of a wide lumen *mercury reservoir*. Upper end of the mercury reservoir is connected to an inflatable rubber bag through a rubber tube.

Graduated circular scale

FIGURE 4.4-33 Aneroid sphygmomanometer.

FIGURE 4.4-34 Procedure of recording blood pressure by auscultatory method.

2. The cuff.

The blood pressure apparatus cuff also known as 'armlet' or 'Riva-Rocci cuff' (after the name of discoverer) consists of an inflatable rubber bag which is enclosed in a cotton bag having a long strip of inelastic cloth. The dimensions of the commonly used rubber bag are 24 cm × 12 cm. It should be at least as wide as half the upper arm's circumference. The bag width (12 cm) should be more in obese adults, about 4-5 cm for children and 2-3 cm for the newborns.

3. Air pump.

It is a rubber bulb with a one-way valve at its free end, and a 'leaky valve' and a knurled screw at the other end where the rubber tube leading to the cuff is attached. The cuff can be inflated by turning the leak-valve screw clockwise and alternately compressing and releasing the bulb. Deflation is achieved by turning the screw anticlockwise.

Procedure.

The blood pressure may be tested with the subject lying supine or sitting, but should be physically and mentally relaxed and free from excitation.

The cuff of the blood pressure apparatus is applied on the upper arm with the centre of the rubber bag lying over the brachial artery which lies medially, and its lower edge should be about 3 cm above the elbow (Fig. 4.4-34).

The blood pressure can be measured using palpatory method, oscillatory method or auscultatory method.

1. Palpatory method.

Palpatory method described by Riva-Rocci in 1896 includes the following steps:

- Palpate and feel pulsations of the radial artery with the tips of finger of left hand.
- Keeping fingers of left hand on the pulse, slowly inflate the cuff using air pump with the right hand until the pulse disappears. Then raise the pressure further by 30–40 mm in the manometer.
- Open the leak valve of air pump and control it so that the pressure gradually falls in steps of 2–4 mm. Note the reading at which pulse just reappears. This reading corresponds to *systolic blood pressure*. After this, deflate the cuff quickly to zero pressure.
- Take three readings in each arm, fully deflating the cuff a few minutes between each reading. Mean of the three readings should be taken as systolic blood pressure. The actual pressure is usually 4–6 mm higher than the recorded value, since initial 2–3 beats are often missed while feeling the pulse.
- *Disadvantage* of the palpatory method is that the diastolic blood pressure cannot be measured by this method.

2. Oscillatory method.

Oscillatory method is not preferred.

- In this method, initial steps up to raising the pressure in the cuff by 30–40 mm after the pulse disappears are same.
- Then the mercury column in the graduated glass tube of manometer is carefully watched while slowly lowering the cuff pressure. The *oscillations* will appear and become prominent once the pressure in the

cuff is roughly equal to the systolic pressure.

3. Auscultatory method.

Auscultatory method, described by Korotkoff in 1905, is the most useful technique.

- Initial steps up to raising the pressure in the cuff by 30–40 mm above the level where the radial artery pulse disappears are similar to palpatory method. However, before inflating the cuff, the point just before the brachial artery bifurcating the cubital space, just medial to the tendon of biceps muscle, is marked.
- Then the diaphragm of stethoscope is placed on the mark in cubital space and is kept in position with the help of thumb and fingers of left hand.
- Pressure in the cuff is lowered slowly by opening the leak valve of the air pump with right hand. While doing so, initially no sound is heard. However, when mercury column is lowered further, a tap sound is heard. The character and quality of sound go on changing while further lowering the mercury column by deflating the cuff, and ultimately the sound disappears. These sounds are called Korotkoff sounds and from these the levels of systolic and diastolic blood pressure are noted as described below. When the sounds disappear, the cuff should be deflated quickly.

Korotkoff sounds

Phases of korotkoff sounds.

Depending upon the characteristic features, the Korotkoff sounds have been described in five phases (Fig. 4.4-35):

- **Phase I sounds** start with a *clear tap* which indicates the *systolic blood pressure*. The clear, tapping and sharp sounds last for 10–12 mmHg fall in mercury column.
- **Phase II sounds** are *murmurish*, i.e. soft and swishing and last for next 14–15 mmHg fall in mercury column.
- **Phase III sounds** are clear, knocking and banging in character and last for next 14–15 mmHg fall in mercury column.

- **Phase IV sounds** start with *sudden muffling* and mark the *diastolic blood pressure*. The muffled sounds are indistinct, dull and faint, as if coming from a distance and last for next 4–5 mmHg fall in mercury column.
- **Phase V** is labelled when no sound is heard. Since the beginners may not appreciate beginning of muffling of sounds and therefore, disappearance of the sound may be considered as a mark of diastolic pressure. However, in some clinical situations such as hyperthyroidism and aortic valve insufficiency where the sounds continue to be heard even when the pressure is low, the level at which muffling of sounds starts is to be taken as diastolic blood pressure.

FIGURE 4.4-35 Phases of Korotkoff sounds.

Mechanism of korotkoff sounds

- Normally, the blood flow through the arteries is streamlined or laminar, and no sounds are heard over them when auscultated.
- As shown in Fig. 4.4-36, while testing blood pressure, when the cuff pressure is raised above the expected systolic pressure level, the blood flow in the brachial artery completely ceases and no sounds are heard. When the cuff pressure is reduced gradually, a time comes when, at the peak of each systole, the intraarterial pressure just exceeds the cuff (extraarterial) pressure. The small amounts of blood that are ejected at high velocity (exceeding the critical velocity) through the partially narrowed artery result in *intermittent turbulence* which produces the sounds. Also, the blood column in the distal part of the artery, i.e. below the cuff, is set into vibrations by the jets of blood striking against it, which contributes to the sounds. These sounds are called *Korotkoff sounds*.
- When the cuff pressure nears the diastolic pressure level, the artery is still partially constricted, but the turbulent flow is now continuous and the sounds have a *muffled quality* (phase IV).
- As the cuff pressure falls further, the blood flow becomes laminar once again and the sounds disappear (phase V).
- The change in character of sounds from phase I to phase IV is related to the degree of turbulence.
- In aortic regurgitation, there occurs a continuous turbulent flow so the muffled sounds continue and does not disappear at all. Therefore, as mentioned earlier, in such cases, the start of muffling of sounds should be considered a mark of diastolic pressure. In fact in this condition, a slight pressure with a stethoscope alone (without the cuff) may produce clear, sharp, snapping sounds, called the *pistol-shot sounds*.

Auscultatory gap. In some patients of hypertension, there may be a gap in the Korotkoff sounds. As the mercury is lowered, a few faint sounds are heard which soon disappear only to reappear once again at a much lower pressure. This brief interruption in the sounds is called the *auscultatory or silent gap*. If the mercury column is raised to this gap only, one may miss the first appearance of sounds, which indicates

systolic pressure, and thus record a false low systolic pressure. To avoid this mistake, the mercury column must always be raised 50-60 mm above the level at which the radial pulse disappears. One can then be sure the cuff pressure is well above the systolic level.

FIGURE 4.4-36 Change in blood flow and production of Korotkoff sounds with change in cuff pressure.

Precautions to be taken while recording blood pressure

1. Basal arterial pressure should always be recorded in the lying down (recumbent) position. This will avoid effect of gravity on blood pressure (page 326) and for this reason the arterial pressure will be same if recorded from any artery.
2. The position of the arm and sphygmomanometer should be at the heart level, again to avoid the effect of gravity.
3. The cuff size should always be appropriate for accurate measurement of blood pressure (see page 327).
4. The palpatory method must always be employed first to avoid auscultatory gap.
5. The cuff pressure should never be kept high for any length of time because the discomfort may cause generalized reflex vasoconstriction,

thus raising the blood pressure.

6. It is a good practice to compare the pressure in the two arms when measuring the pressure for the first time.

7. Last but not the least, the subject should be physically relaxed and free from tension and anxiety.

Note. The systolic blood pressure as measured by sphygmomanometer is usually 10–20 mmHg lower and diastolic pressure is higher by about 8 mmHg than direct arterial cannulation method.

Regulation of blood pressure

Arterial blood pressure is controlled by several mechanisms which under physiological conditions maintain the normal mean arterial pressure (MAP) within a narrow range of 95–100 mmHg. The different mechanisms concerned with regulation of blood pressure have been discussed in detail in [Chapter 4.5](#) on Cardiovascular Regulation and have been briefed here just for orientation about control of blood pressure. Each mechanism performs a specific function. Various mechanisms controlling arterial pressure can be grouped as:

- A. Rapid blood pressure control mechanism,
- B. Intermediate blood pressure control mechanisms and
- C. Long-term blood pressure control mechanisms.

Rapid blood pressure control mechanism (nervous regulating mechanism)

Rapid blood pressure control mechanism or the so-called short-term control mechanism primarily includes the following three nervous reflexes:

1. [Baroreceptor reflexes](#) (see page 340),
2. [Central nervous system ischaemic response](#) (see page 347) and
3. [Chemoreceptor reflexes](#) (see page 346).

Salient features.

The nervous reflexes that rapidly control the blood pressure are described in detail elsewhere. Their salient features are:

- These *act very rapidly*, i.e. within seconds to few minutes of alterations in the blood pressure.
- These are *short-term mechanisms*, i.e. these act for few hours to few days and are thus insignificant in long-term regulation of blood pressure.
- These are useful in preventing *acute decreases in blood pressure* (e.g. during severe haemorrhage) as well as in preventing *excessive increases in blood pressure* (e.g. as might occur in response to excessive blood transfusion).

Intermediate blood pressure control mechanisms

The intermediate blood pressure control mechanisms that are important in blood pressure control after several minutes of acute pressure changes are:

1. Renin–angiotensin vasoconstrictor mechanism (for details see page 348),
2. Stress relaxation and reverse stress relaxation mechanism and
3. Capillary fluid shift mechanism.

Salient features of intermediate blood pressure control mechanisms are:

- These mechanisms come into play after several minutes of acute pressure changes and reach full function within a few hours.
- These mechanisms play their role from few days to few weeks.
- All these mechanisms basically try to control the alterations in blood pressure by altering the blood volume.

Stress relaxation and reverse stress relaxation mechanisms

• Stress relaxation mechanism

refers to vasodilation occurring due to stress on the vascular smooth muscles. When pressure in the vessels become too high (e.g. following massive slow intravenous transfusion), the vessels become stretched and continue to stretch for minutes or hours. This causes relaxation of blood vessels simply by vascular tone adjustment. This leads to an increase in the capacity of the arterial system with a concomitant fall in blood pressure.

• Reverse stress relaxation mechanism

operates when the blood pressure is low due to less stress on the vessels walls and tries to restore it back to normal. For example, when blood pressure falls due to prolonged slow bleeding, there occurs tightening of blood vessel walls by vascular tone adjustment secondary to less stress on the vessel wall (reverse stress relaxation mechanism). This mechanism tries to restore the blood pressure back to normal. This mechanism can correct up to 15% change in blood volume below normal.

Capillary fluid shift mechanism

Capillary fluid shift mechanism helps in restoring both low and high blood pressure back to normal:

- *When blood pressure is raised*, the mean capillary pressure is also high, resulting in shift of fluid from circulation to the interstitial fluid compartments. This reduces the blood volume to restore the arterial pressure (Fig. 4.4-26).
- *When blood pressure is lowered*, the mean capillary pressure is also low, resulting in absorption of fluid from the interstitial compartments to circulation. Thus, the blood volume is increased which helps to return the blood pressure back to normal.

The capillary fluid shift mechanism is about two times more effective than baroreceptor reflex mechanism in controlling the blood pressure, but it acts much more slowly (intermediate-acting mechanism) than baroreceptor mechanism (rapid-acting mechanism).

Long-term blood pressure control mechanisms

Kidneys play main role in the long-term control of blood pressure by the following mechanisms:

1. *Direct mechanism*, i.e. 'renal body fluid feedback mechanism'.
2. *Indirect mechanisms* control kidney functions indirectly via following hormonal mechanisms:
 - i. Aldosterone system and
 - ii. Renin–angiotensin system (see page 348).

Renal–body fluid system for arterial pressure control

The most important mechanism for the long-term control of blood pressure is linked to control of circulatory volume by the kidney, a mechanism known as the *renal–body fluid feedback system*. In fact, it is similar to the capillary fluid shift mechanism except that only the renal glomerular capillaries are involved in the process.

Modes of operation of renal–body fluid feedback system.

The renal–body fluid system corrects blood pressure by causing appropriate changes in blood volume through *diuresis* and *natriuresis*:

- *When blood pressure rises too high*, the kidneys excrete increased quantities of sodium and water because of *pressure natriuresis* and *pressure diuresis*, respectively. As a result of increased renal excretion, the extracellular fluid volume and blood volume both decrease until blood pressure returns to normal and the kidneys excrete normal amounts of sodium and water.
- *When the blood pressure falls too low*, the kidneys reduce the rate of sodium and water excretion, and over a period of hours to days, if the person drinks enough water and eats enough salt to increase blood volume, the blood pressure will return to its previous level. This mechanism being very slow to act is not of major importance in the acute control of arterial pressure. However, it is by far the most potent of all long-term arterial pressure controllers.

The sequence of events in order of occurrence during control of blood pressure by this mechanism is summarized as:

Determinants of the renal-body fluid feedback mechanism.

The two factors that determine the long-term control of arterial pressure by renal-body fluid mechanism are: renal output curve for salt and water and level of salt and water intake. As long as these two factors remain constant, the mean arterial pressure will also remain exactly at the normal level of 100 mmHg. For arterial pressure to deviate from the normal level for long periods of time, one of these two factors must be altered.

[Fig. 4.4-37](#) shows the effect of different arterial pressures on urine volume output by an isolated kidney. The figure demonstrates that:

- As arterial pressure rises, there occurs a marked increase in the output of volume (pressure diuresis) and sodium (pressure natriuresis).
- As long as the arterial pressure will remain above the normal equilibrium point, renal output will exceed the intake of salt and water

resulting in a progressive decline in extracellular fluid volume.

- When blood pressure falls below the equilibrium point, the renal output of water and salt will be lower than the intake resulting in a progressive increase in extracellular volume.
- At the normal arterial pressure, a balance between renal output and intake of salt and water occurs at so-called the *equilibrium point*.
- As shown in [Fig. 4.4-37B](#), due to an abnormality of the kidney, the renal output curve is shifted and the equilibrium point is obtained at a level of high blood pressure (150 mmHg).
- The renal output and salt and water intake demonstrate that theoretically arterial pressure will be raised with increase in salt and water intake. However, in reality, the blood pressure does not rise every time the sodium intake is increased. This is accomplished mainly by decreasing the formation of angiotensin II and aldosterone, which increases the ability of kidney to excrete salt and water, and results in compensatory *left shift of the pressure natriuresis curve*.

FIGURE 4.4-37 Analysis of arterial blood pressure regulation by equating the renal output curve with salt and water intake. The equilibrium point describes the level at which arterial pressure will be regulated.

Salient features of renal–body fluid feedback mechanism.

The salient features of the renal–body fluid feedback mechanism can be summarized as:

- The renal–body fluid feedback mechanism takes several hours to show any significant response.
- These mechanisms operate very powerfully to control arterial pressure over days, weeks and months.
- The effectiveness of these mechanisms becomes steadily greater with time.
- These mechanisms, if given sufficient time, control arterial pressure at the level that provides normal output of salt and water by the kidneys.

- As long as kidney function is unaltered, these mechanisms overcome the disturbances that tend to alter arterial pressure such as increased total peripheral resistance over a long period and thus are able to control the blood pressure.

Conclusion

To conclude, it can be stated that *rapid control* of arterial pressure begins with life-saving measures of the *nervous reflexes*, continues with sustaining characteristics of the *intermediate pressure controls* and finally is stabilized at the *long-term pressure level by the renal–body fluid feedback mechanism*.

Pathological variations in blood pressure

Hypertension

Definition. Hypertension (HT) refers to a condition in which value of systolic blood pressure is persistently more than 140 mmHg and/or that of diastolic blood pressure is above 90 mmHg. If there is an increase only in systolic blood pressure, it is called *systolic hypertension* in which the pulse pressure is raised.

Types of hypertension. It is of two types : primary and secondary hypertension.

1. **Primary hypertension**, also known as *essential hypertension*, is characterized by a raised blood pressure without any underlying disease. Risk factors for primary HT include: heredity, obesity, mental tension and smoking. Blood pressure is raised due to increased peripheral resistance. Primary HT presents in two clinical forms:

- *Benign hypertension*, in which blood pressure is moderately raised. Untreated hypertension over the years may cause cardiac, vascular and renal complication.
- *Malignant hypertension* or accelerated hypertension refers to a sudden marked rise in blood pressure (e.g. systolic up to 250 mmHg and diastolic up to 150 mmHg). Malignant hypertension is an emergency and may

sometimes be even fatal.

2. *Secondary hypertension* refers to a condition in which blood pressure is raised due to some other underlying disease. Common causes of secondary hypertension are:

- *Cardiovascular diseases* producing secondary hypertension are atherosclerosis and coarctation of aorta.
- *Renal diseases* causing secondary hypertension are stenosis of renal artery, glomerulonephritis and tumour of juxtaglomerular cells leading to formation of excess of angiotensin II.

Goldblatt's hypertension, also known as renovascular hypertension, refers to the hypertension due to compression of renal artery or its branches. It can be of two types:

- *One-kidney Goldblatt hypertension*. This happens when one kidney is already removed and the renal artery of other kidney is constricted due to any reason.
- *Two-kidney Goldblatt hypertension*. This occurs when the artery to one kidney is constricted while the artery to other kidney is normal.

Mechanism. Due to occlusion of renal artery, there occurs renal ischaemia, which triggers release of renin causing rapid elevation of blood pressure for the first hour or so. This is followed by a slower additional rise in blood pressure during next several days. This happens because the hyperreninaemia increases angiotensin II levels (for details, see causing severe vasoconstriction and aldosterone release leading on to sodium and water retention.

- *Endocrinal disorders* associated with secondary

hypertension are: Cushing's syndrome (excessive secretion of glucocorticoids from adrenal cortex).

- *Hyperaldosteronism* (excessive secretion of aldosterone or other mineralocorticoids from adrenal cortex) causes renal Na^+ and water retention, consequently leading to expansion of ECF volume and blood pressure rises. Hyperaldosteronism occurs due to mutations in number of genes. In humans, different gene mutations have been identified which are responsible for hypertension.
 - i. Hypertension caused by mutation of a single gene is referred to as monogenic hypertension that is a rare entity (<1%).
 - ii. A hybrid gene encodes adrenocorticotropin-sensitive aldosterone synthetase enzyme that causes hyperaldosteronism, this condition is known as *glucocorticoid-remediable hyperaldosteronism (GRA)*. Normally, glucocorticoids do not suppress aldosterone secretion, but in this autosomal dominant disorder, hypertension can be remedied by administering glucocorticoids that suppress ACTH secretion.
 - iii. The genes coding aldosterone synthase and 11 β -hydroxylase are identical and close to each other on chromosome 8. Therefore, mutation of hybrid gene in GRA also results in 11 β -hydroxylase deficiency, which causes hypertension by increasing the secretion of deoxycorticosterone.
 - iv. In deficiency of 11- β hydroxysteroid type-2 enzyme

due to gene mutation, the cortisol has marked mineralocorticoid effect and the syndrome is known as *apparent mineralocorticoid excess (AMI)*. In this condition, there is loss of specificity for mineralocorticoid receptors. Therefore, clinical picture resembles as of hyperaldosteronism because cortisol acts on mineralocorticoid receptors. The plasma level of aldosterone and renin is low in this syndrome.

v. Mutations of genes for ENaCs (epithelial sodium channels) in *Liddle syndrome* cause increased activity of ENaCs due to reduced degradation of β and γ subunits in collecting ducts, thereby causing an increase in renal Na^+ reabsorption by mineralocorticoids leading to renal Na^+ retention and hypertension.

- *Pheochromocytoma* (tumour of adrenal medulla) secretes adrenaline/noradrenaline/both, causing sustained hypertension (see page 766).
- *Pill hypertension* is produced due to contraceptive pills containing large amount of estrogen that causes increased secretion of angiotensinogen.
- *Neurologic disorders* which may produce secondary hypertension include raised intracranial pressure, tractus solitarius and sectioning of nerve fibres from carotid sinus.
- *Pregnancy-induced hypertension (PIH)* is noticed in some of the pregnant women. Its exact cause is not known. It may be because of some autoimmune processes during pregnancy or the release of some vasoconstrictor agents from placenta or due to excessive secretion of hormones

causing rise in blood pressure.

- **Hypertension in preeclampsia (toxaemia of pregnancy).** Preeclampsia or toxaemia of pregnancy is a syndrome that occurs in approximately 5–10% of expectant mother. Hypertension is one of the major manifestations of this syndrome. The precise cause is not clearly known, but ischaemia of placenta and subsequently release of toxic factors are believed to play role in manifestations of preeclampsia.
- Hypertension occurs due to endothelial dysfunction of vasculature resulting in decreased release of nitrous oxide and other substances causing vasoconstriction, decreased GFR, impaired renal pressure natriuresis and development of hypertension.
- Thickening of glomerular filtration membrane of the kidney due to autoimmune diseases.
- Elevated circulating levels of progesterone.

Effects of hypertension. Sustained elevation of blood pressure most commonly occurs due to increased peripheral resistance and can cause a number of serious disorders.

Left ventricular hypertrophy occurs when resistance against which the left ventricle has to pump the blood (afterload) is elevated for a long period. In left ventricular hypertrophy, total oxygen consumption has already increased due to increased work load. Therefore, coronary blood flow has to be increased to meet this oxygen demand; any decrease in the coronary blood flow is associated with serious complications:

- **Myocardial infarction.** Incidence of myocardial infarction is higher in hypertensive individuals. For details, see page 360.
- **Atherosclerosis.** The incidence of atherosclerosis increases in hypertensives.
- **Thrombosis.** Hypertensive individuals are predisposed to cerebral thrombosis resulting in stroke and haemorrhage.
- **Renal failure** is an additional complication of hypertension.
- **Heart failure** occurs due to increase in the after load. For details, see

page 384.

Treatment. The incidence of heart failure, stroke and renal failure can be avoided by active treatment. Blood pressure can be lowered effectively by use of the following drugs:

- α -adrenergic receptor blockers,
- β -adrenergic receptor blockers,
- Inhibitors of angiotensin converting enzyme and
- Calcium channel blockers.

Details of treatment are beyond the scope of this book. Therefore, for mechanism of action, doses, etc., students are advised to consult pharmacology and medicine books.

Hypotension

Hypotension refers to a condition in which values of blood pressure are below the normal range. Clinically, when the systolic blood pressure is less than 90 mmHg, it is considered hypotension. It is of the following types:

- *Primary hypotension*, also known as essential hypotension, is a disorder of unknown aetiology.
- *Secondary hypotension*, as the name indicates, occurs secondary to some other underlying diseases such as myocardial infarction, neurogenic shock, haemorrhagic shock, hypoactivity of pituitary gland and hypoactivity of adrenal glands.
- *Postural hypotension* refers to sudden fall in blood pressure when patients stand up from lying down posture. It occurs due to some dysfunction of autonomic nervous system.

- Angiogenesis
- Development of Collateral Blood Vessels

Introduction

Cardiovascular control makes *circulatory adjustments* which are essential to cope up with the timely needs of each and every organ of the body and is thus of fundamental importance for survival.

Need for cardiovascular control

Functions served by cardiovascular control are:

- *To increase the blood supply* to active tissues, e.g. during exercise to skeletal and cardiac muscles.
- *Redistribution of blood* to increase or decrease the heat loss from the body as per requirements.
- *Circulatory adjustments* during routine cardiovascular stresses like change in posture, hours of excitement, fear, anxiety, meals, sleep, etc.
- *Maintenance of adequate flow to vital organs* such as brain, heart, and kidney all the times including emergencies such as shock and haemorrhage, even at the expense of the circulation to the rest of the body, as the vital organs may develop irreversible changes in no time. For example, the brain is irreversibly damaged within 3 min of ischaemia, while skin, skeletal muscle, and gastrointestinal tract can tolerate reduction of blood for longer duration. The earlier described functions sub served by the cardiovascular control system, in other words, qualify the need for cardio-vascular control.

Circulatory adjustments

Circulatory adjustments which ensure that all of the organs receive sufficient blood flow are: (1) control of blood volume and (2) control of arterial pressure. These circulatory adjustments are made by the

cardiovascular control mechanisms primarily by regulating following parameters.

A. Regulation of cardiac performance,

i.e. alterations in the activities of heart which include:

1. *Chronotropic action*, i.e. effect on heart rate which may be in the form of:

- Increased heart rate (tachycardia) or positive chronotropic effect.
- Decreased heart rate (bradycardia) or negative chronotropic effect.

2. *Inotropic action*, i.e. effect on force of contraction which may be in the form of:

- Increase in the force of contraction (positive inotropic effect) or
- Decrease in the force of contraction (negative inotropic effect).

3. *Dromotropic action*, i.e. effect on conduction of impulse through the heart, which may be in the form of:

- Increase in the velocity of impulse conduction (positive dromotropic effect) or
- Decrease in the velocity of impulse conduction (negative dromotropic effect).

4. *Bathmotropic action*, i.e. effect on the excitability of the cardiac muscle, which may be in the form of:

- Increased excitability of cardiac muscle (positive

bathmotropic effect) or

- Decreased excitability of cardiac muscle (negative bathmotropic effect).

B. Regulation of performance of blood vessels

which primarily includes:

1. *Alterations in diameter of arterioles* which change the peripheral resistance and also the hydrostatic pressure in the capillaries and
2. *Alteration in diameter of veins* which changes the venous pressure and thus venous return and the cardiac output.

Cardiovascular control mechanisms

The cardiovascular control mechanisms which play their role in making circulatory adjustments during the routine and emergency cardiovascular stresses can be grouped as:

- Neural control mechanism
- Humoral control mechanism and
- Local control mechanisms.

Neural control mechanism

Neural regulation of circulation is of fundamental importance since it responds within seconds. However, neural mechanism has little to do with local adjustments of blood flow to the tissues, except for certain tissues such as skin.

Main role of neural control mechanism

The nervous regulation mainly controls systemic functions of the circulatory system (whenever required) such as:

- Redistribution of blood flow to different parts of the body,
- Increasing pumping activity of heart and

- Rapid control of arterial pressure.

Components of neural control mechanism

The neural cardiovascular regulating mechanism consists of:

A. Medullary cardiovascular control centres.

These are the prime centres concerned with neural control of circulation. These include:

- Medullary sympathetic centre (vasomotor centre),
- Medullary parasympathetic centre (nucleus ambiguus) and
- Medullary relay centre for cardiorespiratory and afferents (nucleus of tractus solitarius, i.e. NTS).

B. Autonomic nervous system supplying the heart and blood vessels.

The regulation of circulation by medullary control centres is exerted almost entirely through the autonomic nervous system (ANS). The sympathetic component of ANS is most important for controlling circulation, and the parasympathetic component mainly contributes to regulation of heart functions.

C. Afferent impulses to medullary centres.

The vasomotor centre (VMC) is influenced by afferent impulses from the higher centres and a large number of other areas.

D. Role of skeletal nerves and muscles in controlling blood pressure.

Medullary cardiovascular control centres

1. Vasomotor centre

Though popularly known as VMC, more appropriately it should be called *medullary sympathetic centre*. It is the primary cardiovascular regulatory centre located in the medulla oblongata of brainstem. It consists of groups of neurons situated bilaterally in the reticular substance of medulla at the floor of fourth ventricle. The medullary cardiovascular centre is constituted by following different areas (Fig. 4.5-

1):

FIGURE 4.5-1 Medullary cardiovascular control centres.

Pressor area

Pressor area is located in the rostral ventrolateral medulla (RVLM). It contains glutaminergic neurons which exert *excitatory* effect on thoracolumbar spinal sympathetic neurons.

- ***Continuous sympathetic vasoconstrictor tone.*** Normally, the neurons forming the pressor area of the VMC show *inherent tonic activity*, i.e. they discharge rhythmically (at a rate of about 1 impulse per second) in a tonic fashion to excite sympathetic preganglionic neurons present in the intermediolateral (IML) grey column of the spinal cord. In this way, the continuous signals are passed to the sympathetic vasoconstrictor nerves fibres over the entire body. This *sympathetic*

vasconstrictor tone maintains a partial state of contraction of blood vessels. When this tone is blocked, for example, by spinal anaesthesia, the blood vessels throughout the body dilate and arterial pressure may fall to as low as 50 mmHg.

- *Stimulation of pressor area* produces:
- *Arteriolar constriction* which increases the systemic blood pressure,
- *Venoconstriction* which decreases blood stored in the venous reservoir and increases venous return,
- *Increase in heart rate* or positive chronotropic effect and
- *Increase in force of contraction* or positive inotropic effect.

Important Note

Cases of essential hypertension are associated with neurovascular compression of RVLM. Magnetic resonance angiography (MRA) in patients with schwannoma or meningiomas lying nearer to RVLM has indicated higher incidence of co existence of hypertension and neurovascular compression due to increased sympathetic activity. For details of hypertension see page 331.

Depressor area

Depressor area is situated bilaterally in the *caudal ventrolateral medulla* (CVLM). Stimulation of neurons forming the depressor area produces decrease in the sympathetic activity due to inhibition of the tonically discharging impulses of the pressor area causing:

- *Arteriolar dilation* which decreases systemic blood pressure,
- *Venodilatation* which increases storage of blood in venous reservoir and decreases venous return and cardiac output,
- *Decrease in the heart rate* or negative chronotropic effect and
- *Decrease in force of contraction* or negative inotropic effect.

2. Medullary parasympathetic centre

Medullary parasympathetic centre or *cardiac vagal centre* (earlier also called cardioinhibitory centre) is now called by its specific name, i.e. the *nucleus ambiguus*. It is located lateral to the medullary reticular formation (the neurons located in this centre are not tonically active). Nucleus ambiguus receives afferents via nucleus tractus solitarius (NTS) and in turn sends inhibitory pathway in the form of vagal fibres to: *heart* to decrease heart rate and force of cardiac contraction.

3. Medullary relay station for cardio-respiratory afferents

NTS of the vagus nerve forms the so-called medullary relay station for cardiorespiratory afferents. It receives afferents from most of the baroreceptors and chemoreceptors. The afferents release the excitatory neurotransmitter glutamate. Cells of the NTS, in turn, relay the information to VMC and cardiac vagal centre (nucleus ambiguus) that control sympathetic and parasympathetic outputs, respectively.

Autonomic nerve supply to heart and blood vessels

Autonomic nerve supply to heart

Sympathetic supply

Spinal sympathetic centre is formed by the neurons located in the intermediolateral (IML) horns of the spinal cord extending from T₁ to L₂ spinal segments.

The IML cells are neurons from which the sympathetic fibres actually originate,

- **Preganglionic sympathetic fibres** (small, myelinated) supplying the heart arise from the neurons lying in the IML horns of the T₁ to T₅-*spinal segments* and pass into the sympathetic trunk to superior, middle and inferior cervical ganglia and upper thoracic ganglia where they synapse (Fig. 4.5-2).
- **Postganglionic fibres** (long, unmyelinated) leave the ganglia and pass via superior, middle and inferior *cardiac sympathetic nerves* and supply to nodal tissues (SA node and AV node) and cardiac muscles (of atria and ventricles Fig.4.5-2). It is important to note that:

- Sympathetics from right side are primarily distributed to SA node.
- Sympathetics from left side are primarily distributed to AV node.

FIGURE 4.5-2 Sympathetic innervation to heart and blood vessels.

Stimulation of cardiac sympathetic nerves

causes:

- *Increased heart rate* (positive chronotropic effect) by increasing rhythmicity of SA node see page 252,
- *Increase in the conduction of impulse* through heart (positive dromotropic action see page 252),

- *Increase in the excitability* of myocardium (positive bathmotropic effect), and
- *Increase in the force of contraction* of myocardium (positive inotropic effect see page 252).

Parasympathetic supply

Parasympathetic fibres to the heart are carried through two vagii (Fig. 4.5-3).

- *Preganglionic fibres* (long, myelinated) arise from the *nucleus ambiguus* located in the medulla and travel along the vagii to reach the heart through their cardiac branches to synapse in the *ganglia* located within the superficial and deep cardiac plexuses and also in the walls of atria.
- *Postganglionic fibres* (small, unmyelinated) are distributed to the atria, SA node, AV node and AV bundle. It is important to note that:
 - The right vagus is distributed mainly to SA node,
 - The left vagus is distributed mainly to AV node,
 - No vagal motor fibres are distributed to the ventricles,
 - Parasympathetic fibres to the heart are *endocardiac*.

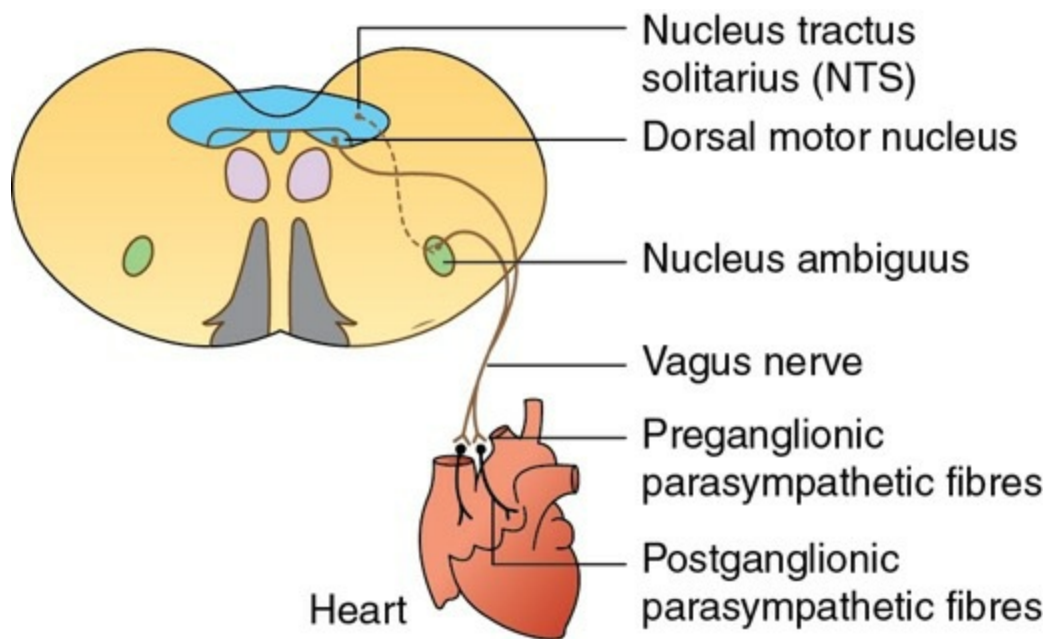

FIGURE 4.5-3 Parasympathetic innervation of the heart.

Stimulation of parasympathic fibres to heart causes:

- *Decrease in heart rate* by decreasing rate of impulse generation by SA node (negative chronotropic effect). For details see page 251.
- *Decrease in conduction of impulse* through the conduction tissue (negative dromotropic effect).
- *Decrease in the excitability of atria only* (negative bathmotropic effect) see page 251.
- *Decrease in the force of contraction of atria only* (negative inotropic effect). There is no effect on force of contraction of ventricles.

Vagal tone.

There is a moderate amount of tonic discharge in the cardiac sympathetic nerves at rest, but there is a good deal of tonic vagal discharge, called the *vagal tone*, in humans and other large animals. Therefore, when vagii are cut in the experimental animals, the heart rate rises. Similarly, in adult humans the resting heart rate which is about 72 beats/min rises to 150–180 beats/min after the administration of vagolytic drugs such as atropine, because of the unopposed sympathetic tone. When both adrenergic and cholinergic systems are blocked in humans, the heart rate is approximately 100 beats/min. Since the resting heart rate is about 72/min, it confirms that at rest, the vagal tone is greater than the

sympathetic tone (see page 251).

Autonomic nerve supply to blood vessels

The autonomic efferents supplying the blood vessels produce two types of effects:

- Vasoconstriction and
- Vasodilatation.

Vasoconstriction effect

Vasoconstriction effect is produced by the sympathetic fibres supplying the blood vessels which originate from the IML horns in T₁ to L₂ spinal segments.

Vasoconstrictor fibres have norepinephrine and sometimes neuropeptide Y as neurotransmitter and are called *noradrenergic fibres*.

These noradrenergic fibres innervate all the blood vessels of the body except the *true capillaries* and cerebral regional circulation. The small arteries and arterioles are more richly innervated as compared to large vessels. Furthermore, arterioles of skin, skeletal muscles and splanchnic arterioles have more supply as compared to those of brain and myocardium.

Sympathetic vasoconstrictor fibres show tonic (i.e. continuous) discharge at the rate of about 1 impulse/s. Therefore, *when the sympathetic nerves are cut (sympathectomy), there occurs:*

- *Vasodilatation* (of arterioles) → decreased peripheral resistance → decreased diastolic blood pressure, and *Venodilatation*– increased venous capacity → decreased venous return → decreased end-diastolic volume → decreased stroke volume → decreased cardiac output → decreased systolic blood pressure.

Stimulation of sympathetic fibres produces:

- *Constriction of arterioles* → increased peripheral resistance → increased diastolic blood pressure and
- *Venoconstriction* → decreased venous capacity → increased venous return → increased end-diastolic

volume → increased stroke volume → increased cardiac output → increased systolic blood pressure. Both these mechanisms are responsible for regional redistribution of blood and at the time of need the blood is diverted from skin, skeletal muscles and splanchnic area to heart and brain.

Vasodilatation effect

Neural vasodilatation effect on blood vessels is produced by following mechanisms:

1. Decrease in discharge of noradrenergic vasoconstrictor nerves.

In most tissues, vasodilation is produced by decreasing the rate of tonic discharge in the vasoconstrictor nerves. When the blood pressure is increased, the increased carotid sinus nerve activity causes central reflexes that inhibit vasoconstriction (producing vasodilation) and tonic effect on heart (producing bradycardia).

2. Sympathetic cholinergic vasodilator nerves.

Some of the organs of the body such as skeletal muscles, heart, lungs, liver, kidney and uterus in addition to adrenergic vasoconstrictor sympathetic fibres also receive innervation by *cholinergic vasodilator sympathetic* fibres having acetylcholine and vaso-inhibitory peptide (VIP) as neurotransmitter. These fibres originate from the cerebral cortex, relay in the hypothalamus and midbrain, and pass through the medulla (without relay in the VMC) to the sympathetic neurons located in the IML grey column of the spinal cord (Fig. 4.5-4). These fibres are not *tonically active*, and get activated only in biological stresses, for example during exercise, child birth, etc. and help in increasing the blood flow.

FIGURE 4.5-4 Pathway of sympathetic vasodilator fibres (on left side), and sympathetic vasoconstrictor system (on right side).

3. Parasympathetic vasodilator nerves.

- Blood vessels, in general, do not have parasympathetic innervation with following exceptions:
- *Sacral outflow parasympathetic fibres* represented by *nervi erigentes* which supplies sexual erectile tissue and is responsible for vasodilatation in external genitalia during sexual excitement.
- *Cranial outflow of parasympathetic fibres* along chorda tympani branch of facial nerve to salivary glands.
- *Cholinergic neurons* that probably originate in the sphenopalatine ganglia also innervate the cerebral vessels and the postganglionic cholinergic neurons on the blood vessels contain acetylcholine, VIP, and PHM- 27 as neurotransmitters.

It is important to note that parasympathetic vasodilator fibres play little role in the control of general circulation. Activation of such nerves only contributes to pleasure and fulfilling important biological functions.

4. Vasodilation by axon reflex.

Conduction of normal sensory afferent impulses from the skin to spinal cord is called *orthodromic conduction*. However, in certain situations, for example, when a firm stroke is applied across the skin, the afferent

impulses in sensory nerves from the skin are relayed *antidromically* down branches of the sensory nerves that innervate blood vessels (Fig. 4.5-5). The antidromic conduction of impulses cause release of substance P from the nerve endings which produces vasodilation and increases capillary permeability. This local neural mechanism (which does not involve the CNS) is called *axon reflex*. It is responsible for local vasodilation and does not contribute in the systemic control of circulation.

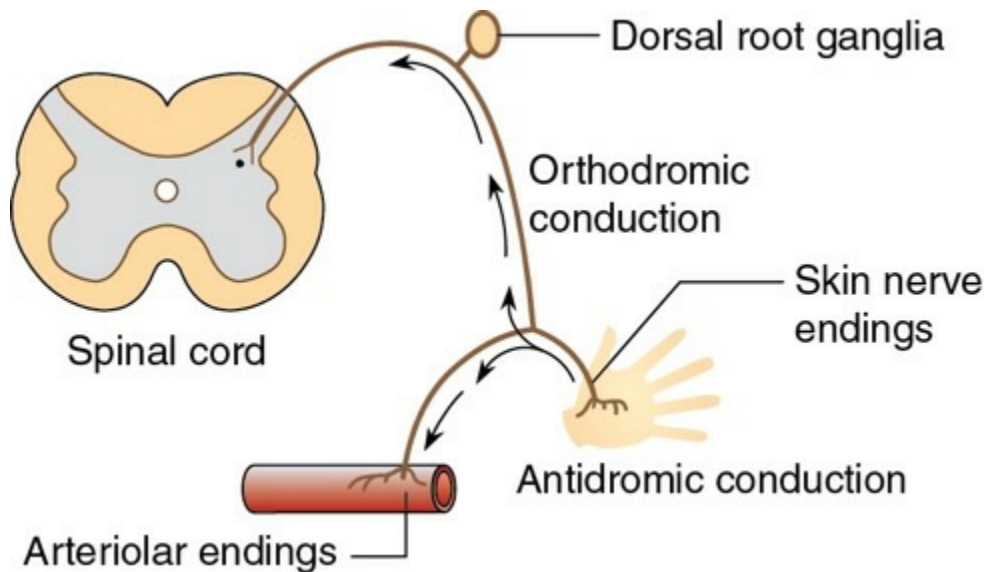

FIGURE 4.5-5 Pathway of axon reflex.

Afferent impulses to medullary cardiovascular control centres

The medullary control centres are influenced by afferent control impulses from the higher centres and a large number of other areas (Fig. 4.5-6). These include:

- Afferent impulses from higher centres controlling VMC,
- Afferent impulses from respiratory centres,
- Cardiovascular reflex mechanisms operating through medullary control centres
- Baroreceptor reflex,

- Chemoreceptor reflexes,
- Direct effects on vasomotor area
- Central nervous system ischaemic response,
- Cushing reflex,
- Afferents from nociceptive stimuli.

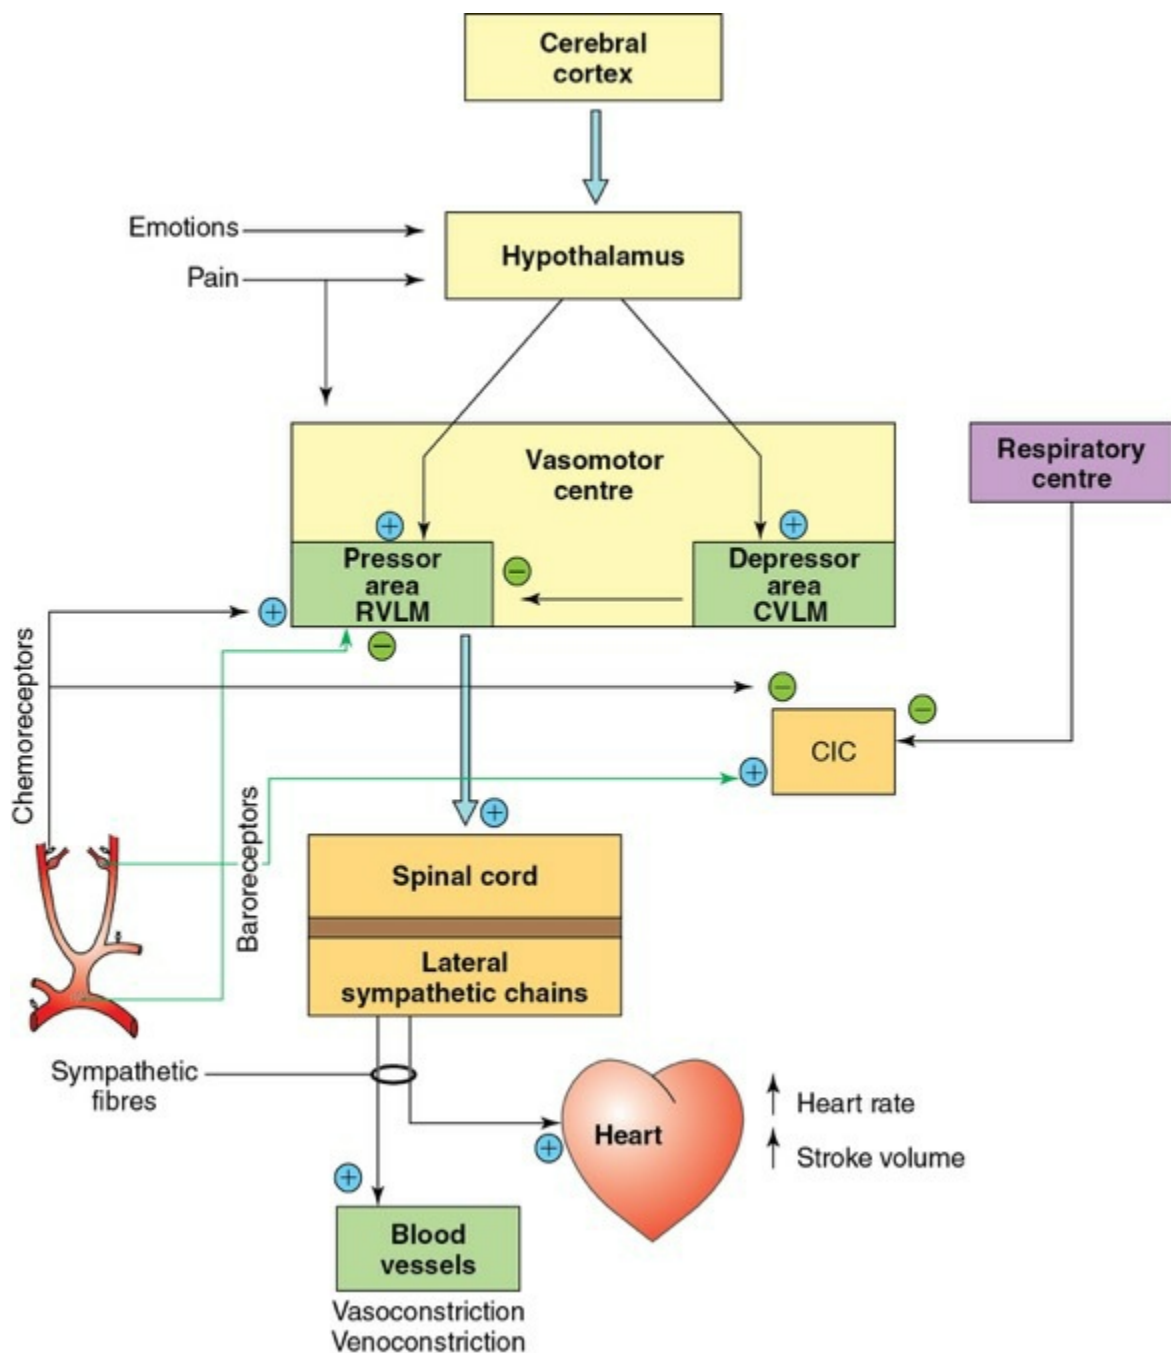

FIGURE 4.5-6 Scheme to show afferent impulses affecting medullary cardiovascular control centres.

Afferent impulses from higher centres controlling vasomotor centre and cardiacvagal centre

Cerebral cortex

Stimulation of various areas of motor cortex leads to complex motor responses that include appropriate cardiovascular adjustments. There are descending tracts to the vasomotor area from cerebral cortex (particularly the limbic cortex) that relay in the hypothalamus. Some examples of the influence of limbic system on the VMC are:

- *Tachycardia and hypertension* produced by emotions such as sexual excitement and anger,
- *Bradycardia and fainting* occurring during sudden emotional shock,
- *Fight or flight response* is a complex set of responses which increases cardiac output and raises blood pressure in anticipation of flight or physical defence.

Hypothalamus

The connections between the hypothalamus and vasomotor area are reciprocal, with afferents from the brainstem closing the loop. The hypothalamus serves to integrate many somatic and autonomic responses. Examples are:

- *Temperature regulation.* The effect of temperature changes on the hypothalamic centres are relayed to the medulla, which causes the vessels of skin to constrict (heat conservation) or to dilate (heat dissipation).
- *Emotional stresses* influence the heart rate and blood pressure by impulses relayed from hypothalamus to stimulate or inhibit the medullary centres.

Reticular formation

Reticular formation of pons, mesencephalon and diencephalon also influences the vasomotor area, for example:

- Pain usually causes rise in blood pressure via afferent impulses in the reticular formation converging on the vasomotor area. However, prolonged severe pain may cause vasodilation and fainting.

Afferent impulses from respiratory centres

Impulses arising from the respiratory centres affect the heart rate by changing the vagal tone and the alterations produced are known as *sinus arrhythmia* which occurs during forced breathing. Sinus arrhythmia is common in some children and in some adults even during quiet breathing.

- *During inspiration*, the impulses arising from the respiratory centres during inspiration inhibit the cardiac vagal centre causing reduced vagal tone and *sinus tachycardia*.
- *During expiration*, the respiratory centres stop sending inhibitory impulses to the cardiac vagal centre causing increased vagal tone and sinus bradycardia.

Cardiovascular reflex mechanisms affecting medullary control centres

Cardiovascular reflex mechanisms are multiple subconscious special nervous control mechanisms that operate through medullary control centres all the time to maintain the arterial pressure within the normal range. Almost all of these are *negative feedback reflex mechanisms* and include:

- Baroreceptor reflex mechanisms and
- Chemoreceptor reflex mechanism.

Baroreceptor reflex mechanisms

Baroreceptors also known as mechanoreceptors or pressure receptors and are the stretch receptors located in the walls of heart and large blood vessels. These are spray type nerve endings, i.e. they are extensively branched, knobby, coiled and intertwined ends of myelinated nerve fibres that resemble golgi tendon organs. These are stimulated by distension of the structures in which they are located, and so they discharge at an increased rate when the pressure in these structures rises. The increased baroreceptor discharge leads to *inhibition* of tonic

discharge of vasoconstrictor nerves and *excitation* of vagal innervation of heart and thereby produces: vasodilation, venodilation, bradycardia, decrease in cardiac output and decrease in blood pressure.

With this definition of baroreceptor reflex mechanism, the baroreceptors will be discussed in detail as under following headings:

Classification and location of baroreceptors

Functional classification

Functionally, baroreceptors can be grouped as:

1. *High-pressure baroreceptors*, which monitor the arterial circulation. These include the baroreceptors located at:

- Carotid sinus,
- Aortic arch,
- Wall of left ventricle,
- Root of right subclavian artery and
- Junction of the thyroid artery with common carotid artery.

2. *Low-pressure baroreceptors* are located in the low-pressure area of circulation and are collectively referred to as *cardiopulmonary receptors*. These include:

- Atrial receptors scattered in the wall of right and left atrium.
- Baroreceptors located in the right atrium at the entrance of the superior and inferior vena cava and in the left atrium at the entrance of pulmonary veins.
- Pulmonary receptors located in the wall of pulmonary

trunk and its divisions into right and left pulmonary artery.

Anatomical classification

Anatomically, baroreceptors can be grouped as:

1. *Arterial baroreceptors*, which are located in the walls of the arteries, distributed mainly in adventitial layer. These can be further divided into two groups:

i. *Systemic arterial baroreceptors* which include the following and these are located at:

- Carotid sinus,
- Aortic arch,
- Root of right subclavian artery and
- Junction of thyroid artery and common carotid artery.

ii. *Pulmonary baroreceptors*, which are located in the wall of pulmonary trunk and its divisions into right and left pulmonary artery.

2. *Cardiac baroreceptors* are located in the walls of heart subendocardially and can be divided into atrial and ventricular receptors which include:

i. *Atrial receptors*

- Atrial stretch receptors with nonmyelinated afferent fibres which are scattered throughout the wall of atria and interatrial septum.
- *Pulmonary venoatrial receptors*, which are located in the

left atrium just at the entrance of pulmonary veins.

ii. *Ventricular receptors*, which are scattered throughout the left ventricle and interventricular septum.

Carotid and aortic arch baroreceptors

Location of carotid and aortic arch baroreceptors

- *Carotid baroreceptors* are located in carotid sinus which is a small dilatation of the internal carotid artery just above the bifurcation of the common carotid artery into external and internal carotid branches (Fig. 4.5-7).
- *Aortic arch baroreceptors* are located in the wall of arch of aorta (Fig. 4.5-7).
- *Other systemic arterial baroreceptors* (similar to carotid and aortic baroreceptors) are also found at the root of right subclavian artery and junction of thyroid artery and in the common carotid artery.

FIGURE 4.5-7 Location of baroreceptors (carotid sinus and aortic arch) and chemoreceptors (carotid bodies and aortic bodies).

Innervation of baroreceptors (fig. 4.5-8)

- *Carotid sinus baroreceptors* are innervated by carotid sinus nerve (Hering's nerve) which is a branch of glossopharyngeal nerve.
- *All other baroreceptors* are supplied by the vagus nerve.
- *Afferent fibres* from the baroreceptors pass via the glossopharyngeal and vagus nerves to the medulla. Most of them end in the nucleus of the tractus solitarius (NTS), where they secrete an excitatory transmitter, presumably, glutamate.
- *Buffer nerves.* The carotid sinus nerve and vagal fibres from the carotid sinus and aortic arch baroreceptors, respectively, are commonly called buffer nerves, as these are involved in buffering the blood pressure, i.e.

preventing sudden rise and fall in blood pressure.

- *Projections from NTS* (excitatory glutaminergic projections) terminate on to the:
- *Depressor area of VMC (CVLM)*, where they stimulate GABA, secreting inhibitory neurons, which produce decrease in the sympathetic activity by inhibiting the tonically discharging impulses from the pressor area of VMC, and *sympathetic preganglionic neurons* of spinal cord and to decrease sympathetic activity, and
- *Cardiac vagal centre* (nucleus ambiguus), after receiving the impulses from NTS, *sends inhibitory* pathway along the vagus nerve to:
- *Heart* through cardiac branches of the vagus nerve to decrease heart rate and force of contraction.

FIGURE 4.5-8 Neural pathway of baroreceptor reflex.

Response of carotid and aortic baroreceptors to pressure

Response from carotid baroreceptors has been studied in detail and that from aortic receptors has not been studied in such great deal. However, there is no reason to believe that responses of aortic receptors differ significantly from those of the carotid receptors. Salient features of these receptor responses to pressure are:

Baroreceptor response.

At normal blood pressure levels, the fibres of the buffer nerves discharge at a low rate which increases when the pressure in the carotid sinus and aortic arch rises, and declines when the pressure falls (Figs 4.5-9 and 4.5-

10).

FIGURE 4.5-9 Discharges (vertical lines) in a single afferent nerve fibre from carotid sinus at various levels of mean arterial pressure, plotted against changes in aortic pressure with time.

FIGURE 4.5-10 Response of carotid baroreceptors at different levels of arterial pressure.

The effect of different arterial pressure levels on the discharge rate in carotid sinus nerve shown in [Figure 4.5-10](#) depicts that:

- From 0 to 50 mmHg levels of mean arterial pressure, carotid baroreceptors are not stimulated at all. The minimum pressure about 50 mmHg at which carotid baroreceptors are stimulated is called *threshold of baroreceptor reflex*.
- Above threshold level the baroreceptors respond progressively more rapidly till the discharge rate reaches a *plateau*, at 180–200mmHg, i.e. there is no further increase in response. Thus, the carotid baroreceptors exhibit a great sensitivity as they respond to pressure that vary from approximately 50–200 mmHg.
- In the normal operating rate at 95–100 mmHg, even a slight change in

pressure causes a strong change in the baroreceptor reflex signals to readjust the arterial pressure back towards the normal. Thus, the baroreceptor feedback mechanism functions most effectively in the pressure range where it is most needed.

- When pressure decreases below normal levels the baroreceptor discharge decreases and reflexly brings the pressure to normal. Conversely, when pressure increases above normal the baroreceptor discharge also increases and reflexly brings the pressure to normal. The effect of carotid receptors response to change in arterial pressure can be demonstrated experimentally as:
 - *Bilateral occlusion of common carotid arteries at their origin* reduces the carotid sinus pressure, as a result the carotid baroreceptors become inactive and lose their inhibitory effect on the VMC and the blood pressure is raised. Because aortic and cardiac baroreceptors respond to raised pressure so the occlusion of both carotid arteries cause only a moderate pressure response. When the common carotid occlusion is removed the arterial pressure returns to normal (Fig. 4.5-11).

FIGURE 4.5-11 Effect of occlusion of both common carotid arteries on arterial pressure in dog.

The carotid baroreceptors respond both to the mean pressure and the pulse pressure.

Thus, the baroreceptor discharge would increase:

- When the mean pressure rises and the pulse pressure remains unchanged or
- When the pulse pressure rises and the mean pressure remains unchanged.

Carotid baroreceptors respond much more to a rapidly changing pressure

than to a stationary pressure, i.e. if the mean arterial pressure is 150 mmHg and at that moment is rising rapidly, the rate of impulse transmission may be as much as twice that when the pressure is stationary at 150 mmHg. Conversely, if the pressure is falling, the rate might be as little as one quarter that for the stationary pressure.

Pressure-buffer system of baroreceptors.

From the above description, it is clear that baroreceptor system opposes both increase as well as decrease in arterial pressure. Therefore, it is called a *pressure-buffer system*, and the nerves from the baroreceptors are called buffer nerves. The role of the pressure-buffer system of baroreceptors can be demonstrated experimentally by bilateral denervation of carotid and aortic baroreceptors.

- The arterial pressure recording for 2 hours from a dog where bilateral buffer nerves have been cut shows extreme variability of the pressure caused by simple routine events such as lying down, standing, excitement, eating and defecation (Fig. 4.5-12B), which are absent in the normal dog with intact innervation (Fig. 4.5-12A).
- The frequency distribution curve of mean arterial pressure recorded for 24 h from a normal dog shows that during most of the day with all routine activities the arterial pressure wave maintained at 95–105 mmHg (Fig. 4.5.13A); while that from a dog where baroreceptors have been denervated shows that the arterial pressure varied extremely from 50 to 160 mmHg (Fig. 4.5-13B).
- From the above experiment it can be confirmed that baroreceptors serve as *pressure-buffer system* and reduce the minute by minute variation in the arterial pressure occurring with daily routine activities.

FIGURE 4.5-12 (A) Two-hour record of arterial pressure in a normal dog with intact innervation, and **(B)** in same dog after several weeks after denervation of baroreceptors.

FIGURE 4.5-13 Frequency distribution curve of the arterial pressure for 24-hour period: **(A)** in a normal dog; and **(B)** in the same dog several weeks after denervation of baroreceptors.

Baroreceptors resetting.

Baroreceptors possess a property to reset themselves in 1–2 days to whatever pressure they are exposed. Therefore, in chronic hypertension the baroreceptor reflex mechanism resets to maintain an elevated rather than a normal arterial pressure. This fact can be demonstrated by perfusion studies on hypertensive experimental animals (Fig. 4.5-14). Little is known about how and why this occurs, but resetting occurs rapidly in experimental animals. It is also rapidly reversible, both in experimental animals and in clinical situations. Because of this property the *baroreceptor system has no role to play for long-term regulation of the mean arterial pressure*. Thus, the baroreceptor reflex mechanism plays an important role only in preventing the extreme variations in blood pressure which occur for a short term and that prolonged regulation of mean arterial pressure requires another control system, principally, the *renal-body fluid-*

pressure control system along with its associated hormonal mechanisms (see page 330).

FIGURE 4.5-14 Percentage fall in systemic blood pressure produced by raising the pressure in the isolated carotid sinus: **(A)** in a normal monkey; and **(B)** in a hypertensive monkey. Note the graph obtained is similar (due to resetting of baroreceptors to raised pressure).

Transmission of baroreceptors response

Receptor potential.

The systemic arterial baroreceptors generate a receptor potential in response to pressure induced distension of the vascular walls. The receptor potential so generated has two components:

- *Dynamic receptor response* is the initial receptor potential, which is proportional to the rate of change in arterial pressure.
- *Static receptor response* is proportional to the new steady pressure and continues without adaptation as long as the pressure is maintained.

Afferent action potentials (APS)

are generated by the receptor potentials and are carried over the sinus and aortic nerves in response to increasing arterial blood pressure. The *action potential frequency* is linearly related to the increase in arterial pressure over a wide range.

Applied Aspects

Carotid sinus massage is used clinically to interrupt paroxysmal atrial tachycardia by inducing a vagally mediated slowing of the heart.

Stokes-Adams syndrome refers to an increased sensitivity of the carotid sinus seen in some elderly individuals who experience syncope as a result of vagally mediated sinus arrest, which causes a prolonged period of ventricular systole.

Effect of carotid clamping and bilateral vagotomy

- Bilateral clamping of the carotid arteries proximal to the carotid sinus lowers the pressure in the sinuses which is followed by a decline in discharge rate from the carotid baroreceptors leading to rise in blood pressure and heart rate.
- When along with bilateral occlusion of the common carotid arteries, bilateral vagotomy is also performed, the blood pressure rises to 300/200 mmHg or higher and is unstable.
- Bilateral destruction of nucleus of tractus solitarius (NTS), the site of termination of the baroreceptor afferents, also causes a marked pressure response producing severe hypertension which can be even fatal.
- These forms of experimentally induced hypertension due to neurogenic lesions are called *neurogenic hypertension*.

Cardiac baroreceptors

Cardiac baroreceptors are located in the walls of heart subendocardially. All cardiac receptors are innervated by vagus nerve. These include:

- Atrial stretch receptors, and
- Ventricular receptors.

Atrial stretch receptors

Atrial stretch receptors present in the walls of atria are also called *low-pressure receptors*.

Types of atrial stretch receptors. Atrial stretch receptors have been studied in detail by Prof AS Paintal (an Indian Scientist) in 1953. These can be divided into following types:

1. Atrial stretch receptors with large myelinated afferent fibres.

These receptors are located at the various *venoatrial junctions* and depending upon their location are named as:

- *Atriocaval receptors*, which are located in the right atrium just at the entrance of superior and inferior vena cavae.
- *Pulmonaryvenoatrial receptors*, which are located in the left atrium just at the entrance of pulmonary vein.

Depending upon the discharge pattern, the atrial stretch receptors with large myelinated afferents fibres are of three types:

- Type A receptors** discharge during atrial systole only and their impulse activity occurs in the PR interval of the electrocardiogram (Fig. 4.5-15).
- Type B receptors** discharge in the later part of atrial diastole when the atria are distended with blood. That is, these receptors discharge just before the onset of atrial contraction and reach peak after T-wave of the electrocardiogram (Fig. 4.5-15). Type B receptor discharge increases when the venous return is increased.
- Intermediate type of receptors** discharge both during atrial systole as well as diastole. Therefore, there discharge pattern is characterized by type A receptors discharge followed by type B receptors discharge.

FIGURE 4.5-15 Discharge pattern of type - A, and type- B atrial stretch receptors as recorded from vagus nerve and their correlation with electrocardiogram recording.

2. Atrial stretch receptors with non-myelinated afferent fibres.

These receptors are scattered throughout the atria and the interatrial septum. Their discharge is sparse (1 impulse/sec) and irregular.

Role of atrial stretch receptors.

The atrial stretch receptors have been associated with following roles in the cardiovascular control:

1. As low-pressure receptors.

the atrial stretch receptors (especially type B receptors) along with pulmonary receptors play an important role to minimize arterial pressure changes in response to change in blood volume. For example, when about 300 ml of blood is suddenly infused into a dog with all the receptors intact, the arterial pressure rises only by about 15 mmHg. With the *systemic arterial baroreceptors* denervated, the pressure rises by about 40 mmHg. If the *low-pressure receptors* are also denervated, the pressure rises by about 100 mmHg. From these observations it is quite clear that even though the low-pressure receptors cannot detect the systemic arterial pressure, they do detect simultaneous increase in pressure in the low-pressure area of circulation caused by increase in volume, and they elicit reflexes parallel to the baroreceptor reflexes to make the total reflex system much more potent for control of arterial pressure. In other words,

the atrial stretch receptors provide information about the circulating blood volume, i.e. greater the venous return, greater will be the discharge from the receptor fibres.

2. Atrial reflex control of heart rate (bainbridge reflex).

Bainbridge noted that sudden rise in atrial pressure after rapid infusion of saline or blood in anaesthetised animals produced tachycardia, if the initial heart rate was low. This effect is known as Bainbridge reflex. Atrial stretch receptors of both the sides may be responsible for this reflex. The afferent signals from these receptors pass through the vagus nerves to the medulla of brain. The efferent signals are transmitted back through both the vagal and the sympathetic nerves to increase the heart rate and force of contraction. Thus, this reflex helps to prevent damming of blood in the veins, atria and pulmonary circulation. This reflex has a different purpose from that of controlling arterial pressure.

3. Atrial reflex control of blood volume (volume reflex).

when there is volume overload the atrial stretch receptors help to return the blood volume back towards normal by following mechanisms, which collectively are called volume reflex:

1. Stretch of the atria causes very significant reflex dilatation of the afferent arterioles in the kidney leading to rise in glomerular capillary pressure, with resultant increase in filtration of fluid into the kidney tubules.

2. *Stretch of the atria also transmits signals to the hypothalamus to decrease the secretion of antidiuretic hormone (ADH), which diminishes the reabsorption of water from tubules (see page 520).*

The mechanisms (1) and (2) reduce the increased blood volume back toward normal.

3. Stretch of the atria also causes release of a chemical called *atrial natriuretic peptide* (ANP) which causes powerful diuresis and thus adds still further to the loss of fluid in the urine and return of blood volume back to normal. For details see page 535.

The above described mechanisms (1, 2 and 3) which combined constitute volume reflex, act as volume controller and thus indirectly act as *pressure controller* as well. Because excess volume increases the cardiac

output and thus the arterial pressure as well.

Ventricular receptors

The ventricular baroreceptors are scattered throughout the left ventricle and interventricular septum. They discharge irregularly. These receptors exhibit following responses:

- **Response to increased left ventricular pressure.**

When the left ventricle is distended in experimental animals, there occurs bradycardia and hypotension. The distension required to produce these effects is so high that no physiological significance can be attached to these receptors. However, left ventricular stretch receptors may play a role in the maintenance of the vagal tone that keep the heart rate low at rest.

- **Bezold-Jarisch reflex or coronary chemoreflex**

refers to reflex apnoea followed by rapid breathing, hypotension and bradycardia which occur following injection of certain drugs like capsaicin, phenylguanide, serotonin, veratidine or nicotine into the coronary arteries supplying the left ventricle (injection into the right coronary artery is ineffective) in experimental animals. This reflex is probably produced by the chemical stimulation of left ventricular stretch receptors. The receptors are probably C fibre endings, and the afferents are vagal. A similar response is produced by stimulation of C fibre endings in the lungs (pulmonary chemoreceptors). The reflex has been named after the person who first reported this response pattern.

- *Physiological significance* of this reflex is uncertain, but it has been speculated that the persistent hypotension in some patients of acute myocardial infarction may be due to stimulation of ventricular receptors by substances released from the necrotic cardiac tissue.
- Defense against chemical toxic pollutants and temperature is also provided by activation of cardiopulmonary reflexes.
- Vasovagal syncope, i.e. syndrome of cardiac slowing and hypotension has also been attributed to activation of this reflex.

Pulmonary baroreceptors

Pulmonary baroreceptors are located in the walls of pulmonary trunk

and its divisions, the right and left pulmonary artery. The pulmonary receptors along with atrial receptors constitute the so-called *low-pressure receptors or cardiopulmonary receptors* and play an important role to minimize arterial pressure changes in response to change in blood volume as discussed above (see page 345).

Role of chemoreceptor reflexes in cardiovascular control

Chemoreceptors are chemosensitive cells that respond to following changes in blood:

- Oxygen lack (decreased PO_2)
- Carbon dioxide excess (increased pCO_2) and
- hydrogen ion excess (decreased pH).

Location of chemoreceptor.

The peripheral chemoreceptors are present in (Fig. 4.5.7):

1. **Carotid bodies.** These are 1–2 mm in size and are located in the bifurcation of each common carotid artery. These are innervated by carotid sinus nerve which is a branch of glossopharyngeal nerve.
2. **Aortic bodies** are one to three in number located adjacent to arch of aorta. These are innervated by aortic nerve (branch of vagus nerve).

Functions of chemoreceptors

1. Respiratory control.

Chemoreceptors are primarily concerned with the regulation of pulmonary ventilation and are discussed in much more detail in [Chapter 5.6](#) page 447.

2. Cardiovascular control.

In physiological conditions, i.e. in healthy individuals breathing normal air, there is very little discharge from the chemoreceptors and there is no contribution to the regulation of the cardio-vascular system. The chemoreceptors exert their role in cardiovascular regulation under following conditions:

- **In hypoxia** there occurs increased chemoreceptor discharge, which not

only produces hyperventilation but also excites the VMC leading to peripheral vasoconstriction and increase in arterial blood pressure. Thus, unlike the inhibitory action of arterial baroreceptors, the chemoreceptors have an excitatory effect on the VMC.

- *In hypotension due to severe haemorrhage*, the increased chemoreceptor discharge may help to raise the arterial blood pressure. The role of chemoreceptors in severe hypotension can be demonstrated experimentally. Bilateral section of sinus and aortic nerves in animals which have been bled severely to produce hypotension, causes further fall in blood pressure. Since in such animals the baroreceptor discharge is already absent, the section of sinus and aortic nerves abolishes the chemoreceptor drive as well. Thus, further fall in blood pressure in such animals indicates that chemoreceptors were contributing to some extent to the maintenance of blood pressure.

Chemoreceptor discharge may contribute to *Mayer's waves*. Mayer waves are observed as slow, regular oscillations in arterial pressure recordings at the rate of about one/20–40 s, during hypotension (produced by haemorrhage in experimental animals). Hypoxia under these conditions stimulates chemoreceptors leading to rise in arterial pressure which improves the blood flow to chemoreceptors and therefore, there is an elimination of stimulus to the chemoreceptors. The BP again falls and a new cycle of chemoreceptor stimulation get activated and again rise in pressure.

Note.

It is important to note that the chemoreceptor reflex is not a powerful arterial pressure controller in the normal arterial pressure range because the chemoreceptors themselves are not stimulated strongly until the arterial pressure falls below 60 mmHg. Therefore, it is at lower pressures that this reflex becomes important and help to prevent still further fall in pressure.

Important Note

Mayer waves should not be confused with Traube-Hering waves, which are fluctuations in blood pressure recordings synchronizing with phases of respiration. In early phase of inspiration inflation of lungs there is vasodilation and fall in blood pressure. This response is mediated via vagal afferents from the lungs that inhibit vasomotor discharge, but in later part of inspiration blood pressure increases due to increase in end

diastolic pressure due to decrease in intra thoracic pressure and rise in intraabdominal pressure.

During expiration first there is rise and further fall in blood pressure occurs due to opposite effects.

Direct effects on vasomotor area

The VMC is directly affected by locally produced hypoxia and hypercapnia. Examples of direct effects are central nervous system ischaemic response and Cushing reflex.

1. Central nervous system ischaemic response

- When blood pressure falls below 60 mmHg, the blood flow to the vasomotor area in the brainstem is decreased enough to cause CNS ischaemia.
- As a result of CNS ischaemia, the CO₂/lactic acid are accumulated locally near the VMC and excite the neurons of VMC strongly.
- Excitation of VMC causes strong sympathetic stimulation leading to vasoconstriction. Peripheral vessels become totally occluded at certain areas, e.g. kidney. There occurs immediate increase in the blood pressure. This most powerful response that activates sympathetic vasoconstrictor system strongly is called *CNS ischaemic response*. This acts as an emergency arterial pressure control system. If rise of pressure does not relieve CNS ischaemia, neural cells begin to suffer and within 3–10 min become totally inactive.

2. Cushing reflex

When intracranial pressure is increased and becomes equal to the arterial pressure, it compresses the arteries in the brain and blood supply to the vasomotor area is compromised. The hypoxia and hypercapnia produced locally increase the discharge from VMC. The resultant rise in systemic pressure tends to restore the blood supply to medulla. This effect, which protects the vital centres in the brain is called *Cushing reflex*. The resultant increase in blood pressure also causes reflex bradycardia via baroreceptor response. Thus, bradycardia is an important feature of raised intracranial pressure.

Important Note

A rise in arterial pCO₂ activates RVLM, but direct peripheral effect of

hypercapnia is vasodilation. The peripheral and direct effects of hypercapnia cancel each other, therefore there is little change in blood pressure, but exposure to high concentration of CO₂ causes vasodilation of cerebral (the effect is mediated via increase in H⁺ concentration in the CSF) and vasoconstriction of splanchnic and cutaneous vessels through activation of peripheral chemoreceptors, hence there is slow rise in blood pressure.

Afferents from nociceptive stimuli.

Afferents carrying pain sensations also affect VMC and evoke either pressor or depressor reflex effect as:

- *Pressor effect* in the form of increase in the blood pressure and tachycardia is caused due to sympathetic activity by *somatic pain afferents*, i.e. unmyelinated C-fibres which stimulate the pressor area of VMC (RVLM).
- *Depressor effect* in the form of hypotension and bradycardia is produced by *visceral pain afferents*, i.e. thin myelinated fibres which synapse with depressor area of VMC (CVLM) and cause inhibition of sympathetic activity.

Role of skeletal nerves and muscles in controlling blood pressure

Though ANS plays the main role in control of circulation, the skeletal muscles and nerves also contribute as:

1. Abdominal compression reflex

Whenever VMC is stimulated, e.g. by baroreceptor reflex or chemoreceptor reflex, other areas of reticular formation of brainstem are also stimulated along with. They send simultaneous impulses through skeletal nerves to skeletal muscles of the body especially abdominal muscles. The contraction of abdominal muscles compresses the abdominal venous reservoirs increasing the venous return to heart and thereby the cardiac output. This response as a whole is called abdominal compression reflex.

2. Role of skeletal muscles during exercise

During exercise, the skeletal muscles especially that of limbs contract and

compress the venous reservoirs. This causes translocation of large quantities of blood from the peripheral vessels into heart and lungs. This increases the cardiac output.

Humoral control mechanisms

Humoral regulation of circulation refers to the regulation by substances secreted into or absorbed into body fluids, e.g. hormones, ions, etc. Most important humoral factors affecting circulation are:

1. Circulating vasodilators,
2. Circulating vasoconstrictors and
3. Ions and other chemical factors.

Circulating vasodilators

The circulating vasodilators include kinins, VIP (see page 578) and ANP (see page 794).

Kinins

Kinins are peptides which cause vasodilation. Two forms of kinins with similar action found are:

- *Bradykinin* is nonapeptide found in the plasma and
- *Lysyl-bradykinin* or kallidin is a decapeptide found in body tissues.

Synthesis and secretion

- The kinins are formed from high molecular weight kininogen (HMWK) and low molecular weight kininogen (LMWK) by the action of plasma and tissue kallikreins:

- Lysyl-bradykinin can be converted to bradykinin by aminopeptidase.

- Kinins are metabolized to inactive fragments by the enzymes kininase I and II and angiotensin-converting enzyme (ACE).

- Kinin release is inhibited by glucocorticoids.

Note: Kininase II is the same enzyme as angiotensin converting enzyme, which removes histidine and leucine from the terminal carboxyl end of angiotensin I

Functions of kinins

- They cause *vasodilation* by relaxing vascular smooth muscle (VSM) via NO and increase *capillary permeability*.
- Kinins play role in regulating blood flow especially to skin, salivary glands and GIT glands. Therefore, they are formed during active secretion in sweat glands, salivary glands, and in exocrine portion of pancreas.
- By regulating blood flow to skin, the kinins probably play a role in thermoregulatory vascular adjustments.
- Kinins appear to be responsible for some episodes of vasodilation in patients with carcinoid tumours.
- Kinins are responsible for inflammation because of their following actions:
 - Increase in vascular permeability especially of venules and capillaries leading to escape of plasma proteins into tissues,
 - Excitation of sensory nerve endings and production of pain (which is enhanced by 5HT) and

- Attraction and migration of leucocytes from blood to tissues.
- Kinins cause contraction of visceral smooth muscles of ileum, uterus and bronchioles (leading to bronchoconstriction in patients with asthma).

Mechanism of action. The actions of kinins are mainly paracrine and quite similar to histamine. Kinins act through their receptors. Two types of bradykinin receptors have been identified (B_1 and B_2), both types of receptors are coupled with G protein. The B_1 receptors mediate pain producing effect of kinins and the B_2 receptors have homology to histamine (H_2) receptors.

Circulating vasoconstrictors

The circulating vasoconstrictors include catecholamines, angiotension II and vasopressin.

Catecholamines

Catecholamines are released on sympathetic stimulation and include epinephrine and norepinephrine. The effects of epinephrine and norepinephrine are brought about by action on α and β adrenergic receptors, which are further subdivided into as: α_1 and α_2 subtypes and β receptors into β_1 , β_2 and β_3 subtypes.

Epinephrine.

It stimulates both α and β adrenergic receptors:

- *Stimulation of α -receptors* results in vasoconstriction in skin and splanchnic areas.
- *Stimulation of β -receptors* results in dilation of the vessels in skeletal muscles, liver and coronary arteries.
- The β receptor induced vasodilation is more dominant than α receptors induced vasoconstriction. So, the net effect is slight lowering of peripheral resistance producing slight fall in diastolic blood pressure.

- β receptor induced increase in stroke volume and heart rate results in higher cardiac output, a rise in systolic blood pressure and widening of pulse pressure.

Norepinephrine.

has a generalized vasoconstrictor action as it has much greater effect on α than on β receptors.

- Therefore, it increases peripheral resistance and raises the diastolic blood pressure.
- Since it has negligible effect on β receptors, so direct cardiac stimulation is insignificant. Rather, there occurs reflex cardiac inhibition due to the rise in diastolic blood pressure.

Renin–angiotensin system

The renin–angiotensin system has important roles in the regulation of blood pressure and in the regulation of extracellular fluid volume.

Renin secretion and angiotensin formation

- *Renin*, a protease enzyme is secreted by *juxtaglomerular cells* of the kidney into the blood. Its secretion is stimulated by a decrease in the blood pressure.
- Renin catalyzes the conversion of *angiotensinogen* (α_2 – globulin substrate present in the plasma) to angiotensin I.
- *Angiotensin I* is converted into angotensin II by the action of *angiotensin converting enzyme* (ACE) present in the endothelium of blood vessels throughout the body, especially in the lungs and kidneys.
- *Angiotensin II* persists in the blood until it is rapidly inactivated by multiple blood and tissue enzymes collectively called *angiotensinases*

Effects of angiotensin II

Angiotensin II has three principal effects by which it can elevate the arterial pressure:

1. Vasoconstriction.

Angiotensin II is the most potent pressor substance being 4 to 8 times more potent than norepinephrine. By producing generalized vasoconstriction of arterioles and veins throughout the body it raises both systolic and diastolic pressure. This effect of angiotensin II is important in intermediate blood pressure control during circumstances such as acute haemorrhage.

2. Decrease in salt and water excretion by kidney.

This action slowly increases extracellular fluid volume, which increases arterial pressure over a period of hours and days. Thus, this effect of angiotensin II plays important role in the long-term control of arterial pressure.

Mechanisms by which angiotensin II causes salt and water retention by the kidneys. Angiotensin II causes salt and water retention by the kidney in two ways:

- *By following direct actions on the kidneys:*
- Angiotensin II constricts the efferent arterioles which diminishes blood flow through the peritubular capillaries, allowing rapid osmotic reabsorption from the tubules.
- Angiotensin II directly stimulates the epithelial cells of renal tubules to increase reabsorption of sodium and water.
- *By stimulating secretion of aldosterone.* Angiotensin II stimulates the adrenal glands to secrete aldosterone which in turn increases salt and water reabsorption by the epithelial cells of the renal tubules.

3. Stimulation of thirst.

Angiotensin II is a powerful stimulator of thirst. It leads to consumption of large volumes of water, leading to a rise in blood volume. This

mechanism also plays some role in long-term control of blood pressure.

Vasopressin

Vasopressin or ADH is a powerful vasoconstrictor, but it is secreted in minute quantities and therefore mainly affects water reabsorption in renal tubules. However, after a severe haemorrhage its concentration rises to a high level and then it has vasoconstrictor effect. Its role in blood pressure regulation is discussed on page 692.

Urotensin II

Urotensin II is a potent vasoconstrictor present in cardiac and vascular tissue. Urotensin II is a polypeptide first isolated from the spinal cord of fish.

Applied

In patients with hypertension and heart failure the levels of urotensin II and its receptors have been shown to be elevated, therefore may be the markers of the disease.

Ions and other chemical factors

The increased concentration of many different ions and chemical factors can also alter local blood flow by causing vasodilation or vasoconstriction.

- Calcium ions cause vasoconstriction,
- Potassium ions cause vasodilatation,
- Hydrogen ions (decreased pH) cause vasodilation,
- Carbon dioxide causes vasodilation in most tissues and marked vasodilation in the brain.
- Glucose or other vasoactive substances, when increased in quantities raise the osmolarity of blood and cause vasodilation.

Local control mechanisms

Need of local control mechanisms

Local cardiovascular control mechanisms are primarily concerned with the control of blood flow to the tissues locally. The ability of the tissues to regulate their own blood flow locally serves many *functions*, a few examples are:

1. Local control of blood flow permits the tissues to maintain adequate nutrition and perform necessary functions in maintaining homeostasis. In general, the blood flow to the tissues is related to rate of metabolism of the organ, greater the rate of metabolism, greater is the blood flow.
2. These mechanisms help in temporarily curtailing blood flow to some organs so as to divert more blood to a metabolically active organ.
3. Control of blood flow to skin helps in control of body temperature.
4. Control of blood flow to kidney allows them to rapidly excrete the waste products of the body.

Classification of local control mechanisms

A. Mechanisms involved in acute control of blood flow:

1. General mechanisms
2. Special mechanisms

B. Mechanisms involved in long-term blood flow regulation.

Mechanisms involved in acute control of blood flow

Acute control occurs within seconds to minutes through constriction or dilation of arterioles, meta-arterioles and precapillary sphincters. The mechanisms involved in acute control of blood flow include:

I. General mechanisms

These are the mechanisms that are present in most tissues of the body are:

1. Autoregulation, i.e. control of flow during changes in arterial pressure,
2. Role of local vasodilator metabolites and factors,

3. Role of local vasoconstrictors,
4. Role of substances secreted by endothelial cells.

1. Autoregulation (control of flow during changes in arterial pressure)

Autoregulation is the ability of an organ or tissue to adjust its vascular resistance and maintain a relatively constant blood flow over a wide range of arterial pressure. For details see page 315.

2. Role of local vasodilator metabolites

The accumulation of local vasodilator metabolites increase local blood flow. The greater the rate of metabolism in the tissue, the greater the rate of production of tissue metabolites.

Metabolic changes that produce vasodilation include:

- *Decrease in O_2 tension and pH* causes vasodilation in most tissues. These changes cause relaxation of the arterioles and precapillary sphincters. Decrease in O_2 tension occurs either due to decreased O_2 availability such as high altitude and in pneumonia or due to increased O_2 demand during increased tissue activity.
- A local fall in pO_2 produces a Hypoxia Inducible Factor-1 α (HIF-1 α) that causes expression of a vasodilatory gene.
- *Increase in pCO_2 and osmolality* also dilates the vessels. The direct dilation action of CO_2 is most pronounced in the skin and brain.
- *Rise in temperature* exerts a direct vasodilator effect, and the temperature rise in active tissues (due to the heat of metabolism) may contribute to vasodilation.
- *Potassium (K^+) and lactate ions* are other substances that accumulate locally and play role in vasodilation especially in skeletal muscles. The vasodilation effect of K^+ is produced by hyperpolarization of VSMs.
- *Histamine* released from damaged cells in injured tissues increases capillary permeability.
- *Adenosine* may play a vasodilator role in cardiac muscles but not in

skeletal muscles. It also inhibits the release of norepinephrine.

Active hyperaemia

refers to the vasodilation which occurs when the tissue metabolic rate increases. The dilation of local blood vessels helps the tissues to receive the additional nutrients required to sustain its new level.

Metabolic theory of autoregulation

states that any vasodilator metabolites which accumulate in the tissues during active metabolism will produce autoregulation. When blood flow decreases, they accumulate and the vessels dilate; when blood flow increases, they are washed away.

Reactive hyperaemia

is a phenomenon by which the local blood flow to the organ is controlled after a period of ischaemia (also see page 315). This phenomenon also appears to be a manifestation of local metabolic blood flow regulation mechanisms. After vascular occlusion, there occurs accumulation of tissue vasodilator metabolites and the development of oxygen deficiency in the tissues. The extra blood flow during reactive hyperaemia lasts long enough to almost exactly repay the tissue oxygen deficiency and to wash out accumulated vasodilator metabolites.

3. Role of localized vasoconstrictors

- *Serotonin* released from platelets in the injured tissue is responsible in part for the vasoconstriction which occurs in haemostasis.
- *Decrease in tissue temperature* causes vasoconstriction, and this local response to cold plays a part in temperature regulation (see page 367).

4. Role of substances released by endothelium

Vascular endothelial cells make up a large and important organ. These cells secrete many growth factors and vasoactive substances which play important role in the local control of blood flow. The vasoactive substances include:

- Prostaglandins and thromboxane A_2 ,
- Endothelium-derived relaxing factor (EDRF), and

- Endothelins.

i. Prostaglandins and thromboxane A₂

- *Prostacyclin* is prostaglandin produced by endothelial cells from arachidonic acid via cyclo-oxygenase pathway. It inhibits platelet aggregation and promotes vasodilation.
- *Thromboxane A₂* is produced by platelets also from arachidonic acid. It promotes platelet aggregation and vasoconstriction.
- *Balance between prostacyclin and thromboxane A₂* fosters localized platelet aggregation and consequent clot formation while preventing excessive extension of clot and maintaining blood flow around it.

Important Note

The prostacyclin-thromboxane A₂ balance can be shifted towards prostacyclin by administering low doses of aspirin. Aspirin produces irreversible inhibition of cyclo-oxygenase. Obviously, this reduces production of both prostacyclin and thromboxane A₂. However, endothelial cells produce new cyclo-oxygenase in a matter of hours whereas platelets cannot manufacture the enzyme, and the level rises only as new platelets enter the circulation. This is slow process because platelets have a half-life of about 4 days. Therefore, administration of small amounts of aspirin for prolonged periods reduces clot formation and has been shown to be of value in preventing myocardial infarction, unstable angina, transient ischaemic attacks and stroke.

ii. Endothelium-derived relaxing factor.

Endothelial derived relaxing factor (EDRF) is the name given to a substance which is released by vascular endothelial cells and produces vasodilation. Later on it was identified to be *nitric oxide (NO)* in chemical structure.

Synthesis of NO.

It is synthesized from arginine (Fig. 4.5.16) in a reaction catalyzed by *nitric oxide synthase (NOS)*. NO synthase is a very complex enzyme, employing co factors like: NADPH, FAD, FMN and Tetrahydrobiopetrin. Three isoforms of NOS have been identified:

- NOS-1, is found in the nervous tissue,
- NOS-2, is found in macrophages and other immune cells, and
- NOS-3 is found in endothelial cells.

NOS-1 and NOS-3 are activated by agents that increase intracellular Ca^{2+} concentration, including the vasodilators acetylcholine and bradykinin, while NOS-2 is activated by cytokinase.

Inactivation of NO.

NO has a very short life (3-5 sec) as it is highly reactive. It is inactivated by haemoglobin. NO and its products are inactivated through oxidation into nitrite (NO_2^-) and nitrate (NO_3^-) which are excreted in urine. The plasma and urine concentration of NO_3^- and cGMP are useful indicators for NO production rate.

Mechanism of vasodilation by NO.

The NO that is synthesized in the endothelium diffuses to smooth muscle cells, where it activates soluble guanylyl cyclase, producing cyclic GMP (Fig. 4.5-16), which in turn mediates the relaxation of VSM by decreasing intracellular Ca^{2+} concentration.

FIGURE 4.5-16 Synthesis and mechanism of action of endothelium-derived relaxing factor (EDRF).

Functions of NO.

It has been recognised by direct and indirect evidences that NO performs many functions in the body which include:

1. *Relaxation of vascular smooth muscle* produced by NO. Serves various functions in different circumstances:

- *Flow-induced vasodilation* is thought to occur due to local release of NO. When flow to a tissue is suddenly increased by arteriolar dilation, the large arteries to the tissue also dilate.
- *Post-stenotic vasodilation* is an example of flow-induced vasodilation. Any narrowing of arterial vessels increases

the local blood flow velocity which stimulates NO release and results in post-stenotic vasodilation.

- *Vasodilation during physical exercise* is also supposed to be flow induced. It is evidenced by an increase in urinary NO_3^- and cyclic GMP excretion rates after submaximal exercise in healthy subjects. Exercise-induced NO release may explain the beneficial effects of endurance training on the cardiovascular system.
- *Tonic release of NO* under basal physiological conditions is necessary to maintain normal blood pressure. This is evidenced by the observation that when various derivatives of arginine that inhibit NO synthase (NOS) are administered to experimental animals, there is prompt rise in blood pressure. Nitroglycerine and other nitro vasodilators that are of great value in the treatment of angina act by stimulating guanylyl cyclase in the same manner as NO does.
- *Penile erection* which is consequent to vasodilation and engorgement of corpora cavernosa is also thought to be produced by release of NO. The drug *sildenafil* (Viagra), a selective inhibitor of GMP specific phosphodiesterase, acts by inhibiting the inactivation of NO.
- *Modulation of effect of vasoconstrictor and vasodilator substances.* Adenosine, ANP, and histamine Via H_2 receptors produce relaxation of VSM that is independent of endothelium. However, acetylcholine, bradykinin, VIP, substance P, and some other polypeptides act via the endothelium. Various vasoconstrictors that act directly on VSM would produce much greater constriction if they did not simultaneously cause the release of NO. Conversely, the vasodilators that have direct actions of VSM produce greater vasodilation by triggering the simultaneous release of NO.

Many of these substances are products of platelet aggregation and cause release of NO, and thus resulting vasodilation helps to keep blood vessels patent with an intact endothelium. This is in contrast to injured blood vessels, where the endothelium is damaged at the site of injury and platelets therefore aggregate and produce vasoconstriction. NO

interferes with the secretion and action of endothelin, a potent vasoconstrictor. There seems to be a balance between endothelium derived vasoconstrictor and vasodilators.

2. ***Inhibition of platelet adhesion and aggregation*** caused by NO is somewhat complementary to its vasodilator effect, both of which are extremely important for the maintenance of normal blood flow.

3. ***Anti-atherosclerotic effect.*** NO decreases LDL oxygenation and inhibits superoxide anion (O_2^-) production by inhibiting NADPH reductase activity. These actions are related to the strong anti-atherosclerotic effect exerted by NO.

4. ***Role of NO in vascular remodelling and angiogenesis*** is also suggested. NO may also be involved in pathogenesis of atherosclerosis. It is interesting in this regard that some patients with heart transplants develop an accelerated form of atherosclerosis in the vessels of the transplant, and there is reason to believe that this is triggered by endothelial damage.

5. ***NO plays role in cytotoxic activity of macrophages,*** including their ability to kill cancer cells.

6. ***NO acts as a mediator of inflammatory*** response, therefore its production is increased in inflammatory disease. NO inhibits leucocyte adhesion and migration.

7. ***In GIT,*** NO produces smooth muscle relaxation.

iii. Endothelins.

Endothelins (ET) are family of three similar polypeptides: ET-1, ET-2 and ET-3. Endothelin-1 produced by endothelial cells is one of the most potent vasoconstrictor agents yet isolated. The structure of ET is similar to polypeptide sarefotoxin, found in venom of a type of snake.

Synthesis and secretion.

In endothelial cells, the product of endothelin-1 gene is processed to a 39-amino acid prohormone, called *big endothelin-1* which is cleaved to form endothelin-1 by endothelin-converting enzyme. Small amounts of big endothelin-1 and endothelin-1 are secreted into the blood, but most of the endothelin-1 is secreted into the tunica media of the blood vessels and act

in a paracrine fashion.

Factors affecting endothelin-1 secretion.

Stimulators of endothelin-1 secretion are angiotensin II, catecholamines, growth factors, hypoxia, insulin, oxidized LDL, HDL, shear stress and thrombin. *Inhibitors* of endothelin-1 secretion include NO, ANP, PGE and prostacyclin.

Mechanism of action.

Endothelin-1 exerts its vasoconstrictor effect through the ET_A receptor which is found predominantly on VSM. ET_B receptor is found on endothelial cells and responds to all the three ET (ET-1, ET-2 and ET-3). When activated ET_B receptor stimulates release of NO and thus favours vasodilation.

Biologic actions of endothelins

include the following:

- *Effect on cardiovascular system.* Endothelin-1 is primarily a local paracrine regulator of vascular tone. Veins are possibly more sensitive than arteries.
- ET increase the heart rate and force of contraction of myocardium.
- ET play a role in closing the ductus arteriosus at birth.
- *Effect on central nervous system.* In the brain, ET play a role in regulating transport across the blood–brain barrier and across the synapses.
- *Effect on kidneys.* In the renal glomerulus endothelin causes contraction of mesangial cells and decreases glomerular filtration rate (GFR), renal blood flow and regulates Na⁺ reabsorption.
- *Effect on endocrines.* ET increase plasma levels of renin, aldosterone, catecholamines and ANP.
- *Effect on lungs.* ET produce bronchospasm.

- **Effect on GIT.** ET enhance glucogenesis and regulate gastrointestinal blood flow. Megacolon (Hirschsprung disease) occurs when cells that form myenteric plexus fail to migrate to the distal colon, has also been associated with endothelin-1 gene.
- **Promitogenic effects.** Stimulate cell growth in numerous cell lines. Carbon monoxide, hydrogen sulphide and nitric oxide are the gaseous transmitters present in cardiovascular tissue also regulate vascular tone, but their relative role yet to be established.

II. Special mechanisms

In addition to the above-described general mechanisms, there are special mechanisms that control blood flow in special areas. These are discussed in relation to specific organs, but the following two are notable mechanisms:

1. Tubuloglomerular feedback mechanism in kidneys

In the kidneys, blood flow control is vested, in part, in a mechanism called *tubuloglomerular feedback*, in which the composition of fluid in the early distal tubule is detected by the macula densa, which is located where the tubule abuts the afferent and efferent arterioles at the juxtaglomerular apparatus. When too much fluid filters from the blood through the glomerulus into the tubular system, feedback signals from the macula densa cause constriction of the afferent arterioles, thereby reducing renal blood flow and GFR back toward normal (see page 487 for further details).

2. Role of concentration of CO₂ and hydrogen controlling blood flow to brain

In the brain, the concentrations of CO₂ and H⁺ play prominent roles in local blood flow control. An increase in CO₂ and H⁺ dilates the cerebral blood vessels, which allows rapid washout of the excess CO₂ and H⁺ ions.

Long-term blood flow regulation

The long-term blood flow regulation develops over a period of days to months to match the metabolic needs of the tissues. Long-term blood flow regulation is required by:

- Ischaemic tissues,

- Tissues that are growing rapidly or
- Tissues that become chronically hyperactive.

The long-term blood flow regulation is brought by an increase in the physiological size of the vessels in a tissue, and in certain circumstances even by an increase in the number of blood vessels. One of the major factors that stimulate the increased vascularity of the tissues is a low oxygen concentration. The growth of the new vessels is called angiogenesis.

Angiogenic factors.

These are the substances which are responsible for angiogenesis. Three of the best characterized angiogenic factors which have been isolated from tumours or from other tissues that are rapidly growing or have inadequate blood supply are:

- Vascular endothelial growth factor (VEGF),
- Fibroblast growth factor (FGF), and
- Angiogenin.

Mechanism of angiogenesis.

Essentially all of the angiogenic factors promote new vessel growth by causing the vessels to sprout from small venules or, occasionally from capillaries. The basement membrane of endothelial cells is dissolved, followed by the rapid production of new endothelial cells that stream out of the vessel in extended cords directed towards the source of angiogenic factor. The cells continue to divide and eventually fold over into a tube. The tube then connects with another tube budding from another donor vessel and forms a capillary loop through which blood begins to flow. If the flow is sufficiently great, smooth muscle cells eventually invade the wall so that some of these vessels grow to be small arterioles and venules, or perhaps even larger vessels.

Development of collateral blood vessels.

Collateral blood vessels refer to those new vessels which develops around a blocked artery or vein and allow the affected tissue to be at least partially resupplied with blood. An important example is the development of collateral blood vessels after thrombosis of one of the

coronary arteries in old people.

CHAPTER

SPLANCHNIC CIRCULATION

- Splanchnic vessels
- Splanchnic circulation: characteristic features
- Intestinal circulation
- Splenic circulation
- Hepatic circulation

Introduction

After discussing the 'dynamics of circulation' and 'cardiovascular regulation mechanisms, it will be worthwhile to know how these basic principles apply to circulation in various regions of the body. This chapter includes:

- Coronary circulation,
- Cerebral circulation,
- Cutaneous circulation,
- Skeletal muscle circulation and
- Splanchnic circulation.

Circulation to other regions, such as pulmonary circulation, renal circulation and fetal circulation have been described in the concerned sections.

Coronary circulation

Coronary blood vessels

Coronary arteries

Two coronary arteries

(right and left) arise from the root of ascending aorta and supply blood to the myocardium.

Right coronary artery (RCA) supplies blood to the right ventricle, right atrium, the posterior part of left ventricle, posterior part of interventricular septum and major portion of the conducting system of heart including SA node.

Left coronary artery (LCA) thus supplies blood mainly to the anterior part of left ventricle, left atrium, anterior part of the interventricular septum and a part of the left branch of bundle of His.

Predominant supply by right coronary artery described above is seen in about 50% individuals. In 20% individuals, the predominant supply to myocardium is by left coronary artery. In 30% individuals it is the balanced supply, i.e. equal supply by the two arteries.

Major coronary arteries,

(i.e. right coronary artery and its main branch posterior interventricular branch, and left coronary artery and its main branches the circumflex artery and anterior interventricular artery) travel in the epicardium of heart (*superficial vessels*) (Fig. 4.6-1) and subdivide sending *penetrating branches* through the myocardium. The penetrating branches subdivide into arcades that distribute blood to the myocardium.

FIGURE 4.6-1 Major coronary arteries and their branches.

End arteries.

Normally, the coronary arteries appear to function as *end arteries*. However, the presence of an arterial plaque or occlusion allows the *anastomoses* present between vessels to become functional. These anastomoses are of two types:

- **Cardiac anastomoses**

are those which are present between branches of two coronary arteries and between the branches of coronary artery and deep venous system.

- **Extracardiac anastomoses**

include those present between the branches of coronary arteries and vessels lying near the heart such as vasa vasora of aorta, vasa vasora of pulmonary arteries, intrathoracic arteries, bronchial arteries and phrenic arteries.

Coronary veins

Coronary sinus

is a wide vein about 2-cm long, which drains most of the venous blood from the myocardium (mainly left ventricle) into the right atrium. Its tributaries are the *great cardiac vein*, the *small cardiac vein*, the *posterior vein of left ventricle* and the *oblique vein of left atrium* (Fig. 4.6-2).

FIGURE 4.6-2 Coronary sinus and its tributaries.

Anterior cardiac vein

draining venous blood mainly from the right ventricle opens directly into the right atrium.

Thebesian veins

and *coronary-luminal vessels* (connections between the coronary vessels and the lumen of heart) constitute the deep venous system. These vessels drain only less than 10% of the venous blood from myocardium directly into the various cardiac chambers, contributing to an *anatomic shunt effect*. The coronary luminal connections carry a larger proportion of the flow in

the right ventricle than in the left ventricle.

Coronary blood flow: Characteristic features

Normal coronary blood flow and oxygen demand

- *A continuous flow of blood* to the heart is essential to maintain an adequate supply of O₂ and nutrients.
- *Normal coronary blood flow* at rest is about 250 ml (70 ml/100 g tissue/min), i.e. about 5% of the resting cardiac output (5 L). Three- to sixfold increase in the coronary blood flow may occur during exercise. Blood flow to the left ventricle (80 ml/100 g/min) is twice the flow to right ventricle. Atrial blood flow is about one-fourth of the ventricular flow.
- *Oxygen consumption by the myocardium* is very high (8 ml/min/100 g at rest). Because of this, even at rest 70–80% of the oxygen is extracted from each unit of the coronary blood compared with the whole body (average of 25%) oxygen extraction at rest. The increased oxygen demand of the myocardium during exercise is met with by almost total (nearly 100%) extraction of oxygen and by manifold increase in the coronary blood flow. Oxygen supply and utilization by myocardium vis-à-vis rest of the body (average) is shown in [Table 4.6-1](#).

TABLE 4.6-1

Oxygen Supply and Consumption by Myocardium vis-à-vis Rest of the Body (Average)

Parameter	Rest of the body (average)	Myocardium
Oxygen content		
– Arterial blood	19 ml%	19 ml%
– Venous blood	14 ml%	06 ml%
A–V O ₂ difference	5 ml%	13 ml%
Coefficient of O ₂ utilization	$5/19 \times 100 = 26\%$	$13/19 \times 100 = 70\%$
Oxygen saturation of venous blood	$14/19 \times 100 = 74\%$ with PO ₂ 40 mmHg	$6/19 \times 100 = 32\%$ with PO ₂ <20 mmHg

Phasic changes in coronary blood flow

The coronary blood flow shows changes during phases of cardiac cycle. The blood flow is determined by the balance between *pressure head* (i.e. aortic pressure) and the resistance (i.e. extravascular pressure exerted by

the myocardium on the coronary vessels) offered to blood flow during various phases of cardiac cycle is shown in Table 4.6-2 and Fig. 4.6-3 and described here:

FIGURE 4.6-3 Blood flow in right and left coronary arteries and coronary sinus during different phases of cardiac cycle. AS = atrial systole, VS = ventricular systole and VD = ventricular diastole.

TABLE 4.6-2

Pressure Gradients between Ventricles and Aorta during Systole and Diastole

Phase of cardiac cycle	Pressure (mmHg)		Pressure gradient (mmHg) between aorta and ventricle		
	Right ventricle	Left ventricle	Aorta	Right ventricle	Left ventricle
Systole	25	121	120	95	-1
Diastole	0	0	80	80	80

Blood flow to left ventricle

During systole,

the tension developed in the left ventricle is so high that it has throttling effect on the branches of coronary arteries penetrating through them. As a result, the average blood flow through the capillaries of left ventricles falls to the extent that during some moments of the isometric contraction phase the blood flow to the left ventricle practically ceases, i.e. becomes zero. This is particularly true for the subendocardial region of the left ventricle. However, the epicardial parts of the left ventricle do receive some flow of blood during systole as the effect of intraventricular pressure is sufficiently dampened in these parts.

During diastole,

the cardiac muscles relax and blood flow increases. *Maximal flow in the left coronary vessels usually occurs during isovolumic relaxation phase*, while the arterial pressure is still relatively high and the myocardium is relaxed. Thus, most of the coronary blood flow (over 70%) occurs during diastole (Fig. 4.6-3). In severe tachycardia, the duration of diastole is drastically reduced. This tends to reduce the coronary blood flow during diastole as well, but due to local metabolic regulation the blood flow to the myocardium is not seriously affected.

Blood flow to right ventricle and atria.

Blood passing through coronary capillaries of right ventricle also shows phasic changes similar to left ventricle. However, the changes in right ventricular flow are far less because force of contraction of the right ventricle is much less (Table 4.6-2). Thus, the blood flow to the right ventricle and atria occurs both during systole and diastole.

Blood flow through coronary sinus.

As shown in Fig. 4.6-3, in the coronary sinus the inflow of blood gradually rises from the *isovolumic ventricular contraction phase* and reaches its peak during *protodiastole phase* and then gradually falls.

Clinical importance of phasic coronary blood supply

1. *Subendocardial region of left ventricle* receives no blood supply during systole so this region is particularly vulnerable to ischaemia and is the *most common site of myocardial infarction*. This is true in spite of the fact that this region has been provided with following *compensatory (protective) mechanisms*:

- *Capillary density* in subendocardial region of left ventricle is much higher (1100 capillaries/mm²) than the epicardial region (750 capillaries/mm²). Therefore, during diastole, flow to the subendocardial region of the left ventricle is considerably higher.
- *Minimum diffusion distance* between the capillaries and myocardial cells is 20% shorter in subendocardial region of left ventricle (16.5 µm) compared with epicardial region (20.5 µm).
- *Myoglobin content* (O₂ storage pigment) is higher in the subendocardial region than the epicardial region of the left ventricle.

2. *In aortic stenosis*, pressure in the left ventricle is much higher than that in aorta, because the ventricle has to force the blood against a narrow aortic orifice. This leads to severe compression of coronary vessels during systole and thus chances of myocardial infarction are increased in such cases.

3. *In congestive heart failure (CHF)*, increase in venous pressure decreases aortic diastolic pressure. As a result, the effective coronary perfusion pressure falls and coronary blood flow decreases.

Measurement of coronary blood flow

1. Nitrous oxide method (Kety method)

Principle.

Nitrous oxide method is the most common method used for measuring coronary blood flow. It gives almost accurate value and is based on the Fick's principle (see page 285).

Procedure.

The individual is made to inhale a mixture of 15% nitrous oxide and air for 10 min.

- During inhalation of gases, serial samples of arterial and coronary sinus venous blood (through a catheter introduced) are taken at fixed intervals for 10 minutes.
- The coronary blood flow (CBF) is then determined from the amount of nitrous oxide taken up per minute (N_2O /min) and the difference of nitrous oxide content of arterial (A) and venous (V) blood, i.e.

$$CBF = \frac{N_2O \text{ taken up/min}}{(A - V)}$$

2. Radionuclides utilization technique

Principle.

The radioactive tracers are pumped into cardiac muscle cells by the enzymes $Na^+ - K^+$ ATPase and equilibrate with the intracellular K^+ pool. Distribution of radioactive tracers is directly proportional to myocardial blood flow and this forms the basis of this technique.

Procedure.

Radionuclide such as thallium-201 (^{201}Tl) is injected intravenously. After 10 min, the amount of ^{201}Tl taken up by the myocardial cells is then measured with the help of gamma-scintillation camera over the chest. The amount of coronary blood flow is calculated from these values. Areas of ischaemia are detected by their low uptake. Some radiotracers such as technetium-99m stannous pyrophosphate (^{99m}Tc -PYP) are selectively taken up by the infarcted tissues only by an unknown mechanism. These substances are used to detect areas of myocardial infarcts which stand out as *hot spots* on the scintiscans of the chest.

3. Coronary angiographic technique

Coronary angiography, when combined with measurement of ^{133}Xe washout using a multiple-crystal scintillation camera, provides detailed analysis of coronary blood flow.

4. Electromagnetic flowmeter technique

- This technique is employed in animals to measure the coronary blood flow. The main advantages of this technique are that it tells the phasic flow and the flow per minute.
- In this technique, blood flow through the left ventricle is determined with the help of electromagnetic flowmeter implanted around the main left coronary artery or around its circumflex branch. The arterial and venous (with the help of a catheter passed into coronary sinus) blood samples are analyzed for O_2 content. From the measured flow, and the difference of O_2 content of arterial and venous blood, the myocardial consumption of O_2 is then determined directly.

Regulation of coronary blood flow

I. Local control mechanism

1. Autoregulation.

Like other vital organs of the body, coronary circulation shows well-developed phenomenon of autoregulation. As described in detail on page 315, autoregulation refers to the ability of an organ/tissue to adjust its vascular resistance and maintain a relatively constant blood flow over a wide range of arterial blood pressure. However, this phenomenon of autoregulation of coronary blood flow fails when blood pressure falls below 70 mmHg and coronary perfusion is seriously compromised.

2. Role of local metabolites.

Metabolic local factors are the most important factors which regulate the coronary blood flow and therefore, they even override the effect of nervous stimulation.

- It is important to note that under resting state about 50–70% of O_2 is released to the myocardium from the haemoglobin of arterial blood (in contrast, haemoglobin releases about 25% of its O_2 content for the body

as a whole). Therefore, not much additional oxygen can be provided to myocardium unless the blood flow increases. Consequently, a direct and almost linear correlation is observed between the coronary blood flow and myocardial O_2 consumption (Fig. 4.6-4). How the O_2 consumption regulates the coronary vascular resistance is not known exactly. Probably following mechanisms are involved:

- **Role of adenosine** (Berne's hypothesis). Adenosine is considered the major factor in production of coronary vasodilation during hypoxic states. In myocardial ischaemia, either due to generalized hypoxia or due to increased myocardial metabolism the intracellular myocardial *adenine nucleotides* are degraded to *adenosine*. The adenosine is capable of crossing myocardial cell membrane and thus comes out in the ECF and gains access to the resistance vessels, including the precapillary sphincters of the coronary system producing an extremely strong vasodilator response (Fig. 4.6-5). The adenosine is then reabsorbed back into the cardiac cells to be reused.
- **Direct effect of O_2** . It has been proposed that a decrease in the tissue PO_2 could also act directly on the arterioles and cause vasodilation.
- **Role of other local metabolites**. Hydrogen ions, bradykinin, CO_2 and prostaglandins are the other suggested vasodilator substances.

FIGURE 4.6-4 Relation between coronary blood flow and myocardial oxygen consumption.

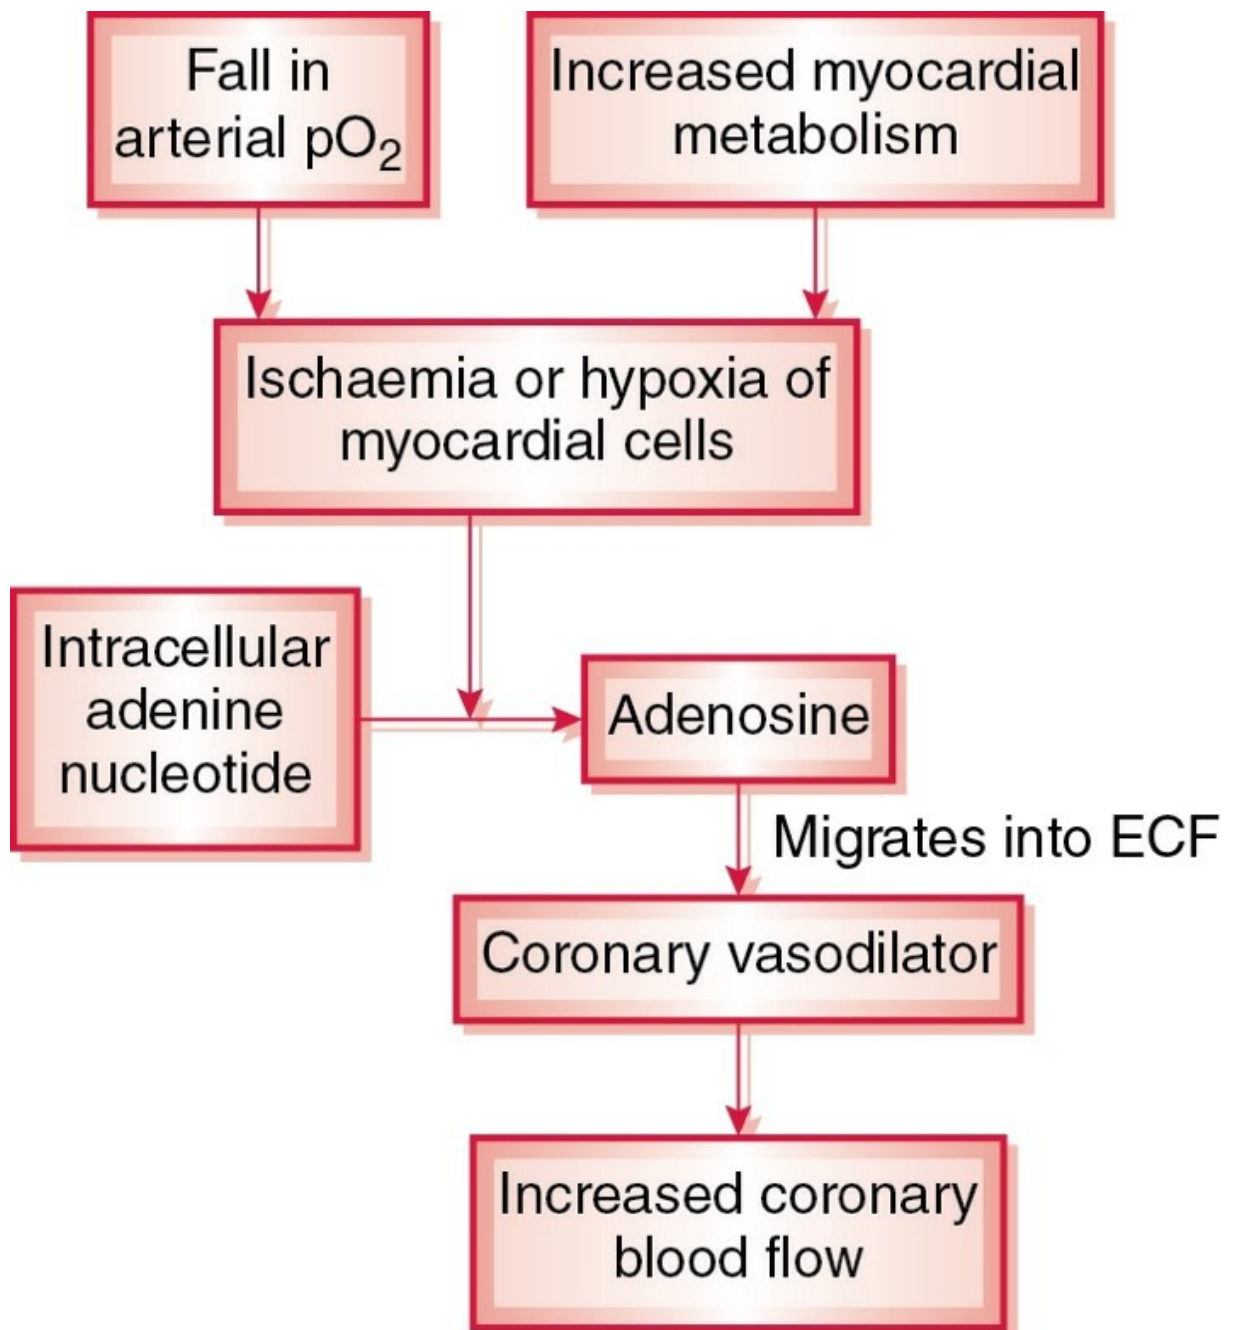

FIGURE 4.6-5 Berne's hypothesis (adenosine mechanism) of increase in coronary blood flow.

3. Role of endothelial cells

- Endothelial cells release several *vasodilator* autacoids that contribute to the physiologic regulation of coronary vasomotor tone. These include EDRF, prostacyclin (PGI₂) and endothelium-derived hyperpolarizing factor (EDHF).
- Endothelial cells also release *vasoconstrictor autacoids* that may have a pathologic role, such as endothelin-1 (ET-1), angiotensin II and

endothelium-derived contracting factors (EDCF).

II. Nervous control mechanism

Autonomic nerves control the coronary blood flow directly as well as indirectly.

1. Direct nervous control.

Direct nervous control on coronary circulation is exerted through sympathetic and parasympathetic nerve supply to the coronary vessels.

- *Parasympathetic nerve fibres* to coronary vessels through vagus are so less that parasympathetic stimulation has very little direct effect, causing vasodilation.
- *Sympathetic nerve fibres* extensively innervate the coronary vessels. The transmitters released at their nerve endings are epinephrine and norepinephrine. The coronary vessels contain both α - and β -receptors.
- Norepinephrine acts on α -receptors and causes vasoconstriction. Epicardial vessels have preponderance of α receptor.
- Epinephrine acts on β -receptors of coronary vessels, causing vasodilation. Intramuscular arteries have preponderance of β -receptors.
- The net result of direct effect of sympathetic stimulation is vasoconstriction.

2. Indirect nervous control.

Indirect control of nervous stimulation on coronary blood flow is through their action on the heart.

- *Sympathetic stimulation* causes increase in the heart rate and increase of force of contraction of the heart. Thus, increased activity of heart helps conversion of ATP to ADP which by producing coronary vasodilation increases the coronary blood flow. This indirect effect of sympathetic stimulation overrides the direct effect of sympathetic

discharge on coronary vasculature. Thus, the overall effect of sympathetic stimulation is coronary vasodilation and increased coronary blood flow.

- **Parasympathetic stimulation** causes decreased heart rate and decreased force of contraction of heart. Thus, indirectly the coronary blood flow is reduced.

3. Neurohumoral control factors.

In addition to direct and indirect nervous control through sympathetic and parasympathetic neurotransmitters, several nonadrenergic–noncholinergic neurotransmitters also play a modulatory role:

- ATP (purine) which is co-released with norepinephrine from nerve terminals produces vasoconstriction through P_1 receptors and vasodilation through P_2 receptors present on vascular smooth muscles.
- *Neuropeptide Y (NPY)* is released with norepinephrine during sympathetic stimulation and causes severe vasoconstriction.
- *Calcitonin gene-related peptide (CGRP)* and substance P which are also found in cardiac nerves cause release of endothelium-derived relaxing factor (EDRF) and produce maximal dilation of epicardial coronary arteries.

Factors affecting coronary blood flow

1. Mean aortic pressure.

This is the force for driving blood into the coronary arteries. Rise in mean aortic pressure increases the blood flow and vice versa. But if pressure remains high for a long time, because of increased work load on the heart, heart will go into congestive heart failure.

2. Muscular exercise.

Normal coronary blood flow (CBF) at rest is about 70 ml/100 g tissue/min. During exercise, CBF increases about 4 times because of sympathetic stimulation by following mechanisms:

- Increased activity of heart,

- Increased cardiac output (≥ 5 -fold) and
- Increase in mean arterial pressure.

3. Emotional excitement.

During emotional excitement states such as fright, auditory and olfactory stimuli, the CBF is increased due to increased sympathetic discharge.

4. Hypotension.

There occurs reflex increase in noradrenergic discharge during hypotension, which produces coronary vasodilation to increase CBF. This effect is observed secondary to the metabolic changes in myocardium at a time when there occurs vasoconstriction of splanchnic, renal and cutaneous vessels.

5. Hormones

affecting CBF are:

- *Thyroid hormones* increase CBF because of increase in metabolism.
- *Adrenaline and noradrenaline* cause increase in CBF as already explained, indirectly by acting on β -receptors in heart.
- *Acetylcholine* may increase CBF by its action on heart similar to parasympathetic stimulation.
- *Pitressin* is known to decrease CBF by increasing coronary resistance.
- *Nicotine* is reported to increase CBF through the liberation of norepinephrine.

6. Heart rate.

When heart rate is increased, stroke volume decreases; therefore, phasic CBF and O_2 consumption per beat also decreases.

7. Effect of ions.

Potassium ions (K^+) in low concentration causes dilation of coronary vessels increasing CBF, whereas, high K^+ ion concentration causes constriction of coronary vessels decreasing CBF.

8. Metabolic factors.

Increased metabolism of the heart increases O₂ consumption leading to relative hypoxia. Hypoxia causes vasodilation due to direct effect and also due to release of adenosine leading to increased CBF.

9. Temperature.

Hyperthermia increases metabolism and so causes increase in CBF while hypothermia decreases metabolic rate and thus decreases CBF as well.

Coronary artery disease

Coronary artery disease (CAD) also known as ischaemic heart disease (IHD) results due to insufficient coronary blood flow.

It is a condition associated with development of atherosclerosis in the coronary arteries, which supply the heart muscles (myocardium). With atherosclerosis, the arterial wall is hardened and its lumen becomes narrow due to plaque formation which may consist of calcium deposits, fatty deposits, smooth muscle proliferation and abnormal inflammatory cells.

Risk Factors for CAD Include:

- *Age and sex.* Men over 60 and women over 65 are more prone.
- *Family history* is a predisposing factor.
- *Diseases* like diabetes, hypercholesterolaemia and hypertension are proven risk factors.
- *Smoking* is a big risk factor.
- *Obesity.*
- *Diet* rich in saturated fats and low in antioxidants.
- *Life style.* Sedentary worker with lack of exercise.

Pathophysiology and manifestations of CAD

Coronary artery atherosclerosis per se or with superadded arterial spasm or thrombus leads to limitation of blood flow to the heart muscle causing ischaemia (cell starvation due to a lack of oxygen) of the myocardial cells. Myocardial ischaemia clinically may manifest as:

1. Stable angina pectoris or
2. Acute coronary syndrome: Unstable angina, myocardial infarction.

Angina pectoris

Definition.

Angina pectoris refers to a transient form of myocardial ischaemia, especially occurring during increased oxygen demand (e.g. during exercise) in patients with coronary artery disease having about 60–70% narrowing of coronary arteries. Superadded thrombus formation causing incomplete coronary occlusion results in an unstable angina.

Characteristic features.

Typically, the angina is described as a feeling of uncomfortable pressure, fullness, squeezing or pain in the substernal region, which may be localized or may be referred to the inner border of left arm, neck or jaw. Pain occurs due to accumulation of anoxic myocardial metabolites and *factor P*, which stimulates pain nerve endings.

Types.

Angina is of two types; stable and unstable.

- **Stable angina**, also known as effort angina, refers to the occurrence of above described features of angina precipitated by some activity (walking, running, exercise, etc.) with minimal or nonexistent symptoms at rest.
- **Unstable angina** occurs at rest and usually lasts for more than 10 min. Attacks are frequent.

Diagnosis

1. *Electrocardiography* The characteristic ECG changes observed during angina episode are:

- ST segment depression, that reverses after disappearance of ischaemia.
- T-wave flattening/inversion may also occur.

Stress test/ exercise electrocardiography is most useful for detecting ischemia that is not present at rest but precipitated by exercise (stress). Exercise testing can be done on motorized treadmill or with bicycle ergometer. The speed of treadmill is increased every 3 min until limited by symptoms.

2. *Laboratory testing* include serum lipid levels,

Treatment

- **Nitroglycerine**—sublingual nitroglycerine is the drug of choice. Nitrates decrease arteriolar and venous tone, reduce preload and after load, and lower the oxygen demand.

Nitrates also improve myocardial blood flow by dilating collaterals and in the presence of increased vasomotor tone.

- *Prevention of further angina attacks include:*
- Aggravating factors like hypertension, strenuous activity, emotional stress and cold temperature should be identified and treated or avoided.
- Nitroglycerine: use of nitroglycerine sublingually/translingually by spray or long acting nitrates should be taken before any strenuous activity.
- Beta blockers prevent angina by reducing myocardial oxygen requirement during exertion or stress. This effect is accomplished by reducing the heart rate, myocardial contractility and blood pressure.
- Calcium channel-blocking agents like verapamil, diltiazem and dihydropyridine prevent angina by reducing myocardial oxygen requirements.

Myocardial infarction.

Myocardial infarction (MI) or acute myocardial infarction (AMI), commonly known as a 'heart attack' refers to a degree of myocardial ischaemia (due to interruption of blood supply) that causes irreversible changes (necrosis, i.e. cell death or infarction) in the myocardium. Commonly, MI occurs when partially occluded coronary artery is constricted further by vasospasm or plaque (most common cause), which triggers formation of thrombus and occludes coronary artery.

Causes of myocardial infarction include:

- Atherosclerosis of coronary arteries,
- Thrombus formation,
- Embolus coming from other areas and
- Spasm of coronary vessels.

Since atheromatous coronary artery stenosis is the commonest cause, it has become synonymous with CAD.

Signs and symptoms

- Sudden severe chest pain is a classical symptom of MI. Pain lasts for more than 30 min and typically may radiate to left arm and left side of neck. Pain occurs due to the anoxic metabolites and necrotic tissue products.
- Associated symptoms often complained with pain are shortness of breath, nausea, vomiting, palpitation, sweating and anxiety (often described as a sense of impending doom).

Note.

Approximately 25% of all myocardial infarction are 'silent', i.e. without chest pain or other symptoms. Silent MI usually occurs in diabetics with associated autonomic neuropathy in elderly and also in patients with heart transplants.

Diagnosis

Diagnosis of MI is made by triad of:

- Typical signs and symptoms associated with
- ECG changes seen on serial tracings and
- Changes in serum levels of certain enzymes and proteins (cardiac biomarkers).

ECG changes in myocardial infarction

are very important to diagnose, localize the area of infarction and to know the duration of infarction. Typical ECG changes (hallmark) seen in MI include:

- Elevation of ST segment in the leads overlying the infarct area and
- Depression of ST segments in the reciprocal leads.

For details see page 269.

Measurement of serum enzymes and proteins related to ML.

Certain enzymes and proteins called as cardio-biomarkers leak into the circulation from the damaged myocardial cells. These include:

- *Troponin-T and troponin-I* are cardiac specific proteins, released 2–4 h after MI. Peak levels are seen after 12 h and persist up to 7 days. These are the most sensitive and specific for MI
- *Creatine Kinase (CK-MB)* levels increase within 4–6 h and lasts for 2–3 days. It is relatively specific when skeletal muscle damage is not present.
- *Lipoprotein(a) [Lp(a)]*. There is a relation between atherosclerosis and circulating levels of Lp(a). Lp(a) interferes with the fibrinolysis by decreasing plasmin generation.
- *Lactate dehydrogenase (LDH)* levels peak within 72 h. LDH is not specific as troponin.
- *Homocysteine*. This substance damages endothelial cells of coronary vessels. There is a strong positive correlation of circulating levels of homocysteine I and MI.

Note.

Homocysteine is converted into nontoxic substance (methionine) by vitamin B₁₂ and folic acid. Therefore, supplements of folate and vitamin B₁₂ lower the incidence of MI.

- **Highly sensitive C-reactive protein** and other inflammatory markers are correlated with the presence of inflammatory cells in the atherosclerotic lesion. Therefore, estimation of plasma C-reactive protein is also helpful in diagnosis.
- **Glycogen phosphorylase isoenzyme BB (GPBB)** is one of the new cardio-biomarkers. A rapid rise in blood levels can be seen in MI and unstable angina within 3 h after process of ischaemia and peak levels are seen within 7 h. It has a high sensitivity and specificity, if estimated early after chest pain.
- **Serum transaminases (AST/ALT)**. These are nonspecific cardiac biomarkers as they exist in other tissues, namely liver skin, RBC, etc. However, rise and fall with characteristic symptoms and ECG changes, these can be used as a marker.

For localization of the infarct and to decide further management other investigations included are;

- **Echocardiography** provides assessment of left ventricular and regional functioning, and can help in diagnosis and management of infarction.
- **Doppler echocardiography** is most convenient procedure for diagnosing postinfarction damage.
- **Scintigraphic studies** with technetium-99m stannous pyrophosphate and thallium 201 identify the regions of ischemia.
- **Radionuclide angiography** demonstrates akinesis in the area of infarction and also measure ejection fraction.

Treatment

In myocardial infarction, treatment should be started immediately to avoid irreversible changes. Therefore, main aim is to restore blood flow to the affected area.

A. *General measures*: Coronary care unit monitoring should be instituted as early as possible.

B. *Drug therapy*

1. *Aspirin* (for mechanism of action see page 242)

Analgesia: To relieve pain, sublingual nitroglycerine should be attempted first, if no relief than intravenous opioids provide effective and rapid analgesia.

2. *Thrombolytic therapy* reduces mortality and limits the infarct size. The greatest benefit occurs if treatment is initiated within first 3 h. Thrombolytic agents commonly used are:

- Streptokinase, the first thrombolytic agent, it is less clot specific and less effective, cause hypotension and allergic reaction, therefore not generally administered.
- Anistreplase (anisoylated plasminogen streptokinase activator complex; APSAC) It is injected as a bolus and provides continued thrombolytic activity.
- Alteplase (recombinant tissue plasminogen activator tPA) is a naturally-occurring thrombolytic agent. Two additional clot-specific agents available are reteplase (closely related to tPA) and tenecteplase (TNK-tPA).
- Heparin-post-thrombolytic management should be done by anticoagulation therapy with intravenous heparin (60 units/kg bolus followed by 12 units/kg/min to maintain a PTT of 50–75 s).

3. *Beta adrenergic agents* (see page 292)

4. *Angiotensin-converting enzyme (ACE) inhibitors* (see page 333)

5. *Calcium channel blockers* (see page 333)

C. *Surgical treatment* includes:

- *Aortic coronary bypass surgery* is performed to remove discrete points of blockage due to atherosclerosis. In this procedure, a section of subcutaneous vein either from arm or leg is removed and then grafting is done from root of aorta to the peripheral artery (beyond the blockage point).
- *Coronary angioplasty*. This procedure is used to open partially blocked coronary vessels. A small balloon-tipped catheter about 1 mm in diameter, is passed under radiographic guidance into the coronary system and pushed through partially occluded vessel till balloon reaches to blocked point. Then, the balloon is inflated under pressure, which stretches the diseased artery. After the procedure, blood flow increases by three- to fourfolds and 75% patients are relieved of ischemic symptoms.
- *Stents* are small stainless steel mesh tubes, which are placed inside the coronary artery (dilated by angioplasty) to keep the artery open and preventing restenosis. The endothelin usually grows over the stents and allows smooth blood flow through the stent. Drug-eluting stents are usually preferred because these slowly release the drugs, which prevent the excessive growth of scar tissue and decrease the incidence of restenosis.

- *Laser beam coronary artery catheterization* is a new procedure alternative to thrombolysis.

Complications.

A variety of complications can occur even after when treatment is initiated promptly in MI. These include:

- Postinfarction angina. Approximately 30% of patients will have postinfarction angina.
- Arrhythmia. Abnormalities of rhythm and conduction are common in MI (for details see page 262)
- Myocardial dysfunction. The severity of myocardial dysfunction is proportionate to the extent of myocardial necrosis. Acute left heart failure, hypotension and shock are common myocardial dysfunctions.
- Mechanical defects in the form of partial or complete rupture of papillary muscle or of interventricular septum or myocardial rupture may occur in less than 1% of acute myocardial infarction.
- Left ventricular aneurysm may develop in 10–20% patients surviving acute MI
- Pericarditis and postmyocardial infarction syndrome (Dressler's syndrome) occurs in less than 5% of patients. This is an autoimmune phenomenon and presents as pericarditis, associated with fever, leucocytosis and pericardial/pleural effusion.
- Mural thrombosis. Mural thrombi are also common, and can be detected by echocardiography or CT scan.

Cerebral circulation

Cerebral blood vessels

Arteries of the brain

- The arteries which supply the brain are derived from two internal

carotid arteries and the basilar artery (formed by union of the right and left vertebral arteries). Branches of the internal carotid arteries and of basilar artery anastomose on the inferior surface of the brain to form the circulus arteriosus (Circle of Willis).

- The *Circle of Willis* (Fig. 4.6-6) is thus basically a free anastomoses between the two internal carotid arteries and the two vertebral arteries, which equalize pressure on the arteries of the two sides. In this way, the circulus arteriosus allows blood that enters by either internal carotid or vertebral artery to be distributed to any part of both cerebral hemispheres.
- *Six large arteries*, taking part in formation of Circle of Willis, supply blood by their central and cortical branches to the brain substance.
- *Anatomical peculiarities of cerebral capillaries* and their role in *blood–brain barrier* are discussed on page 994.

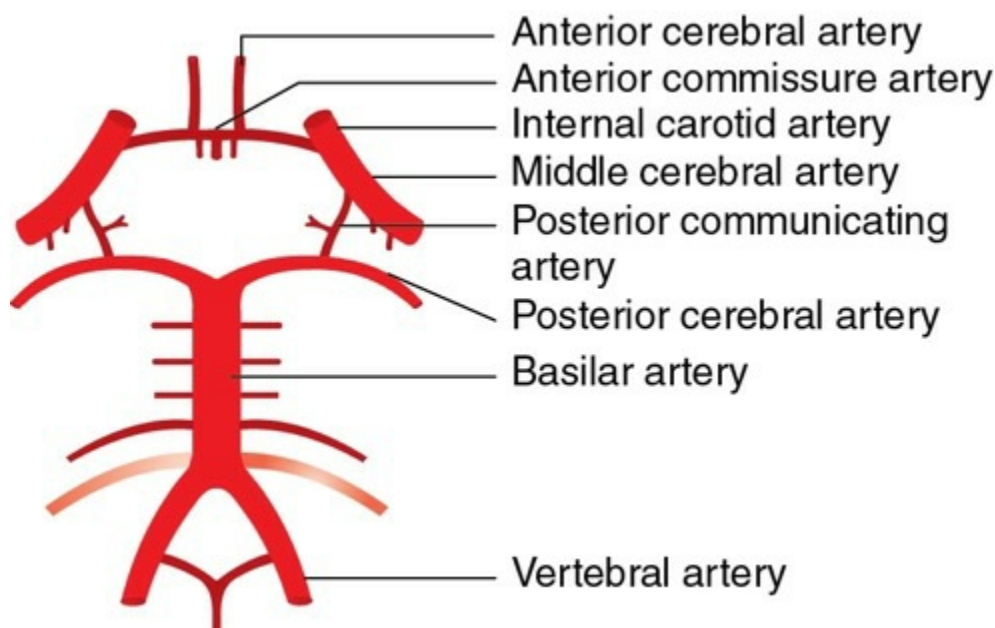

FIGURE 4.6-6 The Circle of Willis.

Venous drainage of the brain

The cerebral hemisphere has two sets of veins: the superficial and deep. The veins draining the brain open into the various dural venous sinuses. Ultimately, the blood from all these sinuses reaches the sigmoid sinuses which become continuous with the two internal jugular veins. The

venous drainage of individual part of the brain is as follows:

Veins of the cerebral hemisphere

- The veins of the cerebral hemisphere consist of two sets: superficial and deep veins.
- *Superficial veins* drain into neighbouring venous sinuses.
- *Deep veins* of the cerebral hemisphere are two internal cerebral veins and two basal veins. The internal cerebral veins join to *great cerebral veins*. Basal veins end in the great cerebral vein which in turn ends in straight sinus.

Cerebral blood flow: Characteristic features

Normal blood flow

- Brain relies on a continuous blood flow for adequate function. It is most susceptible to ischaemia. Interruption of blood flow only for 5–10 s causes a loss of consciousness, and circulatory arrest for only 3–4 min results in irreversible brain damage. The vegetative structures in brainstem are more resistant to hypoxia than cerebral cortex.
- Brain has a very rich blood supply. Normal blood flow to brain (which forms <2% of the body weight) represents approximately 15% of the resting cardiac output (75 ml/min), or about 50–55 ml blood/100 g tissue/min. The average weight of brain is 1400 g, therefore blood flow to brain is about 750ml/min.
- When cerebral blood flow falls below 18 ml/100 g tissue/min (*critical flow level*), there occurs unconsciousness.

Normal O₂ consumption

- Total O₂ consumption of the brain is approximately 50 ml/min (3.3 ml/100 g tissue/min), i.e. 20% of the whole body at rest.
- O₂ consumption of grey matter (GM) is much more (3 ml/100 g tissue/min) than the white matter (WM) which consumes only 0.3 ml/100 g tissue/min. The greater O₂ demand of GM is essential for its

functioning and is made possible because of high density of capillary network (4000 capillaries/mm² of GM).

Distribution of blood

- The major cerebral arteries are not end arteries as they anastomose at Circle of Willis. Because of this, blood flows adequately to different parts of the brain. However, under normal circumstances, blood from each carotid artery is distributed largely to the same side of the brain and very little mixing occurs between the two circulations because a pressure gradient is normally not present due to equal blood pressure on the two sides.
- The major cerebral arteries supply the brain tissue through their central and cortical branches.
- The *central branches* of the cerebral arteries are end arteries, i.e. they do not anastomose with each other. Therefore, thrombosis or rupture of any of them invariably causes infarction.
- *Cortical branches* of the anterior, middle and posterior cerebral arteries supplying the surfaces of hemispheres overlap, forming border zones between the areas supplied by these arteries. However, these border zones susceptible to ischaemic damage and under condition of inadequate perfusion develop the so-called *watershed infarcts*.
- *Anterior watershed infarct* results due to inadequate perfusion of the border zone between supply of anterior and middle cerebral arteries and is characterized by development of contralateral hemiparesis of the leg and expressive language or behavioural changes.
- *Posterior watershed infarct* results due to inadequate perfusion of the border zone between supply of middle and posterior cerebral arteries and commonly produces a partial visual loss accompanied by a variety of language problems.

Measurement of cerebral blood flow

1. Kety method

Principle.

It is based on [Fick's principle](#) (see page 285).

Procedure.

In this method, subject is made to breathe a mixture of 15% nitrous oxide and air for 10 min. During this period, serial samples are taken every minute from the internal jugular vein (representing venous blood from brain) and a peripheral artery. The cerebral blood flow (CBF) then is calculated as:

$$\text{CBF} = \frac{\text{N}_2\text{O taken up by brain tissue per min}}{\text{A - V diff of N}_2\text{O concentration}}$$

Disadvantages

of this technique are:

- It gives an average value but no information about regional differences in the blood flow. For example, a reduction in flow to one part of the brain may be completely compensated by an increase in flow to other part so that total blood flow remains unchanged in spite of the fact that a region may be damaged.
- It measures the blood flow to only perfused areas of brain.
- It can only be used in steady state and not for the measurement of rapidly changing blood flow.

2. By using radioactive substances, i.e. single photon emission computed tomography (SPECT)

Principle.

In this technique, blood flow to a region of brain is measured from the clearance curve of an inert radioactive tracer.

Procedure.

Commonly used radioactive substance in this method is radioactive xenon (^{133}Xe or ^{123}Xe). A known amount of ^{133}Xe gas dissolved in saline is injected within 1–2 s in the internal carotid artery with the help of a thin catheter. The arrival and clearance of the tracers is detected for 10 min by multiple collimated scintillation detector built into a helmet that fits over the cranium. Each detector collimated to scan about 1 cm^2 of brain surface. The output from the detectors is processed in computer and displayed on coloured television screen. The colour is proportional to amount of blood flow. Resolution can be improved by computerized tomographic reconstruction. The mean cerebral blood flow (CBF) in ml/g/min is calculated from the following equation:

$$\text{CBF} = \frac{\lambda b(H_{\text{max}} - H_{10})}{A_{10}}$$

λb = Brain blood partition coefficient,

H_{max} = Maximal height of clearance,

H_{10} = Clearance height at 10 min and

A_{10} = Area under clearance curve.

Advantage

of this technique is that blood flow to different regions of the cerebral cortex can be measured in conscious humans.

3. Positron emission tomography (PET)

It can also be employed to measure regional cerebral blood flow. As blood flow is coupled to brain metabolism, therefore, a short half-life radioisotope such as ^{18}F , ^{11}O or ^{15}O is labelled to a compound such as 2-deoxyglucose and compound is injected.

The arrival and clearance of the tracer is detected by scintillation detector placed over the head. The local uptake of 2-deoxyglucose is a good index of blood flow and its concentration in different parts can be easily monitored.

4. Magnetic resonance imaging (MRI)

In this technique regional concentration of individual metabolites is measured and changes in local O₂ utilization are mapped from which regional cerebral blood flow is studied.

This technique is based on detecting signals from different tissues in a magnetic field. Functional magnetic resonance imaging (fMRI) measures the amount of blood flow in a tissue area. During activity, the local blood flow and oxygen utilization by the tissue increases; therefore, when neural activity increases there is an increase in discharge activity that changes field potentials. The fMRI detects increase in oxygenated blood.

Advantages of fMRI-As fMRI does not involve the use of radioisotope activity, therefore, fMRI can be used at frequent intervals to detect regional brain blood flow changes in same individual during different types of activity (e.g. awake state, during sleep and involvement in specific activity like solving mathematical problems, etc).

Applied Aspects

Certain brain diseases are associated with regional/general changes in cerebral blood flow, which are detected by fMRI. A few conditions are:

- In epileptic seizure, blood flow to ectopic foci increases, whereas it reduces to other parts of brain.
- In Alzheimer disease, first change noticed is decreased metabolic activity and reduced blood flow to superior parietal cortex than to frontal cortex.
- In Huntington disease, there is reduction in blood flow to caudate nuclei.
- In manic depressive disorder, there is generalized reduction of blood flow.
- In schizophrenia, evidence suggests reduction of blood flow to frontal and temporal lobes, and to basal ganglia.

Regulation of cerebral blood flow

The perfusion pressure which determines cerebral blood flow is the difference between the mean arterial pressure at the head level and the internal jugular pressure (cerebral venous pressure). Therefore, the

factors which affect the cerebral blood flow are:

- Arterial blood pressure,
- Intracranial pressure,
- Resistance, i.e. viscosity of the blood and
- Diameter of the cerebral blood vessels.

The cerebral blood flow is regulated by the following mechanisms:

1. Metabolic regulation

Measurement of local cerebral blood flow has revealed that blood flow in individual segments of the brain changes within seconds in response to local neuronal activity. For example, the act of making a fist with the hand causes an immediate increase in blood flow in the motor cortex of the opposite cerebral hemisphere; similarly, the act of reading elevates the blood flow in the occipital cortex and in the language perception area of temporal cortex.

This change in blood flow with the neuronal activity of the particular area of the brain is related to the level of metabolism. The important metabolic factors which play important role are:

i. Carbon dioxide.

Physiologically, $p\text{CO}_2$ is the most potent vasodilator of cerebral blood vessels. With increase in $p\text{CO}_2$ there occurs a linear increase in the cerebral blood flow (Fig. 4.6-7). However, when arterial $p\text{CO}_2$ increases above 80 mmHg, no further increase in cerebral blood flow occurs due to maximal dilation of blood vessels. Similarly, when arterial $p\text{CO}_2$ falls below 20 mmHg, there occurs no further decrease in cerebral blood flow due to cerebral venoconstriction.

FIGURE 4.6-7 Effect of pCO₂ on cerebral blood flow and autoregulation of cerebral blood flow.

It has been observed that a maintained increase of arterial pCO₂ of 1mmHg above its normal range increases cerebral blood flow by 3 ml/100 g/min while a maintained decrease in arterial pCO₂ of 1mmHg below its normal range decreases cerebral blood flow by 1.5 ml/100 g/min. This is an important factor in the production of cerebral symptoms during hyperventilation.

Effect of CO₂ is mediated via change in pH as described: A rise in pCO₂ is associated with a rise in H⁺ concentration. Carbon dioxide easily diffuses through the blood–brain barrier and reaches the CSF. In the CSF, CO₂ combines with water to form carbonic acid, which partially dissociates to form H⁺ ions. The H⁺ ions induce cerebral vasodilation in proportion to their concentration. The H⁺ ions, however, do not cross the blood–brain barrier. Therefore, any substance that increase the acidity of brain and, therefore, the H⁺ ion concentration will increase cerebral blood flow; such substances include lactic acid, pyruvic acid or other acidic compounds that are formed during the course of metabolism.

ii. pO₂.

Slight fall in pO₂ causes vasodilation and produces increase in cerebral blood flow. Any stimuli, which either reduces the O₂ supply to the brain

or increases the O₂ need of the brain, results in rapid formation of *adenosine*, which is potent dilator of pial arterioles.

Inhalation of hyperbaric O₂ causes cerebral vasoconstriction and thus cerebral blood flow decreases. High cerebral pO₂ disrupts neuronal metabolism producing convulsions, coma and death.

iii. K⁺ ions.

An increase in K⁺ concentration in the CSF following hypoxia, electrical stimulation of brain and seizures cause rapid increase in cerebral blood flow. However, increase in K⁺ is not sustained throughout the period of stimulation. Hence, only the initial increase in cerebral blood flow is attributable to the release of K⁺ ions.

2. Autoregulation of cerebral blood flow

Like other vital organs of the body, cerebral circulation also shows phenomenon of autoregulation (for details see page 315). Due to autoregulation, cerebral blood flow remains nearly constant between 60 and 140 mmHg of blood pressure (Fig. 4.6-7). When blood pressure falls below 60 mmHg, the cerebral blood flow becomes extremely compromised, and syncope may result. When blood pressure rises above 140 mmHg, there may occur disruption of blood–brain barrier due to stretching and cerebral oedema or cerebral haemorrhage may result.

- **Mechanism of autoregulation.** Both metabolic and myogenic theories of autoregulation are considered (see details at page 315). In metabolic theory, main regulating substance of cerebral blood flow appears to be pCO₂.

Autoregulation is abolished easily by trauma, hypoxia or other noxious stimuli. In such states, the flow and apparently the pressure in micro-circulation increases with an increase in cerebral perfusion pressure.

3. Role of intracranial pressure in regulation of cerebral blood flow

The intracranial pressure level regulates cerebral blood flow by following two mechanisms:

i. Monro–Kellie doctrine.

According to this doctrine the brain, CSF and blood in the cerebral

vessels are three elements enclosed in a rigid cranial cavity; and when any of them increases, it is at the expense of other two. This relationship helps to maintain the cerebral blood flow when changes in the arterial blood pressure occur at the level of head as explained:

- *When the body is accelerated upwards (positive g.),* blood moves towards the feet and the arterial pressure at the level of head decreases, and theoretically the cerebral blood flow should be severely compromised. However, practically it does not occur so because due to gravity the venous pressure and intracranial pressure are also decreased, and so the pressure on the vessels is decreased. Thus, the blood flow is less severely affected.
- *When the body is accelerated downwards (negative g),* the reverse occurs, i.e. the arterial pressure at the level of head increases and theoretically the cerebral vessels could have ruptured. However, practically it does not occur so, because due to negative 'g' intracranial pressure also rises, which supports the vessels and prevents them for rupturing. The Monro–Kellie doctrine also explains the maintenance of normal cerebral blood flow during posture changes, coughing and Valsalva manoeuvre.

ii. Cushing reflex.

When intracranial pressure is increased and becomes equal to the arterial pressure, it compresses the arteries in the brain and blood supply to vasomotor area is compromised. The hypoxia and hypercapnia produced locally increases the discharge from VMC. The resultant rise in systemic pressure tends to restore the cerebral blood flow. The rise in blood pressure is proportionate to rise in intracranial pressure up to a certain limit, beyond which cerebral circulation ceases. This effect which protects the vital centres in brain is called Cushing reflex. The resultant increase in blood pressure also causes reflex bradycardia via baroreceptor response. Thus, bradycardia is an important feature of raised intracranial pressure.

4. Nervous regulation of cerebral blood flow

The cerebral blood vessels are innervated by noradrenergic vasoconstrictor fibres and cholinergic vasodilator fibres. The precise role of these fibres in regulation of cerebral blood flow is still a matter of debate. However, under normal conditions vasomotor nerves do not

regulate the cerebral blood flow. These nerves may act indirectly by release of substances from the astrocytes which act paracrinally and regulate vasomotor tone.

- *In severe hypertension*, the noradrenergic sympathetic nerves cause vasoconstriction reducing cerebral blood flow. This prevents cerebral vascular haemorrhage and stroke and also protects the integrity of blood–brain barrier, which gets disrupted at high blood pressure.
- *In severe hypotension*, the cholinergic sympathetic vasodilator nerves play role in maintaining the cerebral blood flow.

Applied Aspects

Syncope

Syncope refers to transient fainting, i.e. transient loss of consciousness due to momentary but significant decrease in cerebral blood flow. Syncope may be cardiogenic or noncardiogenic.

Cardiogenic syncope occurs in the following cardiac conditions:

- *Obstruction to cardiac output*, e.g. in aortic stenosis. It usually occurs due to exertion and is also called effort syncope.
- *Cardiac arrhythmias*, such as sinus arrest, heart blocks and Stokes-Adams syndrome.
- *Myocardial infarction*.

Noncardiogenic syncope occurs in following forms:

- *Vasovagal syncope* occurs due to vasovagal reflex causing sudden hypotension and bradycardia.
- *Postural syncope* results due to inadequate vasomotor response to postural changes in blood pressure.

- *Carotid sinus syncope* or the carotid sinus syndrome results due to excessive sensitivity of the carotid sinus to compression, e.g. as by a tight collar.
- *Valsalva manoeuvre syncope* is associated with increased intrathoracic pressure in following situations:
 - Micturition (micturition syncope),
 - Defecation (defecation syncope) and
 - Coughing (tussive syncope).
- *Metabolic syncope* occurs in following situations:
 - *Hyperventilation* leads to hypocapnia, which causes cerebral vasoconstriction and
 - *Hypoglycaemia* impairs the activity of vasomotor centre.

Cutaneous circulation

Cutaneous blood vessels (fig. 4.6-8)

Cutaneous arterioles

form a dense network just under the dermis layer of the skin.

- *Meta-arterioles*, which arise from the arterioles, are relatively high-resistance conduits present between the arterioles and capillaries.
- *Cutaneous capillaries*. The meta-arterioles subdivide into capillary loops, which provide a large surface area for heat exchange.
- *Venules* form an extensive subpapillary venous plexus, which hold large quantity of blood and lie parallel to the surface of skin and play important role in maintaining the body temperature.

- *Arteriovenous anastomoses* are located in the distal parts of the extremities (hands and feet), the nose, lips and ear lobules. These vessels are wide, low-resistance connections that serve as shunts and allow blood to bypass the superficial capillary loops and play major role during control of body temperature.

FIGURE 4.6-8 Arrangement of blood vessels in subcutaneous region.

Cutaneous blood flow: Characteristic features

- *Main function of cutaneous circulation* is to aid in the regulation of body temperature. The metabolic rate of the skin is relatively small so that a minimal amount of blood flow to the skin can supply the nutritive function.
- *Resting cutaneous blood flow*, i.e. the flow when a person is at thermal equilibrium with the environment (at approximately 27°C atmospheric temperature), is about 10–15 ml/min/100 g of skin tissue.
- *During exposure to cold*, when sweating is minimal, the cutaneous blood flow falls to about 1/10th of resting blood flow, i.e. about 1 ml/min/100 g tissue.
- *During exposure to heat*, when sweating is maximum, the cutaneous blood flow may increase 10 times of resting blood flow, i.e. about 150 ml/min/100 g tissue. Maximum cutaneous blood flow that occurs on heat exposure imposes a heavy circulatory load on the heart. That is why persons working under maximal heat loads may simply collapse

with circulatory failure unless supervised adequately.

- **Regional variation in cutaneous blood flow** exists due to presence of A-V anastomoses in abundance in certain area such as hands, feet, nose and ear lobules. During heat stress, the blood flow to the area with rich A-V anastomoses increases much more (about 75 ml/100 g/min) compared with the rest of the skin (about 25 ml/min/100 g tissue).
- **Cutaneous blood flow and skin colour.** The colour of skin is basically determined by the pigment present; however, the amount of blood and degree of oxygenation also affect the skin colour tinge which may be reddish, bluish or some shade in between.

Regulation of cutaneous blood flow

The skin has very little metabolic activity. Consequently, it has little O₂ consumption, i.e. only 0.3 ml/min/100 g compared with 3.3 ml/min/100 g in brain and 9.7 ml/min/100 g in cardiac muscles. Therefore, in contrast to most other tissues, the cutaneous blood flow is predominantly regulated by the nervous control instead of metabolic control.

Nerve supply of cutaneous vessels

- **Sympathetic vasoconstrictor** nerves supplying the cutaneous vessels exhibit a sympathetic constrictor discharge under resting condition. The sympathetic tonic discharge is more marked on AV anastomoses vessels than the other vessels.
- **Parasympathetic vasodilator nerves** do not supply the cutaneous blood vessels. Vasodilation of cutaneous vessels results due to:
 - Reduction of sympathetic vasoconstrictor effect,
 - Local production of bradykinin (a potent vasodilator polypeptide) in sweat glands and
 - Production of other local vasodilator substances (see page 350).

Neural control mechanisms

The cutaneous blood flow is regulated by following neural control mechanisms.

1. Hypothalamic control mechanism.

The reflex increase or decrease in sympathetic discharge to cutaneous vessels during thermoregulation is mediated through the temperature regulation centres of the hypothalamus as:

- ***Under resting conditions***, i.e. when the person is at thermal equilibrium with the environment (at about 27°C atmospheric temperature), the sympathetic vasoconstrictor fibres have a mild tonic discharge. The tonic sympathetic discharge normally keeps the A-V anastomoses closed.
- ***During exposure to heat stress***, the tonic sympathetic discharge is reflexly abolished by a hypothalamic mechanism. Thus, the blood flow to skin is increased by following responses in a chronological sequence:
 - First of all, A-V anastomoses of hands, feet, and ear lobules dilate due to reduction in the sympathetic tonic discharge.
 - Secondly, rest of the cutaneous vessels dilate due to progressive withdrawal of sympathetic vasoconstrictor activity.
 - Finally, sweat glands get activated due to cholinergic sympathetic discharge. The *bradykinin* produced by the secretory activity of the sweat glands acts locally as a powerful vasodilator and increases blood flow to skin.

All the above mechanisms combinedly may increase the cutaneous blood flow to as high as 150 ml/min/100 g tissue. Thus, total cutaneous blood flow during heat stress may be over 3 L/min. The increased blood flow carries heat to the surface of the body, where it is dissipated by *radiation, evaporation* and *conduction* to the environment. If the

environmental temperature is higher than the body temperature, heat can only be dissipated by means of evaporation of sweat; under these conditions radiation and conduction would cause the body to gain heat.

- ***During exposure to cold stress***, via hypothalamic mechanism, there occurs widespread cutaneous vasoconstriction due to increased sympathetic discharge. Consequently, cutaneous blood flow is markedly decreased to as low as 1 ml/min/100 g. Thus, total blood flow to skin during exposure to cold stress may be even less than 50 ml/min. In this way, *heat conservation* is accomplished by markedly diminishing the rate of blood flow to skin. Body heat is preserved because less heat is dissipated to the environment.

For details of [temperature regulation](#) see page 1246.

2. Baroreceptor-mediated reflex

Cutaneous blood vessels participate in baroreceptor-mediated reflexes during conditions of circulatory stress such as exercise and haemorrhage. They exhibit considerable vasoconstriction and act as compensatory mechanism to divert blood from periphery to the central pool.

3. Cortical control mechanism

The *emotions* affect the cutaneous circulation through corticohypothalamic pathway. The impulses are relayed from the corticohypothalamic centres to the thoracolumbar sympathetic cell bodies and thence to the skin vessels. The effects of emotions on cutaneous circulation manifest in following forms:

- ***Blanching of skin*** during situations of fear (pale with fear) occurs due to vasoconstriction mediated through cortical mechanism.
- ***Phenomenon of blushing***, i.e. emotional embarrassment, occurs due to vasodilation of vessels. It is supposed to be the result of bradykinin (a potent vasodilator) release, secondary to a brief corticohypothalamically controlled discharge of sympathetic cholinergic fibres to the sweat glands.

Cutaneous vascular responses

Certain peculiar cutaneous vascular responses are:

- White reaction,

- Triple response,
- Dermatographia,
- Axon reflex,
- Reactive hyperaemia,
- Cold vasodilation and
- Cold vasoconstriction.

White reaction

White reaction refers to appearance of a pale stroke line when a pointed object is drawn lightly over the skin. This occurs due to the fact that the mechanical stimulus initiates contraction of the precapillary sphincter, and blood drains out of the capillaries and small veins. This response appears in about 15 s.

Triple response

Triple response is three-part response, consisting of the red reaction, wheal and flare, which occurs as a normal reaction to the skin which is more in intensity than that simply causes white reaction. In other words, even when the skin is stroked more firmly with a pointed instrument, instead of white reaction, there occurs triple response.

The red reaction

refers to the red line which appears at the site of injury in about 10 s.

- It occurs due to dilation of the precapillary sphincters in the injured area.

The dilation of the precapillary sphincters is not mediated by nerves but is produced by histamine and/or some polypeptides such as bradykinin released from the damaged skin.

- Since it is not neurally mediated, local anaesthesia of skin does not prevent the red reaction.

The flare

refers to the diffusely spreading and irregularly outlined redness of the

skin surrounding the red line.

- It occurs after a few minutes of the appearance of red line.
- It occurs due to the dilation of the arteriole and precapillary sphincters. An arteriole supplies blood to the capillaries in an irregularly outlined area. This explains the irregular outline of flare.
- The dilation of the arteriole increases local blood flow.
- The dilation of arteriole is mediated by nerves, since it is abolished by the local anaesthetic agents.
- Since the blockade of the concerned afferent nerve fibres away from the site of injury does not abolish the response, it is believed that the flare is mediated by the *axon reflex* in the cutaneous fibres, which does not involve the CNS like a typical reflex. For details of axon reflex see page 339.

Wheal

refers to the swelling or localized oedema that develops within the area of flare when the stroke stimulus is strong enough.

- It occurs due to increased capillary permeability with consequent extravasation of fluid.
- The increase in capillary permeability responsible for wheal formation is produced in part by histamine or histamine-like substance released from local mast cells and mediated via H₁ receptors, in part by P substance and calcitonin gene-related peptide, the transmitter released at the central termination of the sensory fibre neurons. Thus, there is histaminergic as well as a peptidergic component of the wheal.

Note. The use of effective nonapeptide antagonist to substance P reduces extravasation of the fluid, thus prevent wheal formation.

Dermatographia

Dermatographia refers to striking triple response that occurs as an unusual reaction in some individuals. Thus, in the prone individuals anything drawn on the skin even with a blunt point becomes conspicuous within a few minutes. The exact cause of dermatographia is

not known. Possibly, it is due to excessive release of the histamine from the involved skin area.

Reactive hyperaemia

Reactive hyperaemia is a phenomenon by which the vessels control blood flow to the organ after a period of *ischaemia* following occlusion of the artery to an organ or tissue. This response of the blood vessels occurs in many organs but is visible in the skin. Due to this phenomenon, the blood flow exceeds the control level when the occlusion is removed. For example, when the blood supply to a limb is occluded, the cutaneous arterioles below the occlusion dilate. When the circulation is re-established, blood flowing into the dilated vessels makes the skin fiery red. Oxygen diffuses a short distance through the skin, and reactive hyperaemia is prevented if the circulation of the limb is occluded in an atmosphere of 100% O₂. Therefore, it has been proposed that the arteriolar dilation is apparently due to local effect of hypoxia. The magnitude and duration of reactive hyperaemia depends upon the duration of occlusion.

Cold vasodilation

As discussed above, normally during exposure to cold stress, there occurs widespread cutaneous vasoconstriction via hypothalamic mechanism. However, prolonged and severe vasoconstriction may lead to tissue damage known as *frostbite*. This usually occurs when skin temperature falls below 10°C. The tissue injury so produced is painful and associated with the release of histamine and/or some other polypeptide, which excites the sensory terminals and produce *vasodilation* due to *axon reflex* operating particularly on A-V anastomoses. In addition, exposure to severe cold promotes the formation of *plasma kinins*, which also produce vasodilation; cold vasodilation is the cause of ruddy cheeks seen in fair-complexioned individuals on a cold day.

Cold vasoconstriction

Exposure to cold causes vasoconstriction via hypothalamic mechanism. Cutaneous vasoconstriction results in decrease in nutrient supply to the skin and also decreases metabolic rate of the tissue. Due to decreased metabolism, the metabolites accumulation is very slow so, unlike in muscles, the local metabolites of the skin are not able to produce local vasodilation and oppose (escape) the sympathetic vasoconstriction. As a result, the maximal vasoconstrictor discharge to the precapillary

resistance vessels of the skin is well sustained. So, prolonged cold-induced vasoconstriction especially in damp conditions results in cutaneous ischaemia-producing lesions such as *trench foot*.

Skeletal muscle circulation

Skeletal muscle blood flow: Characteristic features

At rest

the blood flow to the skeletal muscle is about 2–4 ml/min/100 g of muscle tissue.

- Since the whole body skeletal muscles weight is approximately 30 kg in adults, the total blood flow to the body muscle mass is about 750–800 ml/min.
- At rest, only 20–25% of muscle capillaries have flowing blood.

During exercise.

During strenuous exercise, muscle blood flow can increase up to 20 times, i.e. about 50–80 ml/min/100 g muscle tissue or over 20 L/min to the whole body skeletal mass. This is called exercise hyperaemia.

- The tremendous increase in muscle blood flow mainly occurs due to local metabolite-induced vasodilation (see control of muscle blood flow). During exercise, there occurs dilation of the arterioles and precapillary sphincters, and all the dormant capillaries open up, greatly increasing the surface area and the rate of blood flow to the skeletal muscles.
- During exercise, the blood flow to the muscle is intermittent because during each contraction muscle fibres squeeze the blood vessels passing through them and thus the blood flow decreases or even stops (Fig. 4.6-9). During relaxation period, muscle blood flow increases and myoglobin acts as an O₂ acceptor and it yields its O₂ to the myofibrils during the subsequent muscle contraction.
- Sustained and severe contractions lasting more than 10 s lead to cessation of blood flow, myoglobin supply of O₂ is exhausted and anaerobic metabolites accumulate causing fatigue and ischaemic pain.

- Following heavy phasic exercise, the blood flow does not subside immediately, but falls exponentially from its high level during the exercise to resting values. This is due to the *oxygen debt of exercise* (see page 1208).

FIGURE 4.6-9 Blood flow through skeletal muscles.

Reactive hyperaemia.

When the blood supply to a limb is occluded, the muscular and cutaneous arterioles below the occlusion dilate. When the circulation is re-established, blood flowing into the dilated vessels causes *muscle hyperaemia* (muscle blood flow may increase to 35–40 ml/100 g/min). Reactive hyperaemia seems to be mediated by local hypoxia.

White versus red muscle blood flow. White versus red muscles have been described on page 95. Some of the essential differences related to blood flow are enumerated:

- White muscles constitute 3/4th of the total mass and show rapid phasic contractions. While red muscles constitute 1/4th of total mass and show steady prolonged contraction. These muscles are concerned with maintenance of posture.
- White muscles have a resting blood flow 2–4 ml/min/100 g, which may increase to 50–80 ml/min/100 g, during maximal exercise. While red muscle fibres employ aerobic metabolism and contract all the times. So, their O₂ demand is much higher (30 ml/min/100 g).
- White muscles are prone to O₂ debt, red muscles do not, because of greater surface area of the capillary bed (three times the size of white muscles) and higher resting blood flow the red muscles are unlikely to be exposed to O₂ debt.

Regulation of muscle blood flow

The blood flow to the skeletal muscles is regulated by autoregulation mechanism, metabolic control mechanism and nervous control mechanism. These mechanisms exhibit their role in different situations as described.

1. Autoregulation mechanism

Autoregulation is the ability of an organ or tissue to adjust its vascular resistance and maintain a relative constant blood flow over a range of arterial pressure. Mechanism of autoregulation is well developed in skeletal muscles like that of kidney, heart and brain. The precapillary resistance vessels in the skeletal muscles have a *high basal myogenic tone*. A rise of the transmural pressure excites a stretch-induced contraction of the sphincter smooth muscles, which by raising the precapillary vessel tone protects the capillaries from an undue rise of pressure (*myogenic theory of autoregulation*) also (see page 315). These responses are particularly important in leg muscles, where they reduce the rate of capillary filtration in erect posture and thus prevent pedal oedema under normal circumstances.

2. Metabolic control mechanism

Local metabolic control mechanism is chiefly responsible for the tremendous increase in skeletal muscle blood flow during exercise (exercise hyperaemia). The muscle contraction increases the metabolic rate of tissue, which in turn reduces *oxygen concentration* in the muscle.

The decreased tissue pO_2 leads on to vasodilation. In addition, the exercising skeletal muscle, potassium ions, hydrogen ions, lactic acid, carbon dioxide and further rise of *tissue temperature* due to muscular activity may also contribute to the dilation of arterioles and precapillary sphincter. As a result, there is 10- to 100-fold increase in the number of open capillaries in the skeletal muscles.

Metabolic control also explains the *reactive hyperaemia* that occurs following a period of occlusion of arterial blood supply, as discussed above.

3. Nervous control mechanisms

Vessels of the skeletal muscles are supplied by both sympathetic vasoconstrictor and sympathetic vasodilator fibres.

Sympathetic vasoconstrictor control

- ***Under resting conditions***, the noradrenergic sympathetic nerve fibres discharge at a rate of 1 impulse/s in recumbent position and 2–3 impulses/s in the upright position. This sympathetic discharge contributes relatively small part to the high basal tone of the resistance vessels of the muscles. Most of the basal tone of these vessels is myogenic. Because of this relatively low sympathetic contribution to the total basal tone, blockade or the permanent loss (by surgical removal) of sympathetic vasoconstrictor supply to the skeletal muscles only doubles the blood flow.
- ***During muscular exercise***. Because of the low sympathetic contribution to total basal tone, it is obvious that *exercise hyperaemia* is independent of sympathetic discharge to muscle vessels and is due to metabolic factors as described above.

Further, skeletal blood vessels contain both α -adrenergic and β -adrenergic receptors. Alpha receptors are located in close proximity of the terminals of vasoconstrictor sympathetic nerve fibres, and β receptors are independent of any innervation. During strenuous exercise norepinephrine and epinephrine are released into the systemic circulation from adrenal medulla, which tend to produce vasoconstriction and vasodilation by acting on α - and β -receptors, respectively. These two factors tend to counter each other and hence may not contribute significantly to the increased skeletal blood flow during exercise.

- *During circulatory shock and other type of circulatory stress* the sympathetic vasoconstrictor mechanism assumes a great physiological importance. Sympathetic vasoconstriction reduces muscle blood flow profoundly. Since the muscle capillary bed is very large, these help in diverting substantial amount of blood from the muscles towards the heart and other vital organs.

Sympathetic vasodilator fibres

- Skeletal blood vessels are also supplied by sympathetic vasodilator fibres. In some animals, these fibres release acetylcholine at their nerve endings, but in primates the vasodilator effect is believed to be caused by epinephrine-exciting β -adrenergic receptors in the skeletal muscle vasculature.
- These fibres are activated by *corticohypothalamic reticulospinal pathways* (see page 338), which are quite separate from the *VMC–thoracolumbar pathways*. Therefore, they are not influenced by the baroreceptor and chemoreceptor afferents and do not participate in changes in peripheral resistance by usual cardiovascular reflexes.
- These fibres probably operate during emergencies, i.e. during mental stress and emotions. Since there is stimulation of different areas in hypothalamus in these situations, therefore due to activation of corticohypothalamic reticular pathway there occurs vasodilation in muscle blood vessels also.
- Some experiments suggest that the sympathetic vasodilator system might cause initial vasodilation in skeletal muscles to allow anticipatory increase in blood flow, even before the onset of exercise.
- These fibres play an important role in preventing the sudden rise in systemic blood pressure at the beginning of exercise, i.e. these provide a *safety valve mechanism*. Just before the start of exercise, there occurs a considerable increase in the sympathetic activity. This is brought by the mere thought of exercise. As a result, the increase in stroke volume and heart rate should produce a marked increase in the blood pressure to a dangerous level. However, this does not happen so, because the discharge of sympathetic vasodilator fibres reduces the total peripheral resistance and thus lowers the blood pressure to safety level. Since the sympathetic vasodilator fibres dilate only the arterioles and not the

precapillary sphincters, they do not increase the blood flow to the muscles. When exercise commences, the precapillary sphincters are dilated by the local metabolites and blood flow to the muscle is increased tremendously.

Splanchnic circulation

Splanchnic vessels

Splanchnic circulation includes the combined vascular beds of the intestines, pancreas, spleen and liver. The main vessels which constitute the splanchnic circulation are:

- **Arteries** supplying the blood to intestines, pancreas, spleen and liver (Fig. 4.6-10) include:
 - *Coeliac trunk* is about 1 cm long and after arising from the abdominal aorta it divides into three main branches the *left gastric artery, hepatic artery and splenic artery,*
 - *Superior mesenteric artery* and
 - *Inferior mesenteric artery.*
- **Hepatic portal system** is formed by the veins draining blood from the abdominal part of the GIT. The veins comprising the hepatic portal system are shown in Fig. 4.6-11. All these veins end in the *portal vein*. The portal vein supplies the blood collected from GIT to the liver by its right and left branches.
- **Hepatic veins** are terminal parts of an elaborate venous tree that permeates the liver. The hepatic veins emerging from the liver tissue end in the inferior vena cava.

FIGURE 4.6-10 Splanchnic circulation.

FIGURE 4.6-11 Tributaries of portal vein.

Splanchnic circulation: Characteristic features

- During rest, the abdominal GIT, viscera and liver receive about 1500 ml blood per minute (about 30% of cardiac output) via coeliac, superior mesenteric and inferior mesenteric arteries (Fig. 4.6-10).
- If the entire GIT becomes simultaneously active, the splanchnic blood flow would have increased to about 4.0 L/min. However, since during digestion and absorption, the GIT is sequentially activated, the maximum circulation is about 3.0 L/min.
- The unique feature of the splanchnic circulation is that the venous blood from GIT viscera is not directly carried to the heart through systemic veins, but is carried to the liver forming hepatic portal system.

For the purpose of discussion the splanchnic circulation is considered to consist of three parts:

- Intestinal (mesenteric) circulation,
- Splenic circulation and
- Hepatic circulation.

Intestinal circulation

Intestinal or mesenteric circulation

is constituted by the blood supplied to the intestines and pancreas (about 100 ml/min) by a series of parallel circulations via the branches of superior and inferior mesenteric arteries.

Extensive anastomoses

between the vessels constituting mesenteric circulation, but blockage of a large intestinal artery still leads to infarction of the below.

The blood flow to intestinal mucosa

is much more (about 5 times) than that of rest of the intestinal wall ([Table 4.6-3](#)).

TABLE 4.6-3

Blood Flow to Intestines (in ml/100 g/min)

Structure	At rest	During maximum metabolic activity
• Intestinal mucosa	50–60	300–400
• Rest of the intestinal wall	10	40

Capillary filtration coefficient

for mucosal capillaries is about 10 times than that for skeletal muscles, that is why the mucosal vessels have an enormous capillary surface available for absorption and pore bound secretion.

During metabolic activity

the blood flow to GIT increases ([Table 4.6-3](#)) due to vagal activity (in the stomach), humoral activity, the local release of bradykinin from the mucosal glands and metabolites in the intestinal tract itself.

- *Countercurrent system* exists in the capillaries and venules in a villus, i.e. the direction of blood flow in the capillaries and venules in a villus is opposite to that in the main arteriole ([Fig. 4.6-12](#)). This system has

both advantages and disadvantages.

- *Advantages of countercurrent system* of villus blood vessels shows that it slows down the entrance of rapidly absorbed solutes into the blood as explained below:

The lipid-soluble substances when carried in the *venous descending limb* of vascular hair pin loop pass by diffusion across into the *ascending arterial limb* because of a concentration gradient (Fig. 4.6-12A). In this way, high concentration of absorbed substances reaches in outer parts of the villi and then these substances leave relatively slowly via the venous blood.

- *Disadvantage of countercurrent system* of villus blood vessels is that it decreases pO_2 at the tip of villi as explained.

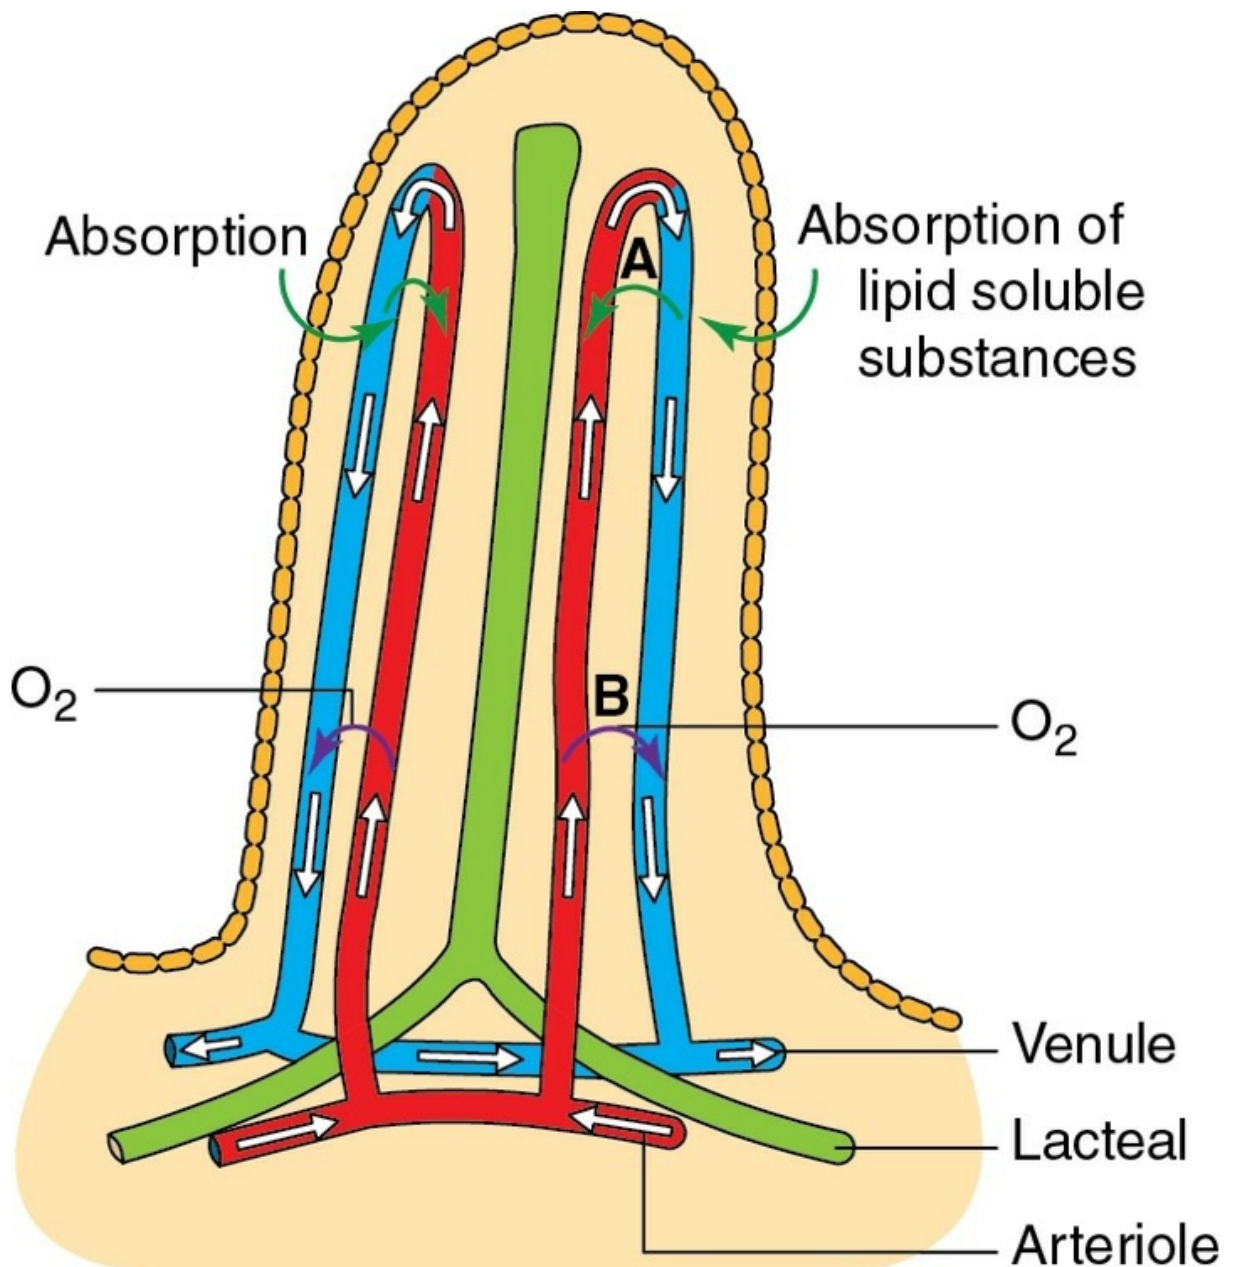

FIGURE 4.6-12 Countercurrent system of villus blood vessels depicting transfer of lipid-soluble substances from venous limb to arterial limb (**A**) and that of O_2 from arterial to venous limb (**B**).

This system permits diffusion of O_2 from the ascending arterial limb of villi into the descending venous limb (Fig. 4.6-12B). In this way, at low flow rates substantial amount of O_2 from the arterioles is shifted to venules near the base of villi resulting in decrease in O_2 supply to the mucosal cells at the tips of villi. When intestinal blood flow is very low, the transfer of O_2 from arterioles to venules is exaggerated and may cause extensive necrosis of intestinal villi.

Regulation of intestinal circulation

1. **Local chemical control (functional hyperaemia).** During increased intestinal activity, i.e. after food ingestion there occurs a marked increase in the intestinal blood flow (*functional hyperaemia*). It is proposed that *gastrin, secretin, bradykinin and cholecystinin*, which are secreted from mucosal glands during food ingestion, cause local vasodilation and augment the blood flow.

The absorption of digested food is also associated with increased intestinal blood flow. The principal mediators of mesenteric hyperaemia present in the digested food are glucose and fatty acids.

- As the digestive and reabsorptive process proceed in different parts of the alimentary canal in a sequential manner the blood flow also increases in the same pattern and so the maximum blood flow during these activities is about 3 L/min.

2. **Neural regulation.** The splanchnic vessels are richly innervated by noradrenergic sympathetic nerve fibres. These nerve fibres have mild tonic discharge, which causes a moderate vascular resistance in the splanchnic blood vessels. The direct effect of sympathetic stimulation is intense vasoconstriction of the arterioles leading to decrease blood flow. After few minutes of the vasoconstriction, blood flow returns back to normal by 'autoregulatory escape' phenomenon. Autoregulatory escape is the local metabolic vasodilator mechanism elicited by ischemia that overrides sympathetic vasoconstriction. Therefore, sympathectomy causes only 25% increase in intestinal blood flow.

The main role of neural regulation of splanchnic vessels is in time of cardiovascular crisis, e.g. sudden hypotension, when more blood is to be transferred from the splanchnic vessels to systemic circulation. Under such situation, the splanchnic vasomotor nerves participate in the baroreceptor-mediated reflexes and their stimulation brings about a rise in systemic blood pressure. The main reason for this rise is not an increase in peripheral resistance but venoconstriction, which squeezes out blood from mesenteric circulation. This role of neural mechanism includes all the splanchnic vessels, viz. intestinal, splenic and hepatic. The spleen and liver are major reservoirs of the blood. In this way, during hours of crisis more blood is available to heart muscles and the

brain than to the intestine, spleen and liver.

3. **Autoregulation**, i.e. ability to adjust its vascular resistance and maintenance of relatively constant blood flow over a wide range of arterial blood pressure is well developed in mesenteric vessels like that in vessels of kidneys, brain, heart and skeletal muscles. The main mechanism responsible for autoregulation in mesenteric vessels is *metabolic*, though the *myogenic* mechanism may also play some role. The principal metabolic mediator here is *adenosine*. However, potassium ions and altered osmolality may also contribute to autoregulation.

Splenic circulation

Splenic artery,

which is branch of coeliac trunk, supplies about 200 ml of blood/min to the spleen during rest via its splenic branches, which enter the hilum of the spleen.

Spleen serves as reservoir of blood.

In spleen, two structures are involved in storage of blood, namely splenic venous sinuses and splenic pulp. The small arteries and arterioles open directly into the splenic venous sinuses (Fig. 4.6-13). Due to dilation of venous sinuses, a large amount of blood is stored in spleen and the spleen distends. The capillaries of the splenic pulp are highly permeable. So, lot of blood cells pass through the capillary membrane and are stored in the pulp.

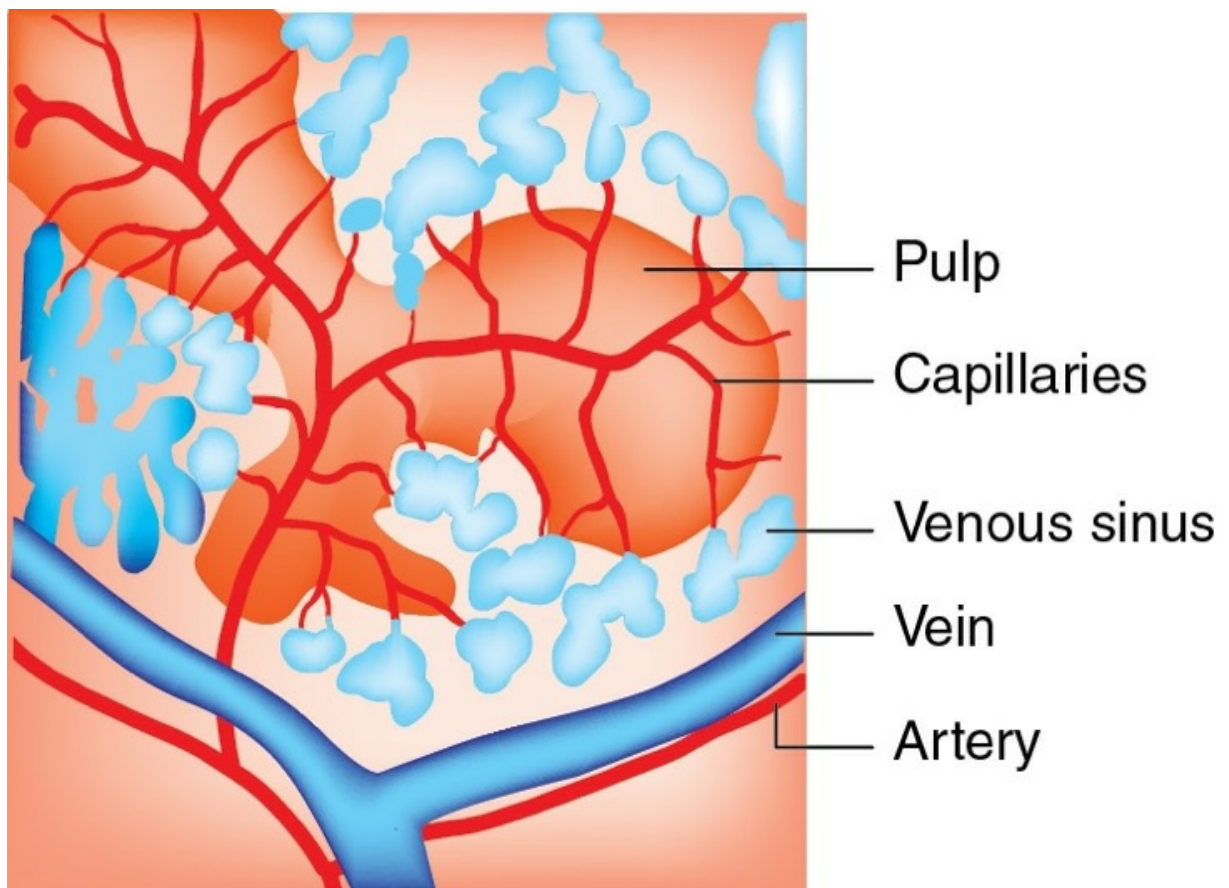

FIGURE 4.6-13 Storage of blood in splenic venous sinuses and splenic pulp.

The constriction of splenic venous sinuses

by sympathetic stimulation causes release of blood into the circulation.

Regulation of splenic blood flow

Regulation of splenic blood flow is similar to that of intestinal blood flow. As mentioned earlier, the main role of neural control of splanchnic vessels is to transfer blood to circulation during hours of crisis. The spleen in the dogs and other carnivores contain lot of smooth muscles in its capsule, which contract strongly on sympathetic stimulation and discharge lot of blood into the circulation. This function of spleen is quantitatively not important in human. However, reservoir function of the whole visceral circulation plays a vital role in this mechanism.

Hepatic circulation

Characteristic features of hepatic circulation

- **Source of blood.**

Liver receives about 1500 ml blood/min from two sources:

- **Hepatic artery**

which is a branch of coeliac trunk supplies about 20–25% (300–400 ml) of the total blood which caters to the metabolic requirements of the liver tissue.

- **Portal vein**

which collects blood from the mesenteric and splenic vascular bed supplies about 75–80% (1100–1200 ml/min) of the total blood.

The hepatic and portal blood streams meet in the sinusoids.

Functional unit of liver

The functional unit of liver is *acinus*. The acini have been likened to grapes or berries, each on a vascular stem. There are about 10000 acini in human liver. Thus, each acinus is at the end of vascular stalk containing terminal branches of portal vein, hepatic arteries and bile ducts (Fig. 4.6-14). Blood flows from these terminal vessels into the sinusoids, which represent the capillary network of the liver. The sinusoids radiate toward the periphery of acinus, where they drain into the terminal branches of hepatic veins. Blood from these terminal hepatic venules drains into progressively larger branches of the hepatic veins, which are tributaries of the inferior vena cava. For details, see page 616.

FIGURE 4.6-14 Concept of acinus as functional unit of liver.

Zones of acinus.

Each acinus can be considered to have three zones: 1, 2 and 3 based on the pattern of vessels in the acinus described above. The blood supply to different zones of acinus is:

- **Zone 1** refers to the central portion of acinus immediately surrounding the terminal hepatic arteriole and terminal portal venule. This zone is *well oxygenated*. Enzymes involved in oxidative metabolism and gluconeogenesis predominate here.
- **Zone 2**, i.e. the intermediate zone which is present in between zone 1 and 3 is *moderately well oxygenated*. It contains a mixed complement of enzymes.
- **Zone 3** refers to most peripheral part of the acinus. It is least well oxygenated and most susceptible to anoxic injury. It is rich in enzymes involved in glycolysis, lipid and drug metabolism.

Hepatic artery versus portal vein blood flow

Pressure gradients and hepatic arterial and venous blood flow. The mean pressure in the hepatic artery branches that converge on the sinusoids is about 90 mmHg and that in the terminal portal venules

which converge on the sinusoids is 10 mmHg. The hepatic venous pressure is about 5 mmHg (Fig. 4.6-15). From the above pressures, one would expect that sinusoid pressure to be very high. However, the sinusoidal pressure is only 10 mmHg. This is because of the fact that due to high presinusoidal resistance in hepatic arterial tree there is a marked pressure drop along the hepatic arterioles. The pressure drop in the hepatic arterial tree is adjusted so that there is an *inverse relationship between hepatic arterial and portal venous blood flow*. That is when portal venous blood flow is low the hepatic arterial blood flow increases and when the portal venous blood flow is high the hepatic arterial blood flow decreases. This inverse relationship may be maintained in part by the rate at which adenosine is removed from the region around the arterioles. According to this hypothesis, adenosine is produced by metabolism at a constant rate. When portal flow is reduced, it is washed away more slowly, and local accumulation of adenosine dilates the terminal arterioles increasing the hepatic arterial blood flow and vice versa. Thus, the hepatic arteriolar blood flow has *autoregulation* but the portal vein blood flow system does not have autoregulation.

FIGURE 4.6-15 Pressure gradient across the blood vessels of an acinus.

Important Note

- As portal pressures do not increase linearly with portal blood flow, therefore, is important to prevent fluid loss through highly permeable

liver sinusoids. Ascitis in cirrhosis of liver occurs because the parenchymal cells get destroyed and replaced with fibrous tissue that greatly increases resistance to blood flow. High hepatic vascular pressure can cause fluid transudation into the peritoneal cavity from hepatic and portal capillaries (ascitis).

Oxygen supply to liver. The hepatic arterial flow contributes 30% and rest of the 70% of the O_2 used by the liver is contributed by the portal blood flow. This is because of the fact that about 80% of the blood entering the liver is from portal venous system and 20% is from hepatic arterial system. During periods of activity, i.e. ingestion and digestion there is marked increase of portal blood flow (functional hyperaemia) which compensates for the reduced content of O_2 per 100 ml of blood.

Though the rate of O_2 delivery to the liver is varied, it tends to maintain a constant O_2 consumption. This is made possible because of two reasons: firstly the extraction of O_2 from the hepatic blood is very efficient, and secondly liver has the capability to compensate by an appropriate change in the fraction of O_2 extracted from the blood. This extraction is facilitated by the distance between the presinusoidal vessels at the centre of acinus and postsinusoidal vessels at the periphery of acinus. In other words, the substantial distance between these types of vessels prevents a countercurrent exchange of O_2 as seen in intestinal villi.

Filtration across hepatic sinusoids

The hepatic sinusoids are perforated and show large fenestrations; and therefore, allow a free exchange of macromolecules across their wall compared with capillaries elsewhere in the body. Because of this reason, the liver lymph has very high protein contents (6 g/100 ml), i.e. similar to that of plasma while the lymph from other places has low protein contents (2 g/100 ml).

Regulation of hepatic circulation

1. Autoregulation.

The hepatic arterial blood flow is autoregulated and the portal blood flow is not autoregulated. As described above, the hepatic arterial blood flow changes reciprocally with portal blood flow and that the adenosine is involved in this adjustment.

2. Functional hyperaemia

of the intestinal tract after meals is associated with increased portal blood flow to liver.

3. Neural regulation.

The hepatic vessels are innervated by the noradrenergic sympathetic nerve fibres via T₃ to T₁₁ roots and splanchnic nerves and the vasoconstrictor fibres reach the liver from hepatic plexus. There is no known vasodilator innervation to the liver vasculature. The liver serves as a blood reservoir, storing about 400 ml of blood in its sinusoids. The sympathetic nerves constrict the presinusoidal resistance vessels in the portal venous system and hepatic arterial system. As described in the neural control of intestinal blood flow, the neural effects on capacitance vessels are more important. Sympathetic stimulation causes a marked reduction in the capacitance of the portal system and other splanchnic capacitance vessels, and mobilizes about 1 L of blood towards the heart in less than a minute. In severe shock, hepatic blood flow gets reduced markedly and may produce patchy necrosis of the liver.

- Nonprogressive shock
- Progressive shock
 - Refractory shock
 - Physiology in treatment of shock
 - Heart failure

Cardiovascular homeostasis in health

Cardiovascular homeostasis in health refers to the compensatory adjustments of the cardiovascular system (CVS) to challenges faced by the circulation in everyday life. The common situations during which cardiovascular adjustment are required in day to day life include:

- Gravitational changes,
- Intrathoracic pressure changes and
- Exercise.

Cardiovascular adjustments during gravitational changes

Gravitational changes occur under following conditions in life:

- Posture change from lying to standing,
- Prolonged quiet standing,
- Gravity acceleration (positive g), deceleration (negative g) and zero gravity (zero g).

Adjustments during posture change from lying to standing

When posture is changed from lying (recumbent) to standing (erect) the haemodynamic changes occur as a result of the effect of gravity on the blood column which tends to reduce the cardiac output and blood pressure. However, since in humans the compensatory mechanisms are so well developed that in normal persons no effect is felt on posture changes in day-to-day life. The sequence of events which occurs during change in posture from lying to standing is explained below.

In standing position, due to *hydrostatic (gravitational) effect of blood column*, for every centimetre below or above the heart level, the pressure increases or decreases by 0.77 mmHg, respectively. Therefore, in normal adults, the blood pressure at the level of feet (about 100 cm below heart level) in both arteries and veins is increased approximately by 80 mmHg. Thus, the mean arterial pressure and venous pressure which are 90 and 10 mmHg, respectively, in supine position will change to 170 and 90 mmHg, respectively, on standing.

Increased intraluminal pressure has no effect on thick-walled arteries, but the thin-walled veins distend and accommodate more blood. If the individual does not move, the *venous pooling* of 300–500 ml of blood occurs in the lower extremities.

Venous pooling results in decreased venous return and so the cardiac output and thence the blood pressure is also reduced.

A drop in the blood pressure in carotid sinus and aortic arch within seconds triggers the *baroreceptor-mediated compensatory mechanism* which causes the following changes.

- **Heart rate** is increased by 5–10 beats/min.
- **Force of cardiac contraction** is increased leading to increase in stroke volume and cardiac output.
- **Peripheral resistance** is increased due to arteriolar constriction in the cutaneous, renal and splanchnic circulation. Increase in peripheral resistance increases the diastolic pressure.
- **Venoconstriction** in the body transfers blood from the capacitance vessels towards the heart increasing the venous return.
- **Increased secretion of renin and aldosterone** also helps in normalization of blood pressure.

In spite of the above mentioned compensatory changes, the stroke volume and cardiac output in standing posture are about 25% less than in supine position. However, due to 25% increase in the total peripheral resistance, the blood pressure becomes almost normal.

The above events are summarized in Fig. 4.7-1.

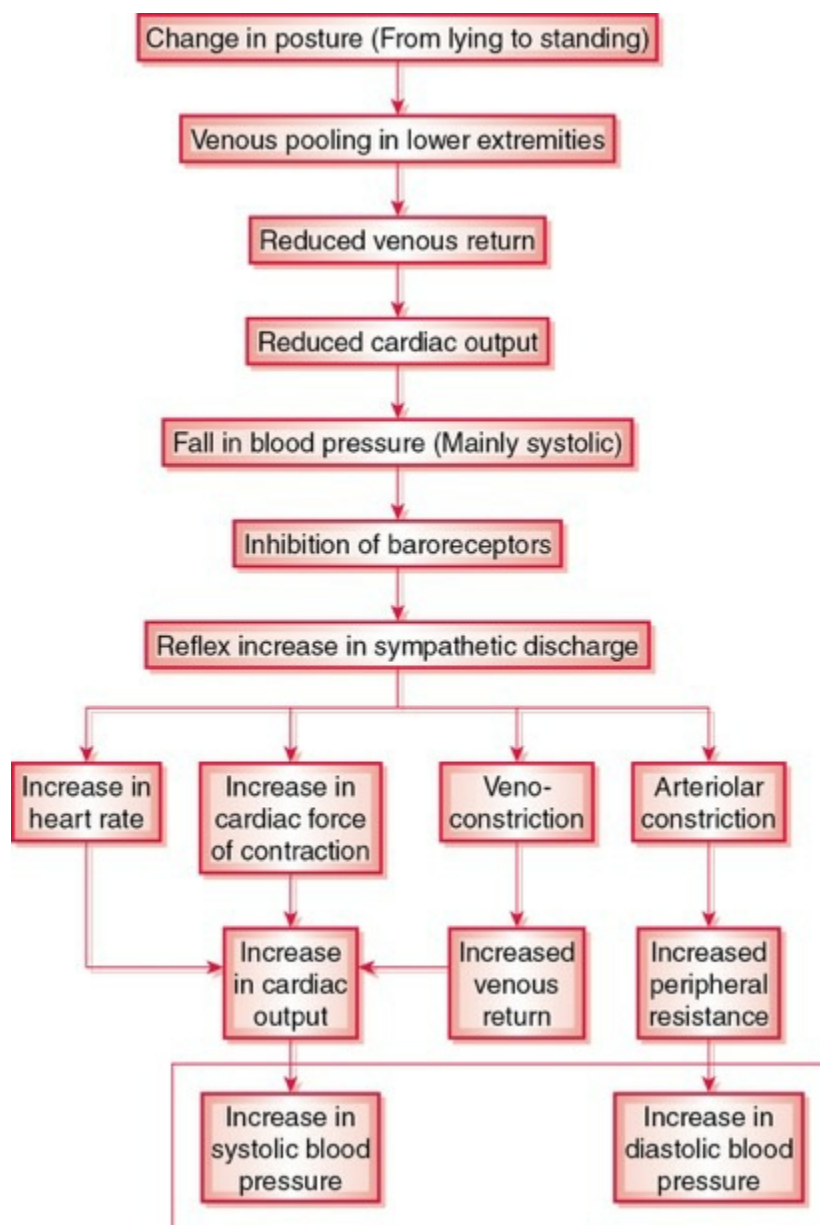

FIGURE 4.7-1 Summary of events maintaining normal blood pressure during change of posture from lying to standing.

Net effects on CVS of rising from the supine to upright position

Average net effects which occur on the CVS of rising from supine to upright position after the compensatory mechanism are

- *Central venous pressure* is decreased slightly (3 mmHg).
- *Heart rate* is increased by 25%.
- *Abdominal and limb flow* is decreased by 25%.
- *Stroke volume* is decreased by 40%.
- *Cardiac output* is decreased by 25%.
- *Total peripheral resistance* is increased by 25%.
- *Systolic blood pressure* is slightly reduced due to fall in stroke volume.
- *Diastolic blood pressure* is slightly increased due to increased total peripheral resistance.
- *Pulse pressure* (systolic BP – diastolic BP) is reduced.
- *Mean arterial pressure* is nearly unchanged.

Maintenance of cerebral blood flow

Cerebral blood flow in standing position is maintained by certain additional compensatory changes:

- ***Decrease in jugular venous pressure (JVP)*** to 5 mmHg due to gravity compensates for the drop in arterial pressure at head level to 20–40 mmHg by reducing the drop in perfusion pressure (arterial pressure minus venous pressure).
- ***Fall in intracranial pressure*** due to fall in venous pressure reduces cerebral vascular resistance and thus facilitates cerebral blood flow.
- ***Increased $p\text{CO}_2$ and decreased $p\text{O}_2$ and decreased $p\text{H}$*** in brain tissues occurring due to decreased cerebral blood flow causes vasodilation, improving the blood flow.

Because of the operation of the above-mentioned *autoregulatory mechanisms*, the cerebral blood flow decreases only 20% on standing. In addition, the amount of O_2 extracted per unit of blood increases, and the net effect is that cerebral O_2 consumption is about the same in supine and erect positions.

The above events are summarized in Fig. 4.7-2.

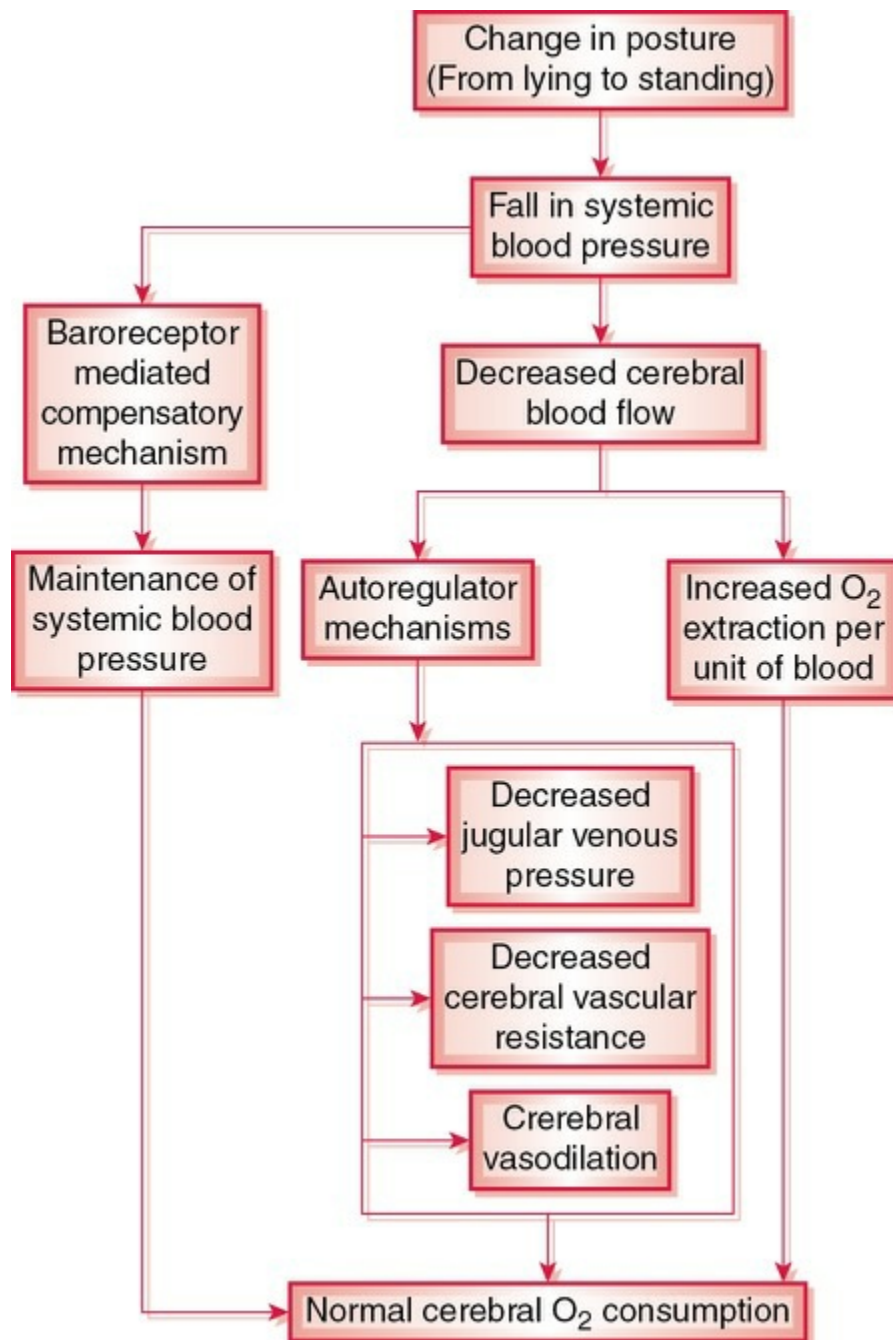

FIGURE 4.7-2 Summary of events maintaining normal cerebral O₂ consumption in standing posture.

For details see page 380

Changes during prolonged quiet standing

When one changes posture from lying to standing, certain cardiovascular adjustments occur (described above) which maintain the almost normal blood pressure and normal blood flow to various organs of the body.

The prolonged standing presents an additional problem due to increasing interstitial fluid volume in the lower extremities. If the person keeps on moving, the operation of 'muscle pump' (see page 289) keeps the venous pressure below 30 mmHg at the feet level and maintains adequate venous return. However, on prolonged quiet standing (a situation particularly met with military or police personnel, i.e. standing in attention for long periods), along with the venous pooling, the fluid begins to accumulate in the interstitial spaces because of increased hydrostatic pressure in the capillaries. The cardiac output is decreased due to decreased venous return. A stage may come when cerebral blood flow decreases to less than about 60% and symptoms of cerebral ischaemia develop. The individual may faint and fall down.

The fainting, in a sense, is also a homeostatic mechanism, because falling to horizontal position promptly restores venous return, cardiac output and cerebral blood flow to adequate levels.

Postural hypotension

In postural hypotension or *orthostatic hypotension* there occurs a sudden fall in blood pressure on changing posture from lying to erect, which causes symptoms of cerebral ischaemia. The individual experiences transient blurring of vision, dizziness or even fainting. It is diagnosed by recording blood pressure in lying and standing postures. A decrease in systolic blood pressure by 30 mmHg or more on standing from supine position is diagnostic.

Pathophysiology

Postural hypotension develops in individuals in whom the cardiovascular compensatory mechanism (described above) which maintains normal blood pressure and adequate cerebral blood flow is very slow to develop.

Causes of postural hypotension

1. Decreased blood volume.

The effects of gravity on the circulation in humans depend in part upon the blood volume. When the blood volume is low, the compensatory mechanisms are slow to develop and the individual may suffer from postural hypotension.

2. Sympatholytic drugs.

Postural hypotension is common in patients receiving sympatholytic drugs.

3. Dysfunctions of sympathetic nervous system

are obviously associated with postural hypotension. Dysfunction of sympathetic nervous system may be grouped as

- i. Surgical sympathectomy
- ii. Autonomic neuropathy occurring in diseases such as diabetes mellitus, syphilis and Parkinson's disease
- iii. Primary autonomic failure seen in following conditions:
 - Bradbury–Eggleston syndrome (idiopathic orthostatic hypotension),
 - Shy–Drager syndrome (multiple system atrophy),
 - Riley–Day syndrome (familial dysautonomia),
 - Congenital deficiency of dopamine β -hydroxylase with little or no production of norepinephrine and epinephrine.

Note.

Patients with *primary hyperaldosteronism* also have abnormal baroreceptor reflexes. However, these patients generally do not have postural hypotension, because their blood volume is expanded sufficiently to maintain cardiac output in spite of the changes in posture.

Treatment

Mineralocorticoids are used to treat patients with postural hypotension. Of course, wherever possible, the causative disease should be ameliorated.

Cardiovascular effects of gravity acceleration and deceleration

When the body moves upwards,

the force due to acceleration acting in the long axis of the body from head to foot is called *positive g* (*g* represents the unit of gravity force), and 1 *g* refers to the force of gravity on earth's surface.

When the body moves downwards from height towards the earth, the force due to deceleration acting in the long axis of the body from foot to head is called *negative g*.

Positive g and negative g effects are experienced during the take off and landing of space rockets, landing of airplanes, parachute jumping and in elevators (lifts) while going up and down.

- Since the 'positive *g* and negative *g*' effects are experienced when there is a acceleration or deceleration along the long axis of the body, the astronauts avoid these effects by positioning themselves perpendicular to the direction of *g*, i.e. in a *chest-to-back direction*.

Effect of positive *g*

The effects of 'positive *g*' on the CVS are due to throwing down of blood in lower part of the body and similar to those occurring from change of posture from lying to standing, but they are multiplied depending upon the speed of acceleration.

At acceleration less than 5 *g*

the compensatory mechanisms (described in effect of posture change) are able to maintain vital cardiovascular status. *Cardiac output* is maintained for a time when blood is drawn from the pulmonary venous reservoir and as the force of cardiac contraction is increased, *cerebral circulation* is protected due to associated fall in the JVP and intracranial pressure.

At acceleration more than 5 *g*

with body in long axis, the pressure in the veins in the lower limbs rises to over 450 mmHg. The consequent passive dilatation of veins of the lower limbs retains so much blood that the venous return and therefore, cardiac output is markedly reduced. Under such a situation, vision fails (*blackout*) in about 5 s and unconsciousness almost hits immediately thereafter.

Antigravity suit

or the *g*-suit is used by the astronauts to effectively cushion the effects of gravitational force. The '*g*-suit' is a double walled pressure suit

containing water or compressed air. When there is 'positive g', there is a tendency of venous pooling and simultaneously the water in the g-suit also rushes to the lower parts. The g-suit is regulated in such a way that it compresses the abdomen and legs with a force proportionate to the positive g. This decreases venous pooling and helps to maintain venous return.

Effect of negative g

The effects of 'negative g' on the CVS are due to the rushing up of blood towards head when the body suddenly moves down. As a result of accumulation of blood in the head and neck, following changes occur:

- *Cardiac output* is increased due to general increase in venous return. Most of the cardiac output, however, moves towards upper parts of the body.
- *Cerebral arterial pressure* is increased markedly. In spite of the great increase in cerebral arterial pressure, the vessels in the brain do not rupture, because there occurs a corresponding *increase in intracranial pressure and their walls are supported*. In other words, the CSF acts like a g-suit.
- Blood vessels of head and neck show intense congestion.
- *Ecchymosis* appears around the eyes.
- *Severe throbbing headache, pain, and eventually*
- *Mental confusion* (red out).

Effect of zero gravity

The 'zero gravity' situation occurs when the astronauts in a spacecraft go out of the earth's gravitational effect, e.g. during orbital flights to other planets. The absence of gravity leads to:

- Weightlessness,
- Movements of the body become effortless,
- Absence of hydrostatic pressure on the blood column.

A data of 14 months stay in the zero gravity zone are available, which

shows the following documental effects.

Effects on the CVS

- *Transient postural hypotension* has been present after return to earth from space flights, and full readaptation to normal gravity has been reported to occur in 4 weeks.
- *Some atrophy of myocardium* is reported to occur, because of the fact that heart did not have to function for increases in cardiac output required in everyday life as on earth. *More severe disuse atrophy of myocardium* is speculated in prolonged period of weightlessness during future trips to planets.

Other effects of zero gravity

- *Flaccidity and atrophy of skeletal muscles* to some extent occurs since, due to zero gravity the muscular effect is much reduced when objects to be moved are weightless and the normal proprioceptive input is decreased. A programme of regular exercises against resistance, e.g. pushing against a wall of spacecraft or stretching a heavy rubber band may decrease the muscle atrophy.
- *Space motion sickness*, (the nausea, vomiting and vertigo) develops in astronauts, when they are first exposed to 'zero gravity' and often wears off after a few days of space flight. It can occur with re-entering in the gravity. It occurs due to vestibular apparatus dysfunctioning.
- *Changes in the blood* noted are:
 - Loss of plasma volume, probably because of head ward shift of body fluids, with subsequent diuresis,
 - Loss of red cell mass and
 - Alterations in the plasma lymphocytes.
- *Bone mineral* is lost steadily with increased Ca^{2+} excretion. A loss of body Ca^{2+} is equivalent to 0.4% of the total body Ca^{2+} per month initially, but later tapers off during prolonged space flight. Further, a

high-calcium diet helps to overcome this problem.

- *Psychological problems* associated with isolation and monotony of prolonged space flight are also a matter of concern.

Cardiovascular adjustments during intrathoracic pressure changes

Intrathoracic pressure changes are not uncommon in everyday life. Depending upon the mechanism of intrathoracic pressure changes, the activities responsible for these may be grouped into Valsalva manoeuvre and Muller's manoeuvre.

Valsalva manoeuvre

Valsalva manoeuvre refers to a forced expiration against a closed glottis. The common everyday activities in which Valsalva manoeuvre effect is seen on the intrathoracic pressure are straining during defecation, initial phase of coughing and straining during parturition.

Intrathoracic pressure changes during Valsalva manoeuvre and their effects on CVS

The changes exerted on the CVS due to a sudden and sharp rise in intrathoracic pressure occurring due to Valsalva manoeuvre effect can be described in four phases (Fig. 4.7-3).

- *Phase 1* is characterized by a transient rise in the arterial pressure. It coincides with compression of the aorta due to sudden increase in the intrathoracic pressure.
- *Phase 2*, which follows phase 1 is characterized by:
 - A fall in arterial pressure which plateaus after few seconds owing to reflex vasoconstriction.
 - Heart rate usually increases slightly.

Mechanism. The phase 2 changes in CVS are initiated by a decrease in venous return which occurs due to increase in intrathoracic pressure changes. The sequence of events which follow decreased cardiac

output is depicted in [Fig. 4.7-3](#).

- *Phase 3* is characterized by a transient fall in blood pressure which follows 1–2 s after release of the strain. It coincides with release of pressure compressing the aorta due to decreased intrathoracic pressure. In other words, events in phase 3 are just reverse of the events in phase 1.
- *Phase 4* is characterized by:
 - *Increase in arterial blood pressure* above the resting level within 10 s. This overshoot of blood pressure is due to the lingering effect of vasoconstriction induced during phase 2. The blood pressure returns to resting level after about 1.5 min of strain release.
 - *Slowing of heart rate* occurs due to baroreceptor-mediated vagal stimulation in response to overshoot of blood pressure.

FIGURE 4.7-3 Response to Valsalva manoeuvre in a normal man: **A**, intrathoracic pressure changes; and **B**, arterial pressure changes (in phase 1, 2, 3, 4).

Clinical application of valsalva manoeuvre

In clinical practice, Valsalva manoeuvre is employed for testing of baroreceptor reflexes and also as a test for autonomic insufficiency where the vagal response may be impaired.

- **Procedure.** The subject is asked to blow for about 15 s into a mouthpiece which is attached to a sphygmomanometer at a pressure of 40 mmHg. A continuous recording of ECG is made during and after this manoeuvre.
- **Interpretation of results.** Results of this test are interpreted in the form of *Valsalva ratio*. Valsalva ratio is the ratio of the longest RR interval (noted within 20 beats of the end of Valsalva manoeuvre) to the

shortest RR interval (noted during the Valsalva manoeuvre). The normal Valsalva ratio is >1.5 , but in autonomic insufficiency, the Valsalva ratio is less than 1.11.

Muller's manoeuvre

Muller's manoeuvre refers to forced inspiration against closed glottis. It is just the reverse of the Valsalva manoeuvre, i.e. it reduces the intrathoracic pressure (up to 80 mmHg). Therefore, the cardiovascular changes occurring during Muller's manoeuvre are exactly opposite to those which occur during Valsalva manoeuvre described above.

Cardiovascular adjustments during muscular exercise

Severe muscular exercise is the most stressful physiological condition that the cardiovascular homeostasis mechanisms face in everyday life. In addition to CVS adjustments, respiratory and other adjustments also occur in the body, so they are comprehensively discussed in [Chapter 12.1](#) on 'Physiology of exercise' (see page 1209).

Cardiovascular homeostasis in diseases

Cardiovascular homeostasis mechanism operates in almost all cardiorespiratory and many other multiorgan diseases. The most important conditions which need special description are:

- Circulatory shock and
- Cardiac failure.

Circulatory shock

Circulatory shock or simply called as shock is a syndrome (collection of different entities that share certain common features) characterized by *serious reduction of tissue perfusion* with a relatively or absolutely inadequate cardiac output. In other words, the shock is a condition characterized by inadequate delivery of oxygen and nutrients to critical organs such as heart, brain, liver, kidneys and gastrointestinal tract.

Types and causes of shock

Depending upon the cause of inadequacy of cardiac output (relative or absolute) the circulatory shock may be of the following types:

- I. Hypovolaemic shock,
- II. Low-resistance or distributive or vasogenic shock,
- III. Cardiogenic shock and
- IV. Obstructive shock.

I. Hypovolaemic shock

Hypovolaemic shock also known as cold shock is caused by a low blood volume resulting in decreased cardiac output.

Causes.

Depending on the causes, the hypovolaemic shock may be of following types:

1. *Haemorrhagic shock* occurs as a result of external or internal blood loss caused by ruptured vessels.
2. *Dehydration shock*. Fluid loss, when insufficient amount, can dehydrate the body and reduce the circulating blood volume. Fluid loss can occur from
 - Gastrointestinal tract (GIT) in diarrhoea or vomiting.
 - *Kidney* in diabetes mellitus, diabetes insipidus or excessive use of diuretics.
 - *Skin* in burns, exudative lesions and sweating. In burns, large part of the skin gets denuded and large amount of plasma is exuded through the exposed parts. Hypovolaemia due to plasma loss is a common complication of severe burns (burns shock).
3. *Traumatic shock* is a special type of hypovolaemic shock in which there is associated neurogenic shock caused by severe pain which

inhibits the vasomotor centre (VMC).

II. Low-resistance or distributive or vasogenic shock

Low-resistance or distributive or vasogenic shock occurs when neural reflexes or toxic substances cause excessive vasodilation within the vascular system. Due to vasodilation, the size of capacitance vessels is increased and thus the cardiac output is decreased in spite of normal blood volume. Low-resistance shock is also called *warm shock* because skin is warm and not cold and moist as it is in hypovolaemic shock.

Causes.

Depending upon the causes, the low-resistance shock is of the following types:

1. *Neurogenic shock* occurs due to two types of nervous effects:

i. *Marked reduction in sympathetic vasomotor tone* is responsible for most cases of neurogenic shock as seen in:

- Deep general anaesthesia,
- Spinal anaesthesia,
- Brain damage, prolonged ischaemia causes inactivation of VMC (Note: Short periods of medullary ischaemia increase vasomotor activity),
- Effects of antihypertensive drugs and
- Postural syncope.

ii. *Pronounced increased in the vagal tone* of the heart is responsible for neurogenic shock in some cases, as seen in:

- Vasovagal syncope or emotional fainting.

2. **Anaphylactic shock.** Anaphylaxis refers to an acute allergic reaction. Large quantities of histamine and histamine-like substances released in allergic reaction cause widespread and marked *vasodilation* reducing peripheral resistance. Also, there is a marked *increase in capillary permeability* leading to fluid loss and adding hypovolaemic element to the low-resistance shock.

3. **Septicaemic shock.** Septicaemia is a condition in which bacteria circulate and multiply in the blood and form toxic products and cause high fever. Septicaemia may occur in conditions like acute peritonitis, perforation of bowel, strangulated bowel, puerperal sepsis, etc. Septicaemic shock develops due to the following effects of bacteria and toxic products:

- Marked vasodilatation due to peripheral arteriolar paralysis,
- Sludging of blood, presumably caused by red cell agglutination in response to degenerating tissues and
- Disseminated intravascular coagulation (DIC).

4. **Endotoxic shock** refers to the shock produced by endotoxins released by gram-negative bacteria. Endotoxins produce shock due to their following effects:

- Marked vasodilation reducing peripheral resistance,
- Depressing myocardial contractility reducing cardiac output and
- Increasing capillary permeability and causing hypovolaemia.

III. Cardiogenic shock

Cardiogenic shock occurs due to decreased pumping ability of the heart because of some cardiac abnormality. Severe depression of the systolic cardiac performance is the key factor in causing this type of shock. Since the heart is not able to pump out all the venous return, there occurs congestion of the lungs and viscera and that is why it is also called *congested shock*.

Causes

of cardiogenic shock are:

1. *Myocardial* infarction involving 40% or more of the left ventricular myocardium is the commonest cause.

2. *Other causes are:*

- Cardiac arrhythmias,
- Congestive heart failure,
- Toxic states of heart and
- Severe valvular dysfunctions.

IV. Obstructive shock

Obstructive shock or more precise to be, the extracardiac obstructive shock occurs due to impairment of ventricular filling during diastole due to some external pressure on the heart. Due to decreased ventricular filling, the stroke volume and hence the cardiac output is decreased causing circulatory shock.

Causes

of obstructive effusion shock are:

1. Pericardial cardiac tamponade, i.e. bleeding into the pericardium with external pressure on the heart,
2. Tension pneumothorax,
3. Constrictive pericarditis,

4. Pulmonary embolism and
5. Post end-expiratory pressure respiration.

Stages and clinical features of shock

Stages and clinical features of all types of shock are similar with minor differences. However, since the haemorrhagic shock is of more common, the discussion in this section will be centred on it. Depending upon the severity, the circulatory shock can be divided into three stages:

- First stage or nonprogressive shock,
- Second stage or progressive shock and
- Third stage or refractory (irreversible) shock.

I. First stage of shock or nonprogressive shock

Nonprogressive shock also known as *compensated shock* or initial stage of shock occurs when there is a moderate reduction in cardiac output secondary to fluid loss or venous pooling or negative inotropic effect on the heart depending upon the type of shock.

Hypovolaemic shock due to acute blood loss, in other words, the *haemorrhagic shock*, occurs when at least 10% to 15% of total blood volume is lost. Thus, about 10% of the total blood volume may be lost without any significant effect.

Compensatory mechanisms of rapid onset (short-term mechanisms) immediately set into motion following the acute loss of blood and try to maintain the blood flow to vital organs in spite of reduced cardiac output. These mechanisms are effective in immediately controlling the blood pressure in nonprogressive shock and are followed by long-term compensatory mechanisms which restore the circulatory plasma proteins and red cell mass in 4–8 weeks. The compensatory mechanisms are described below in detail.

A. Rapid compensatory mechanisms (neural mechanism).

Rapid or the so-called short-term control mechanisms primarily include the following three nervous reflexes.

1. *Baroreceptor reflex*. When the blood pressure is decreased there occurs decrease in the impulse discharge from the arterial baroreceptors (for detail see page 340). Even when the blood pressure has not fallen, the

decrease in pulse pressure is sufficient to decrease the impulse discharge from baroreceptors. As a result there is a generalized increase in the sympathetic vasomotor discharge to heart, arterioles and veins. There occurs generalized vasoconstriction (sparing vessels of brain and heart). Vasoconstriction is more marked in the cutaneous, splanchnic, renal and skeletal muscle vessels. This causes shifting of greater amount of blood in circulation. Venoconstriction on account of sympathetic stimulation also causes increased shifting of stored venous blood in circulation leading to increased venous return and cardiac output. In kidneys both afferent and efferent blood vessels constrict, but afferent vessels constrict to a greater extent leading to reduction in GFR. All these mechanisms maintain blood pressure at such a level that the blood flow to the vital organs like heart and brain is not affected. However, blood flow to the vital organs is provided at the cost of other body tissues such as skin, abdominal viscera, kidney, and skeletal muscles.

2. **Chemoreceptor reflex.** Acute haemorrhage causes loss of red blood cells leading to reduced O₂ carrying capacity. The resultant anaemia and stagnant hypoxia as well as acidosis stimulate chemoreceptors which also excite VMC to cause the same effects as these caused by baroreceptor reflex. Fall in blood pressure below 60 mmHg usually initiates chemoreceptor reflex.

3. **CNS ischaemic response.** When blood pressure falls below 50 mmHg this response is initiated (for details see page 347). It causes more powerful sympathetic stimulation. This effect of central nervous system ischaemic response is called 'Last-ditch stand' of sympathetic reflexes.

The rapid compensatory mechanisms discussed above account for following:

Symptoms and signs

observed in patients with shock:

- **Pale, cold and moist skin** occurs due to decreased blood flow to skin and increased sweating (due to increased sympathetic discharge).
- **Cyanotic tinge of skin** may sometimes occur because of increased O₂ extraction from the blood.
- **Tachycardia and fall in pulse pressure** produce *thin and thready pulse*,

the characteristic feature of hypovolaemic shock.

- *Increased rate and force of respiration* is due to greater sinoaortic chemoreceptors discharge.
- *Oliguria*, another important feature of hypovolaemic shock is due to renal arteriolar constriction.
- *Restlessness and apprehension* may occur due to stimulation of brainstem reticular formation by circulating catecholamines, since haemorrhage is a potent stimulator of secretion of these hormones from the adrenal medulla.

B. Intermediate compensatory mechanisms.

1. Renin–angiotensin vasoconstrictor mechanism (see page 348),
 2. Reverse stress relaxation (see page 329) and
 3. Capillary fluid shift mechanism (see page 330).
- The angiotensin–vasopressin, as well as reverse stress relaxation mechanism require 10 min to 1 h to respond completely and help in raising the arterial pressure or circulatory filling pressure, thereby increases venous return to the heart.
 - Readjustment of blood volume by absorption of fluid from interstitial spaces and intestinal tract, as well as oral ingestion and absorption of additional quantity of water and salt may require 1–48 h.

C. Long-term compensatory mechanisms.

1. *Restoration of plasma volume and proteins.* After a moderate haemorrhage, the plasma volume is restored to normal in 12–72 h. However, the improvement in blood volume is merely because of the increase in the amount of plasma water along with electrolyte content. The plasma protein concentration and haematocrit value is actually

reduced (*haemodilution*). There is rapid entry of preformed albumin from extravascular stores. After this initial influx, albumin and rest of the plasma protein loss are restored by hepatic synthesis over a period of 3–4 days.

2. **Restoration of red cell mass.** In the mean time, there is excess release of erythropoietin which increases the rate of cell production in the bone marrow within 10 days. Normal cell mass is restored in 4–8 weeks.

Note.

Under normal circumstances, the circulatory compensatory mechanisms described above eventually cause full recovery without help of outside therapy during the stage of nonprogressive shock. However, a timely outside therapy may hasten the recovery.

II. Progressive shock

Second stage of the circulatory shock is a progressive stage which occurs after a 15–25% loss of total blood volume. In this stage, the compensatory mechanisms are not able to stop the progression of the shock. In other words, the *intense arteriolar vasoconstriction* seen in this stage is usually not adequate for maintenance of normal blood pressure. In progressive shock, the structures of circulatory system begin to deteriorate and various types of *positive feedback mechanisms* develop. Therefore, timely therapeutic interventions are essential in this stage, otherwise the vicious cycle of positive feedback mechanisms will cause progressive decrease in the cardiac output and ultimately the patient will go into a stage of refractory shock.

Positive feedback cycles.

Positive feedback cycles responsible for continuous progression of shock, if not interrupted by therapeutic intervention, leading to refractory stage are (Figs 4.7-4, 4.7-5):

1. **Cardiac failure.** Due to severe decrease in arterial pressure, particularly diastolic pressure, the coronary blood flow also decreases, and coronary ischaemia occurs. This weakens the myocardium and further decreases cardiac output and blood pressure. This positive feedback causes progressive cardiac deterioration and may ultimately cause complete heart failure.

2. **Vasomotor failure.** Blood flow to heart and brain is usually preserved

when cardiac output is decreased. However, there occurs very severe fall in blood pressure, there may occur cerebral ischaemia and failure of medullary VMC. Failure of VMC results in marked vascular dilatation causing venous pooling and decreased venous return. The cardiac output and blood pressure are further decreased.

3. *Peripheral circulatory failure.* Due to prolonged and intense vasoconstriction, there occurs hypoxia and accumulation of metabolites in the body tissues. The peripheral circulatory failure results from following changes:

- Capillaries and venules dilate due to the effect of local metabolites and there occurs peripheral venous pooling.
- Prolonged capillary hypoxia results in increase in capillary permeability, and large quantity of fluid begin to transudate into the tissues. This decreases the blood volume and increases the shock.
- The pooling and sluggish blood flow in microcirculation leads to *intravascular clotting of blood*. Even if the vessels do not become plugged, the tendency for the cells to stick to each other makes it more difficult for the blood to flow through microvasculature, giving rise to a condition called *sludged blood*.

4. *Septicaemia and toxaemia.* Due to prolonged vasoconstriction of splanchnic vessels there occurs hypoxia of GIT. The hypoxic damage causes a breakdown of normal protective mucosal barrier in the gut leading to the entry of the intestinal bacteria into the portal circulation. Simultaneous deterioration of hepatic functions permit bacteria and bacterial endotoxins to reach the systemic circulation leading to septicaemia and toxaemia. The endotoxins cause widespread failure of arteriolar and precapillary sphincter functions and cardiac depression. There occurs extensive vasodilatation. At this stage, no amount of treatment can restore the circulatory functions to normal.

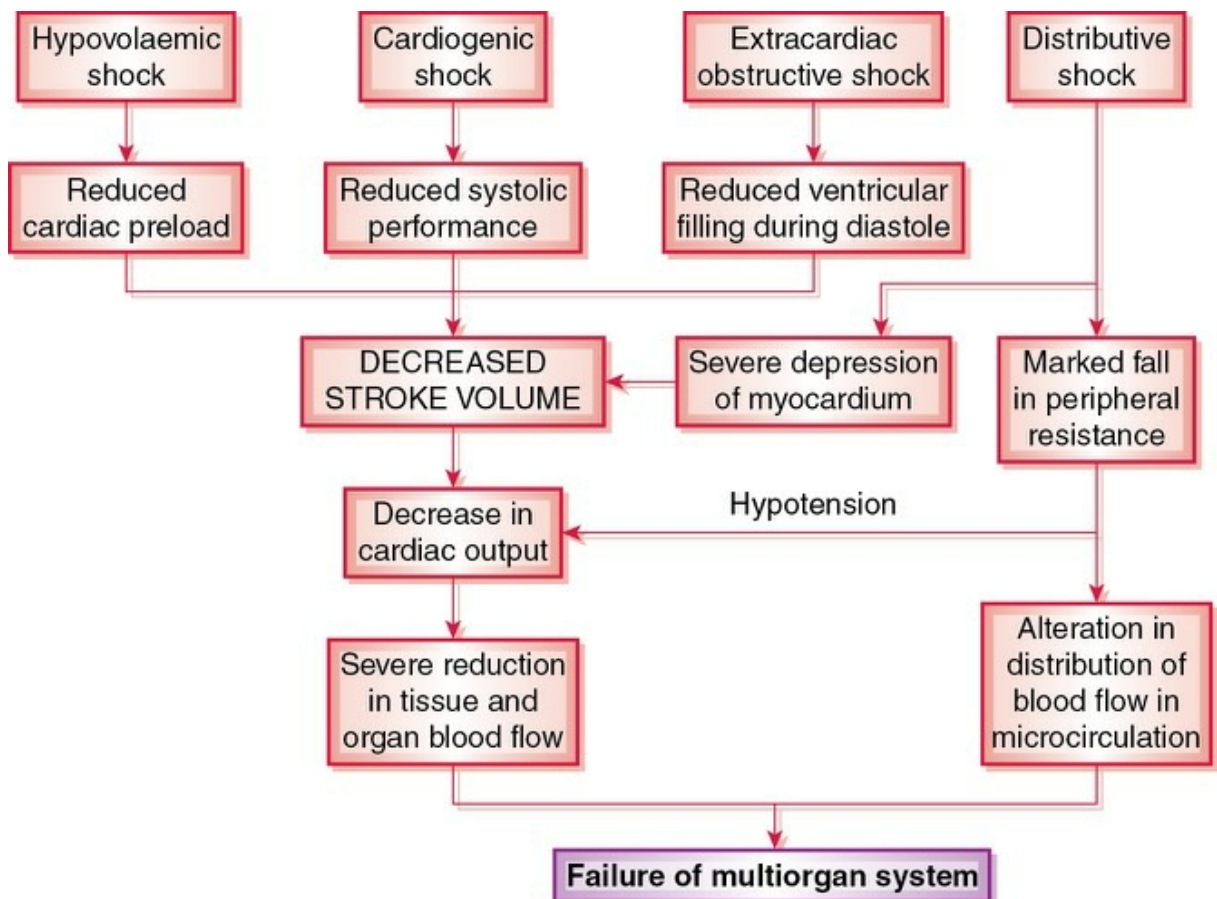

FIGURE 4.7-4 Chain of events that ultimately cause failure of multiple organ system and refractive shock in different types of shocks.

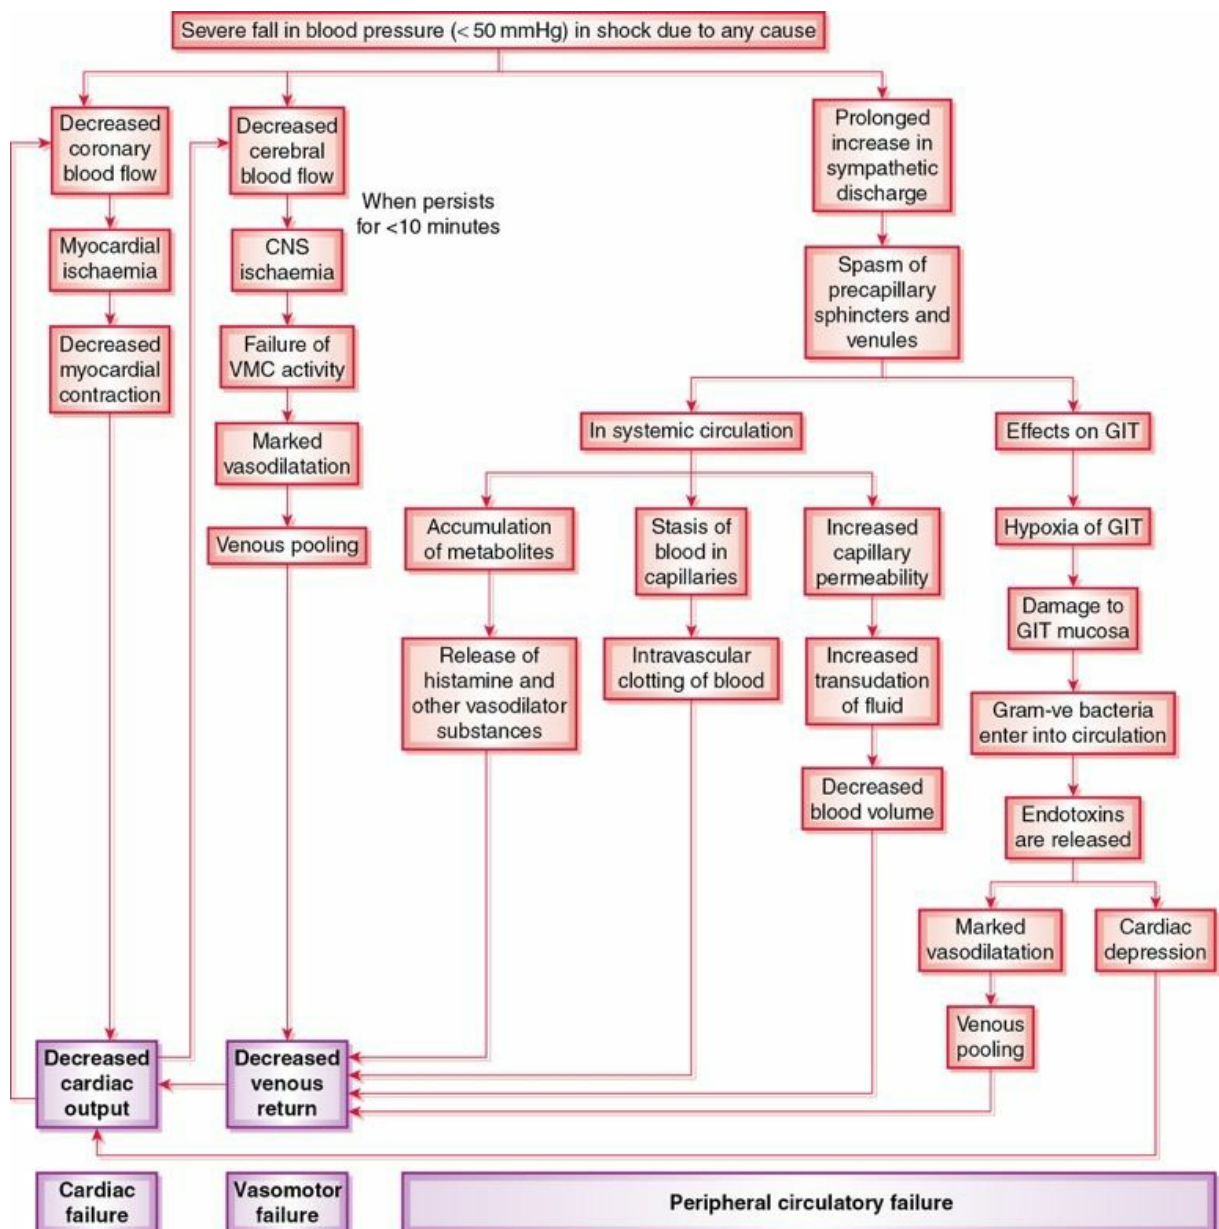

FIGURE 4.7-5 Chain of events of various positive feedback cycles which cause progression of shock to refractory stage. **NOTE:** In severe haemorrhage (blood loss > 40% of blood volume), the refractory shock develops due to these chain of events.

Effect on body tissues in progressive shock.

In progressive shock, there occurs *widespread cellular degeneration* in the body tissues. Generalized cellular damage usually occurs first in highly metabolic tissues such as liver, lung and heart. Liver cells are usually the first to be affected because hepatic cells have very high rate of metabolism and also liver is the first organ exposed to toxins from the intestine through the portal vein.

The different damaging cellular effects that are known to occur

include:

- Great decrease in active transport of sodium and potassium through cell membrane results in the accumulation of sodium in the cells and loss of potassium from the cells. So, the cell begins to swell.
- Mitochondrial activity in liver cells as well as in cells of many other tissues of the body is decreased.
- Lysosomes begin to split in tissues throughout the body, with release of hydrolases that causes widespread intracellular damage.
- Cellular metabolism of nutrients, such as glucose is eventually greatly depressed in last stages of shock. The activity of some hormones are depressed as well, including a marked suppression of insulin action.
- Poor delivery of oxygen to tissues, greatly diminishes oxidative metabolism and the cells switch to anaerobic glycolysis. This leads to the accumulation of lactic acid in the blood. Moreover the sluggish blood flow through the tissue also results in the accumulation of CO₂ in tissue. The CO₂ dissolves in water to produce H⁺ ions causing acidosis. Acidosis causes vasodilation which further aggravates the shock and a vicious cycle starts.

III. Refractory shock

As mentioned above, when the shock is in the progressive stage and is not treated adequately, a vicious cycle of various positive feedback mechanisms (Fig. 4.7-5) set in and patient passes into the third stage of shock, the *refractory shock* (previously known as *irreversible shock*). In this stage, all therapeutic interventions are usually ineffective and eventually the patient dies.

Causes of refractiveness (point of no return) of shock.

The main factor responsible for irreversibility of shock is the *depletion of high-energy phosphate compounds*. The high-energy phosphate reserves in the cells of the body, especially liver and heart are greatly diminished in severe degrees of shock. The adenosine triphosphate degraded in the cells to adenosine diphosphate and adenosine monophosphate and finally to adenosine. The adenosine diffuses out of the cell and is converted to uric acid, which cannot reenter the cell. New adenosine is synthesized rather slowly (at a rate of 2% of the total cellular amount per

hour), hence once depleted, the high-energy phosphate stores of the body cells are difficult to replenish during shock and this contributes to the final stage of irreversibility.

Tissue damage in refractory shock.

Slowly, necrosis of some cells of body sets in especially the cells adjacent to the venous ends of capillaries which receive less nutrition than the cells near the arterial ends of same capillaries. Patchy necrosis first appears in the cells of liver, kidney tubules, lungs and heart.

- In the kidney, there may occur *acute tubular necrosis* leading to acute renal failure and uraemic death.
- Deterioration of the lungs often leads to respiratory distress, the *shock lung syndrome*.

Treatment of shock with physiological basis

The treatment of shock is aimed at correcting the causes and helping physiological compensatory mechanisms.

1. General measures for shock

treatment are

- **Room temperature.** Where the patients of shock are kept should be cold. If exposed to warm, there will be sweating which will cause further hypovolaemia and aggravate the shock. It is important to note that most patients with shock are cold and therefore reflex warming of the body of a shock patient with water bottles or providing warm environment such as covering the patient with blankets, etc. will abolish the sympathetic discharge. So, the compensatory mechanism will be disturbed and shock will be aggravated and patient may even die.
- **Raising the foot end of the patient's bed** by 6" to 12" (*Trendelenburg position*) helps in promoting the venous return and thereby increasing the cardiac output. It is especially useful in haemorrhagic and neurogenic shock when the blood pressure is too low.

2. Replacement therapy

is very useful in hypovolaemic shock.

- ***In haemorrhagic shock*** the best therapy is transfusion of whole *blood*. When whole blood is not available the *plasma* may be used. Plasma maintains the colloid osmotic pressure of the blood, but the haematocrit decreases with this therapy. If neither whole blood nor plasma is available, a plasma substitute such as *dextran* may be used. Dextran is a large polysaccharide which does not pass through capillary pores. It therefore promotes osmosis of water from the interstitial fluid to intravascular spaces, thereby increasing the plasma volume.
- *In patients with burns or interstitial obstruction*, plasma infusion is the appropriate therapy. If plasma is not available *dextran* can be used.
- *In hypovolaemic shock due to dehydration* intravenous infusion of *balanced electrolytic solution* (e.g. lactated Ringer's solution) is the appropriate therapy.

3. Sympathomimetic drugs

are useful as:

- Sympathomimetic drugs are usually not useful in haemorrhagic shock where the sympathetic system is already very active.
- These are especially useful in *neurogenic shock* and *anaphylactic shock* where the cause of shock is marked vasodilation due to lost neurogenic vascular tone.
- *Dopamine* should be the sympathomimetic drug of choice, because it produces renal vasodilation and at the same time, produces vasoconstriction elsewhere in the body. It also has a positive inotropic effect on heart.
- Epinephrine or norepinephrine drug may also be used when dopamine is not available.

4. Oxygen therapy.

Oxygen therapy may have some beneficial effects. In general, it does not have marked effect since the hypoxia of shock is of the anaemic or stagnant type and not of hypoxic type.

5. Glucocorticoids.

Glucocorticoids are useful in shock because of their below-mentioned effects. They are particularly useful in anaphylactic shock:

- They increase the strength of heart in the last stages of shock,
- By stabilizing lysosomal membranes, they prevent release of enzymes of cells and
- They help in metabolism of glucose by the severely damaged cells.

Heart failure

Heart failure is a pathophysiological state of the heart when cardiac performance is too low to maintain the cardiac output to meet the demands of the metabolizing tissues.

Pathophysiology

Cardiac failure can occur in the following three situations ([Fig. 4.7-6](#)):

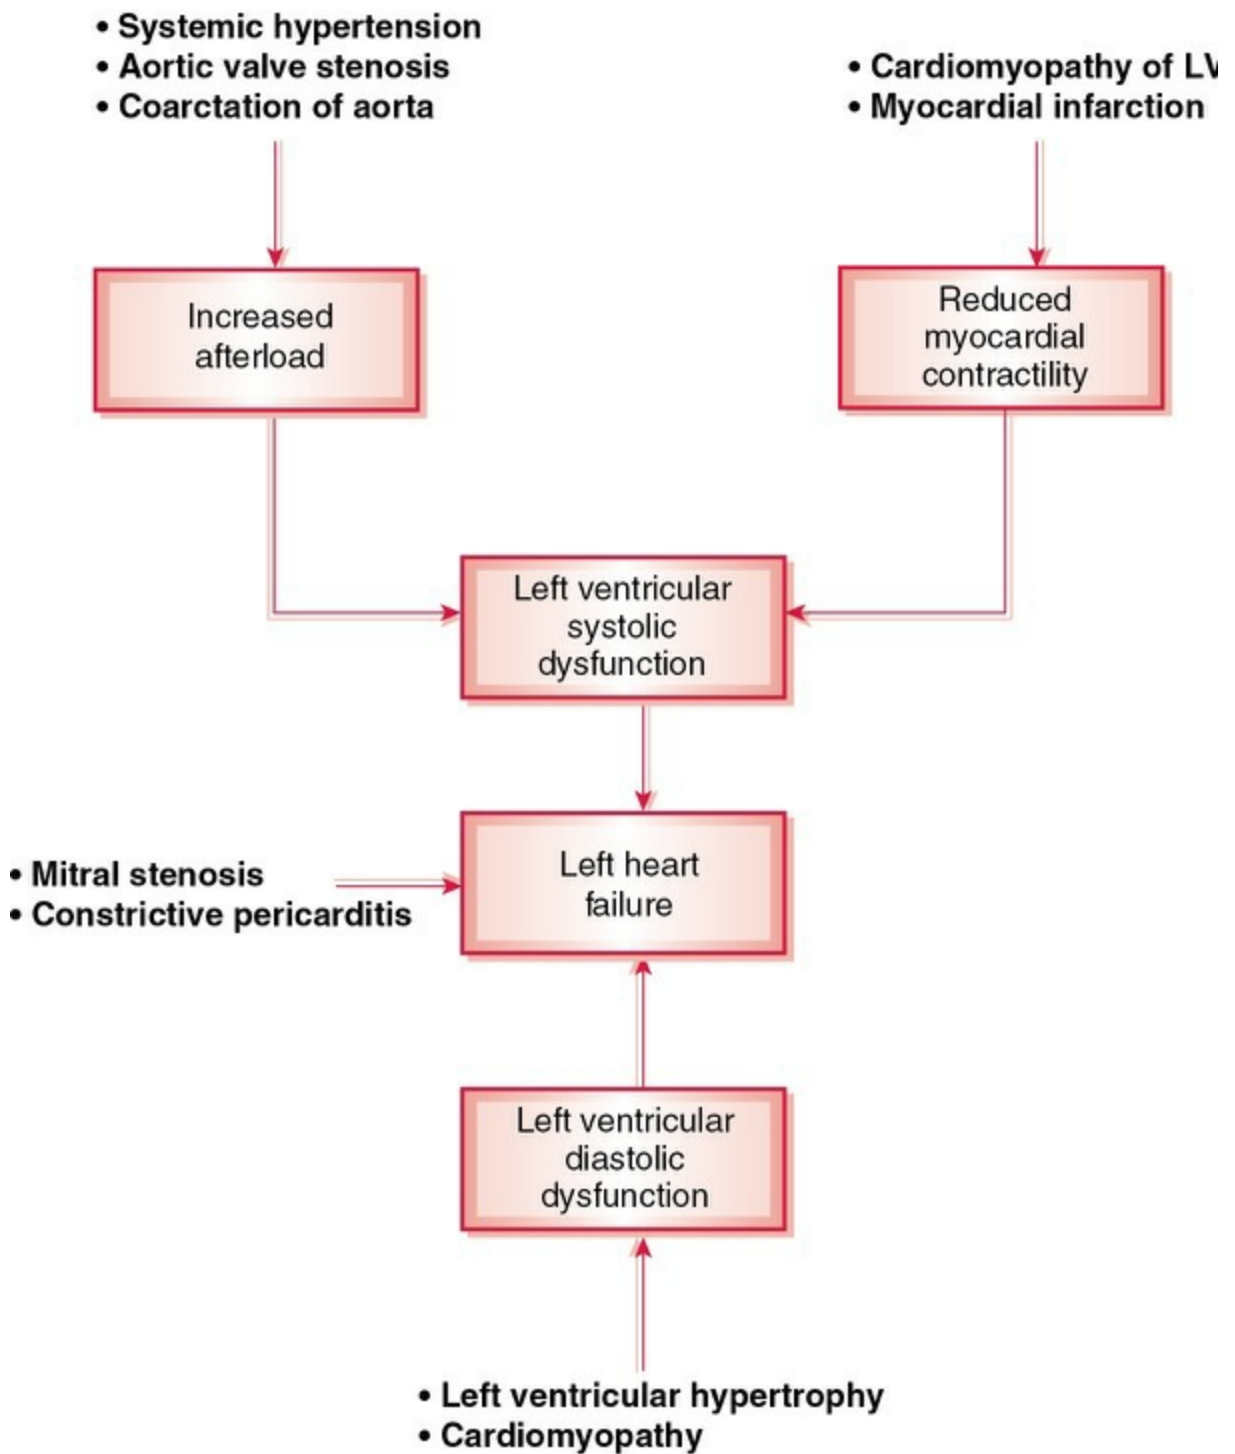

FIGURE 4.7-6 Pathophysiology of heart failure.

1. Increase in preload.

According to *Starling law of heart*, an increase in preload (end-diastolic volume) augments cardiac function, but when there is too much increase in preload then (it operates through descending limb of Starling curve, see page 246) it leads to ventricular dilatation and heart failure.

2. Increase in afterload

(resistance), e.g. in hypertension, there is resistance to outflow of blood from the heart which causes overstretching leading to ventricular dilatation and heart failure.

3. Reduction in myocardial contractility,

i.e. decrease in pumping ability of the heart decreases the cardiac output.

The interaction of these three variables leads to development of cardiac failure.

Types and causes of heart failure

Heart failures can be classified by various ways.

I. Depending on the onset

1. Acute heart failure

develops suddenly as in patient with myocardial infarction.

2. Chronic heart failure

develops due to gradual deterioration of heart functions, as in patients suffering from valvular diseases.

II. Depending on the operation of compensatory mechanisms

1. Compensated heart failure.

It means impairment of cardiac performance is being compensated by certain adaptive changes that prevent development of overt heart failure. The adaptive changes are of two types (Fig. 4.7-7):

i. *Local changes*, which are in the form of:

- Enlargement of chambers of heart,
- Myocardial hypertrophy and
- Increase in heart rate.

ii. *Systemic changes* are:

- Activation of renin–angiotensin–aldosterone system and

sympathetic system and

- Release of antidiuretic hormone and atrial natriuretic peptide.

Initially, compensatory changes improve cardiac performance, but as the disease advances they fail and become counterproductive.

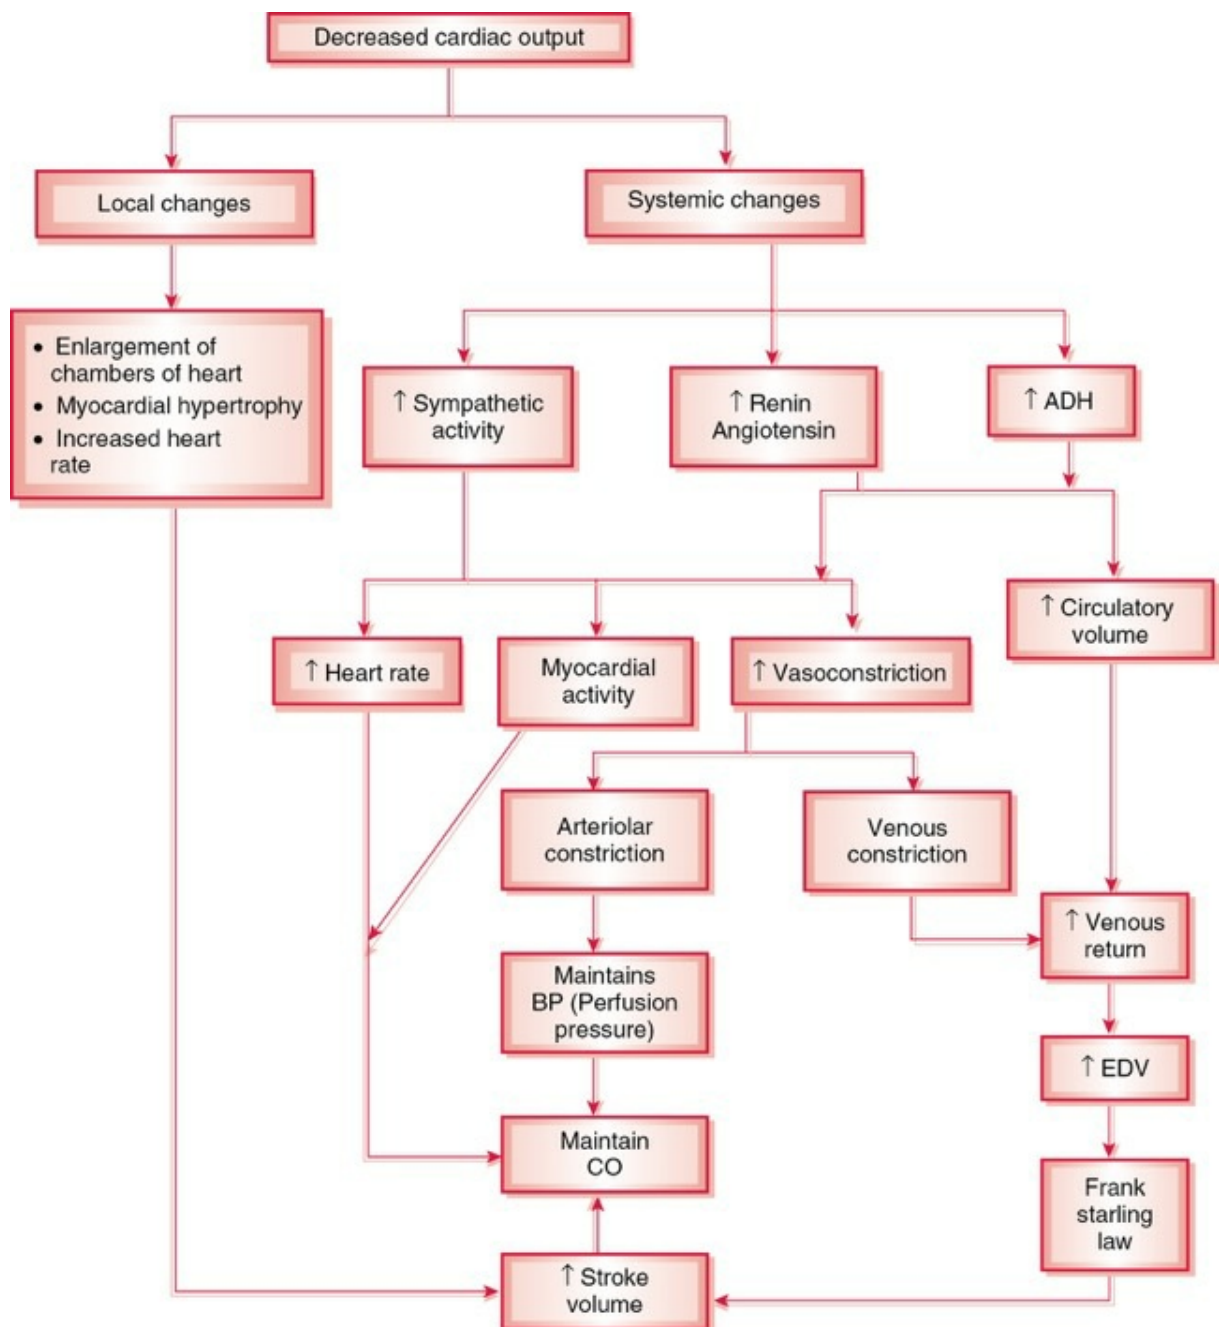

FIGURE 4.7-7 Compensatory/adaptive changes in heart failure.

2. Decompensated or overt heart failure.

In the presence of certain precipitating factors such as infections, anaemia, pregnancy, thyrotoxicosis, arrhythmia and myocardial infarction or due to failure of compensatory mechanisms, compensated heart failure leads to decompensated heart failure.

III. Depending on the involvement of side of heart

1. Left heart failure.

Anatomically, left heart comprises left atrium, left ventricle, aortic valve and mitral valve. The left heart failure (LHF), therefore, refers to reduction in left ventricular output leading to elevation of left ventricular volume and pressure and its transmission to left atrium and pulmonary veins. The conditions causing LHF are:

i. *Left ventricular outflow obstruction* due to:

- Systemic hypertension
- Aortic valve stenosis
- Coarctation of aorta

ii. *Left ventricular inflow obstruction* due to mitral stenosis

iii. *Reduced ventricular contractility* due to:

- Cardiomyopathy particularly involving left ventricle and
- Anterior wall myocardial infarction.

2. Right heart failure.

Like left heart anatomically right heart includes right atrium, right ventricle and tricuspid and pulmonary valves. Right heart failure is a condition in which there is reduction in right ventricular output leading to rise in right ventricular and right atrial pressure, which further causes rise in JVP, oedema, congestive hepatomegaly and congestion of viscera except lungs.

3. Biventricular (congestive) heart failure.

In this condition, there is simultaneous involvement of right and left heart due to disease of myocardium, or left ventricular failure and after sometime involves the right heart also.

IV. Depending on inadequate cardiac output

1. Forward heart failure

results due to inadequate cardiac output and

2. Backward heart failure

is the one in which decreased cardiac output results in the elevation of the end-diastolic volume and thus increases the ventricular pressure. The elevation of left and right ventricular pressure results in pulmonary and systemic congestion, respectively.

V. Systolic and diastolic heart failure

1. Systolic heart failure

occurs due to poor myocardial contractility (systolic dysfunction) and

2. Diastolic heart failure

results due to poor ventricular filling because of defective relaxation.

Both systolic and diastolic heart failures coexist particularly in myocardial infarction.

VI. High-output and low-output failure

1. High-output failure

is a state in which cardiac output remains high, i.e. at the upper limit of normal cardiac output (3.5 l/m²/min) even though cardiac functions are depressed. Various conditions which result in high output failure are:

- Fever,
- Thyrotoxicosis,
- Anaemia and
- Beriberi.

2. Low-output failure.

In this state, cardiac output remains at its lowest limit ($2.5 \text{ l/m}^2/\text{min}$) at rest and in stressful conditions becomes further depressed, as in the case of heart failure secondary to ischaemic heart disease, hypertension, valvular and pericardial diseases.

Clinical features

Clinical features depend on the underlying disease and type of heart failure and these are as follows (Fig. 4.7-8):

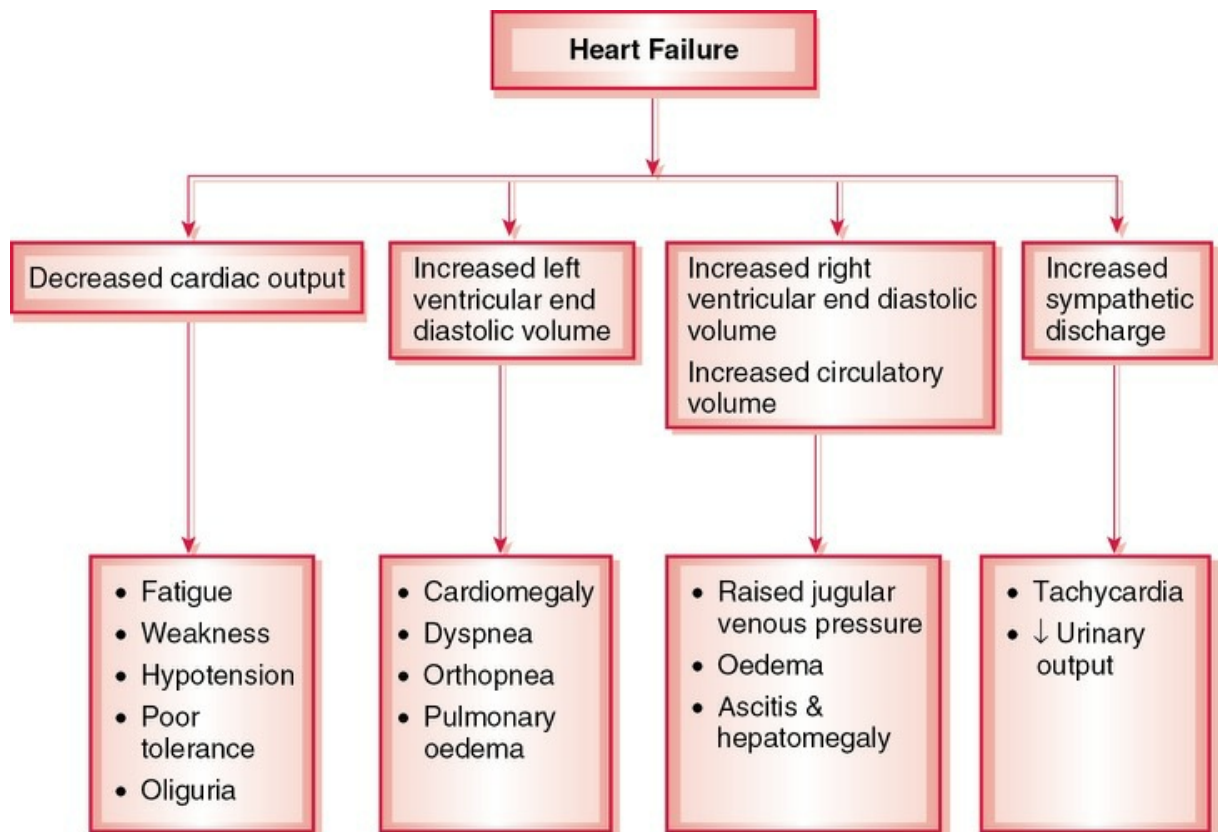

FIGURE 4.7-8 Pathophysiological features leading to sign and symptoms in heart failure.

1. Features due to low cardiac output

are:

- Fatigue,
- Hypotension,
- Poor tolerance to stress and

- Oliguria.

2. Features due to LHK

are:

- Cardiomegaly,
- Cardiac arrhythmia,
- Dyspnoea and orthopnoea.

3. Features due to right heart failure

are:

- Rise in JVP,
- Hepatomegaly,
- Peripheral oedema, ascites and hydrothorax.

4. Features of chronic heart failure:

- Raised JVP,
- Oedema,
- Congestive hepatomegaly.

Diagnosis

Diagnosis of heart failure is mainly based on its clinical features and following investigations are performed to establish the nature, severity, and complications which have occurred.

1. Electrocardiography

(ECG) findings may reveal arrhythmia, ventricular hypertrophy and myocardial infarction.

2. Radiography of chest

may show enlargement of heart, congestion of lungs and certain valvular defects.

3. Biochemical tests

include estimation of blood urea and electrolytes for renal failure, hypokalaemia and hyponatraemia.

Treatment

The basic principles of treatment of heart failure are aimed at to:

- Remove the precipitating factors,
- Correct the underlying cause,
- Control the congestive heart failure state and
- Prevent complications.

In general, following measures are employed as a treatment of cardiac failure.

A. To reduce cardiac work load

- Complete bed rest is advised or patient is hospitalized for 1–2 weeks,
- Small and light meals are recommended and
- Drugs (like sedatives and antianxiety) are prescribed.

B. To improve myocardial contractility

Drugs like cardiac glycosides (digitalis) and sympathomimetic amines (dopamine) are prescribed.

C. To control fluid retention.

Dietary salt intake is restricted, and diuretics are given.

D. To reduce afterload,

use of vasodilator drugs specially angiotensin converting enzyme inhibitors (captopril and enalapril) is recommended.

Respiratory System

OUTLINE

Introduction

5.1. Respiratory tract: Structure and functions

5.2. Pulmonary ventilation

5.3. Pulmonary circulation

5.4. Pulmonary diffusion

5.5. Transport of gases

5.6. Regulation of respiration

5.7. Respiration: Applied aspects

Introduction

The word respiration has been derived from the Latin word 'respirae' which means to breathe. The primary role of the respiratory system is to provide O₂ to the tissues for metabolic needs and remove the CO₂ formed

by them. An adult body consumes about 250 ml of O₂ and produces about 200 ml of CO₂ per minute. Respiration entails two processes: the external respiration and internal respiration.

The *internal respiration* or tissue respiration refers to utilization of O₂ and production of CO₂ by the tissue. It is generally considered the domain of biochemistry.

The *external respiration* includes supply of O₂ to the tissues from the environment and excretion of CO₂ released by the tissues into the atmosphere. The process of external respiration involves three major events:

- *Pulmonary ventilation*, i.e. exchange of gases between the environment and lungs. It includes mechanics of respiration.
- *Pulmonary diffusion* refers to transfer of gases from alveoli to the blood by diffusion across the respiratory membrane. To understand the process of pulmonary diffusion it is essential to understand facts about *pulmonary circulation* and the *properties of gases* and the laws governing diffusion of gases.
- *Transport of gases* from the blood to the body cells and back.

The *respiratory adjustments in health and diseases* are essential for life; and to understand these, knowledge about *regulation of respiration* is must.

The study of respiration without the concepts about functional anatomy of the respiratory system will not be easy, and so has been discussed in the very first chapter of this section.

FUNCTIONS OF RESPIRATORY SYSTEM

- Respiratory Functions
- Nonrespiratory Functions
 - Functions of Defence Mechanism
 - Functions of Pulmonary Circulation
 - Metabolic Functions
 - Functions of Respiratory Muscles

Functional anatomy

The chief organs of the respiratory system are right and left *lungs*. The oxygen contained in the atmospheric air reaches the lungs by passing through a series of *respiratory passages* which also serve for removal of

CO₂ from the alveoli to the atmosphere. The respiratory system also includes a pump that ventilates the lung. This pump consists of the chest wall and respiratory muscles. Salient points about functional anatomy of respiratory passages and lungs are discussed here. Functional anatomy of chest wall and respiratory muscles is discussed in [Chapter 5.2](#) on 'Pulmonary Ventilation' which includes the mechanics of respiration.

Respiratory passages

Respiratory passages include the following structures ([Fig. 5.1-1](#)):

FIGURE 5.1-1 The air passages.

1. Nasal cavities.

The air enters the body through right and left anterior (external) nares which open into the right and left nasal cavities. Through the posterior (internal) nares, the nasal cavities open into the pharynx. The nasal cavities warm up the air to the body temperature, humidify the air to

100% saturation, clean and filter the air of its particulate content by channeling the air through a tortuous path between the turbinates. The particles are deposited at the bends where they adhere to the mucus layering the nasal cavity.

2. Pharynx.

From above downwards the pharynx is divided into nasopharynx, oropharynx and laryngopharynx. Air from nasal cavities enters the nasopharynx and passes down through the oropharynx and laryngopharynx to larynx. From the mouth the air can directly pass to oropharynx.

3. Larynx.

It is continuous above with laryngopharynx and below with trachea. The air passes through the glottis (the triangular space between vocal cords) into the trachea. Apart from being a respiratory passage, the larynx also acts as a voice box.

4. Tracheobronchial tree.

The air passages between trachea and alveoli divide 23 times to form the extensive tracheobronchial tree (Fig. 5.1-2). These multiple divisions greatly increase the total cross-sectional area of the airway from 2.5 cm² in the trachea to 11,800 cm² in the alveoli. Consequently, the velocity of air flow in the small airway declines to very low values. The 23 generation divisions of tracheobronchial tree have been numbered as:

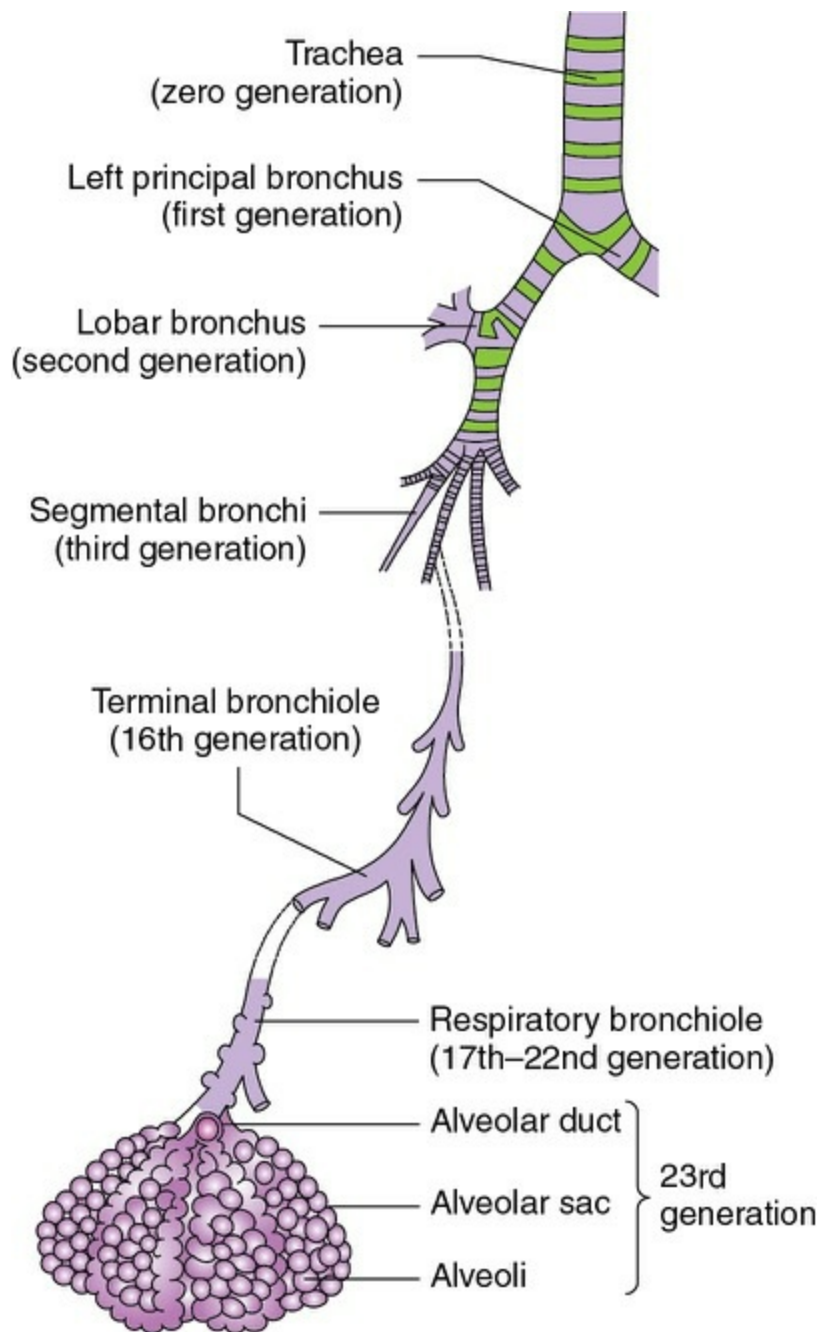

FIGURE 5.1-2 The tracheobronchial tree.

The trachea is designated as generation zero.

The principal bronchi right and left which are two major divisions of trachea constitute the first generation.

- *Lobar bronchi*, which are division of the principal bronchus form the second generation.
- *Segmental bronchi* which are further division of each lobar bronchus forms the third generation. Each segmental bronchus divides into several generations of branches that ultimately end in very small tubes called *bronchioles*.

- *Terminal bronchioles* is the name given to 16th generation of the divisions. Upto this generation of division no exchange of gases is possible.
- *Respiratory bronchiole* is the name given to 17th–22nd generation of divisions. These are labelled as respiratory bronchioles, because some exchange of gases is possible in these tubes.

Alveolar ducts and in the alveoli or the alveolar sacs which form the 23rd generation division. It is here that most of the O₂ and CO₂ exchange occurs.

Thus, from the functional point of view the tracheo-bronchial tree can be divided into two major zones:

- Conducting zone** of the air passages is formed by the first 16 generations of passages and it only transports gases from and to the exterior. Thus, conducting zone starts from trachea and extends upto terminal bronchioles. Since no exchange of gases is possible here, so starting from nose to the terminal bronchioles forms the so-called *dead space* which has a total capacity of approximately 150 ml.
- Respiratory zone.** The remaining seven generations of the tracheobronchial tree which includes the respiratory bronchioles, alveolar ducts and alveoli form the respiratory zone, where exchange of gases occurs. Its volume is approximately 4 L.

Histological features of the tracheobronchial tree

1. Cartilaginous rings

are present in trachea and initial bronchi of few generations. These are absent in terminal bronchioles and respiratory bronchioles. The cartilaginous rings of trachea are incomplete on their posterior aspect. This allows some contraction of trachea but tracheal lumen cannot be completely obliterated easily.

2. Smooth muscles.

Ends of cartilaginous rings of trachea are approximated by transverse smooth muscle fibres. In bronchi, bands of fibres tend to become circular so that in terminal bronchioles they are present in large amount and form a sphincter. Smooth muscles are not present in alveoli.

3. Epithelial lining

in trachea and large bronchi is columnar and becomes cuboidal in bronchioles and simple squamous in alveoli. The epithelial cells of the tracheobronchial tree are ciliated. Cilia are absent in alveoli. Efficiency of ciliated cells of trachea and bronchi in propelling mucus and waste products is of higher order. Cilia are not influenced by nerve impulses. The mucous secreting goblet cells and deep serous glands are present in trachea and bronchi but are absent in bronchioles and alveoli (Fig. 5.1-3).

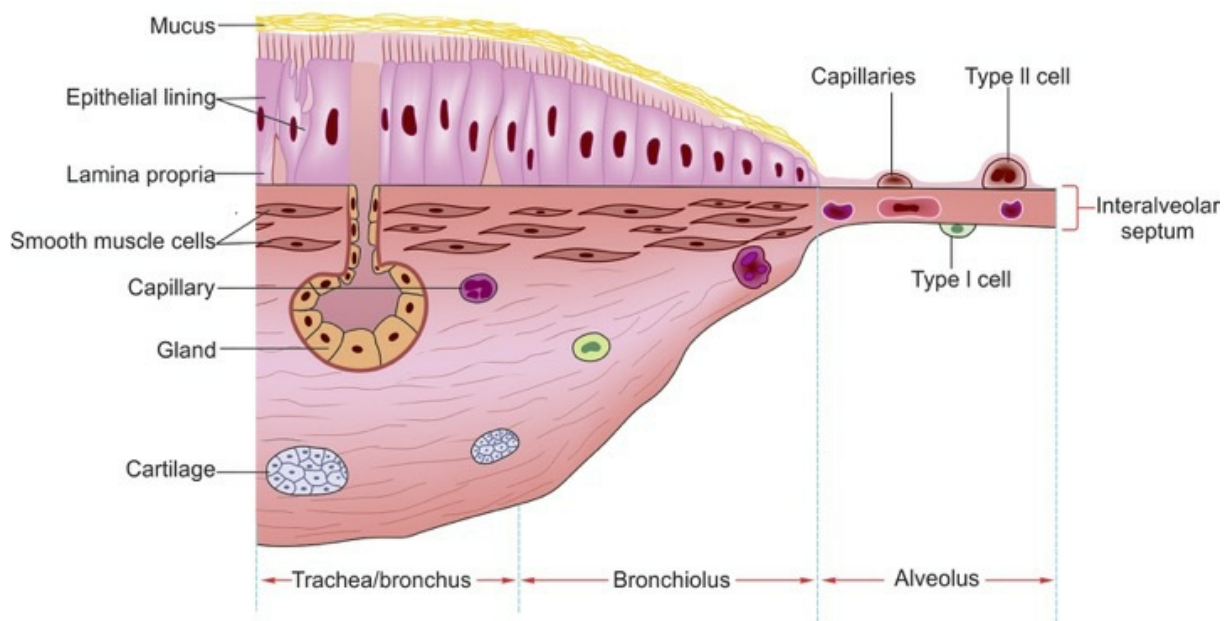

FIGURE 5.1-3 Histological features of epithelial lining of tracheobronchial tree.

Respiratory parenchyma

Each respiratory unit consists of one respiratory bronchiole which opens into a number of alveolar ducts, and each alveolar duct in turn opens into number of alveoli. The two lungs contain about 300 million alveoli. Each alveolus has a diameter of about $0.2 \mu\text{m}$. The alveoli are surrounded by pulmonary capillaries. The total area of the alveolar walls in contact with capillaries in both the lungs is about 70 m^2 .

Microscopic structure of alveolus (fig. 5.1-4)

Each alveolus is lined by two types of epithelial cells:

- *Type I cells* are flat cells with large cytoplasmic extensions and are the primary lining cells.

- **Type II cells** (granular pneumocytes) are thicker and contain numerous lamellar inclusion bodies. These cells secrete *surfactant*.

FIGURE 5.1-4 Microscopic structure of alveolus.

The alveolar wall also contains:

- Other *special type of epithelial cells*,
- *Pulmonary alveolar macrophages* (PAM) which are active phagocytic cells,
- *Lymphocytes*,
- *Plasma cells* which form and secrete immunoglobulins,
- *Amine precursor uptake and decarboxylation* (APUD) *cells* which store and secrete many biologically active peptidases, e.g. vasoactive intestinal peptide (VIP) and substance P, etc.
- *Mast cells* which contain heparin, various lipids, histamine and various proteases that participate in allergic reactions.

Communication between the two alveoli occurs through small pores, called *pores of Kohn*.

Respiratory membrane

It is the name given to the tissues which separate the capillary blood

from the alveolar air. It is important to understand the structure of a respiratory membrane for better understanding of diffusion of gases between alveoli and capillary blood, so it is described in detail in [Chapter 5.4](#) on Pulmonary Diffusion (page 418).

Blood supply

Conducting airway is supplied by systemic blood, whereas the respiratory zone of the lung is supplied by deoxygenated (venous) blood coming through pulmonary arteries to lungs. Blood is oxygenated in lungs and is returned to left atrium via pulmonary veins.

Innervation

The walls of bronchi and bronchioles are innervated by the autonomic nervous system.

- *Parasympathetic* fibres innervate through vagus nerve. Their stimulation causes cholinergic discharge producing bronchoconstriction and increased bronchial secretion via muscarinic receptors.
- *Sympathetic nerves* supplying the lungs when stimulated causes bronchodilation and decreased bronchial secretion via adrenergic receptors, predominantly by β_2 receptors while α_1 adrenergic receptors inhibit bronchial secretions.
- *Afferents* from the lungs pass through vagi nerves.

Functions of the respiratory system

Respiratory functions

The main function of the respiratory system in general and lung in particular is exchange of gases between atmosphere and blood.

Nonrespiratory functions

Besides the respiratory functions the respiratory system performs many important nonrespiratory functions which include:

A. Functions subserved by lung defence mechanisms

Epithelial cells in the mucosal lining of the conducting zone secrete various molecules that are involved in lung defense mechanism. These

include secretory immunoglobulins (IgA), collectins, surfactant proteins —(SP-A) and (SP-D), defensins, chemokines, cytokines, etc.

1. Immunoglobulin-a (IgA)

is secreted in the bronchial secretion and protects against respiratory infections. *Ciliary escalator action* is an important defence system against air-borne infection. The dust particles in the inhaled air are often laden with bacteria. While passing through the repeatedly branched bronchial tree the dust particles and the bacteria are caught in the mucous layer present at the mucosal surface of respiratory passages and are moved up towards pharynx by the rhythmic upward beating action of cilia [Fig. 5.1-5](#) and swallowed. Cigarette smoke disturbs the ciliary function. That explains the higher incidence of respiratory infections in smokers than in nonsmokers.

Applied Aspects

Cystic fibrosis is an autosomal recessive disorder occurs due to abnormal gene (located on long arm of chromosome 7), that encodes cystic fibrosis transmembrane conductance regulator (CFTR). The basic abnormality lies in transport protein for Cl⁻ on apical membrane of epithelial lining of respiratory, gastrointestinal and genitourinary tracts.

FIGURE 5.1-5 Ciliary escalator action of the respiratory mucosa.

Normally in the airways of epithelial cells, Cl^- channel (transport protein) transports Cl^- out of the cell, resulting in retention of Na^+ on the mucosal surfaces that causes water to transport through intercellular spaces. In cystic fibrosis, due to abnormal Cl^- channel, there is inhibition of Cl^- transport out of cell leading to greater influx of Na^+ in the cell \rightarrow deficiency of Na^+ \rightarrow dehydration of luminal border of epithelial cell \rightarrow making mucous thick and viscid leading to deficient mucociliary escalator clearance \rightarrow leading to infection.

The mutations in CFTR gene that cause cystic fibrosis are grouped into five classes based on their cellular functions as :

Class I mutation	: Inhibits synthesis of Cl^- channel protein
Class II mutation	: Causes defective processing of channel protein
Class III mutation	: Blocks the regulation of channel protein
Class IV mutation	: Causes altered conductance through channel protein
Class V mutation	: Reduces synthesis of channel protein

Therapeutic measures advised in cystic fibrosis include:

- Chest physiotherapy and mucolytic agents should be used to loosen thick mucus.
- Antibiotics – to prevent infection.
- Bronchodilators and anti-inflammatory agents to expand and clear the airways.

2. Pulmonary alveolar macrophages

play an important role in the defence system by following mechanisms:

- Being actively phagocytic cells they ingest the inhaled bacteria and small particles.
- Help in processing inhaled antigens for immunologic attack.
- PAMs secrete substances that attract polymorphonuclear cells to the lungs.
- By some secretions they stimulate granulocyte and monocyte formation in the bone marrow.

Note. The detrimental function of PAM is to digest substances inhaled in cigarette smoke or other irritants. During the digestive process they release lysosomal products into the extracellular spaces and cause inflammatory reaction.

3. Cough reflex.

The laryngeal, tracheal and bronchial mucous membranes contain vagal afferent terminals which act as *irritant receptors*. Stimulation of these receptors by chemical or mechanical stimuli (excessive mucus, inadvertently inhaled foodstuff, etc.) produces a bout of coughing which helps in the expulsion of the foreign material.

For details of [cough reflex](#) see page 446.

B. Functions subserved by pulmonary circulation

1. Reservoir for left ventricle.

When left ventricle output becomes transiently greater than systemic venous return, the blood stored in pulmonary circulation helps in maintaining the left ventricular output for few strokes.

2. Pulmonary circulation acts as a filter

and filters out particles from the blood, which may include: small fibrin or blood clots, detached cancer cells, fat cells, gas bubbles, agglutinated RBCs, masses of platelets and debris from stored blood.

The filtered particles in the lung are removed by lytic enzyme in capillary endothelium, ingestion by macrophages and penetration into the lymphatic system.

3. Removal of fluid from alveoli.

Because of low pulmonary hydrostatic pressure, the fluid entering the alveoli is absorbed by the capillaries. This protects the gas exchange function of lungs and opposes transudation of fluid from capillaries to the alveoli.

4. Role in absorption of drugs.

Certain drugs that rapidly pass through the alveolar capillary barrier by diffusion are administered by inhalation, e.g. anaesthetic gases, aerosol and other bronchodilators.

C. Metabolic functions of lungs

1. Surfactant

produced in the lungs plays an important role in respiration (for details see page 405).

2. Protein synthesis

for maintenance of the structural framework.

3. Conversion of angiotensin I to II

is performed by the enzyme angiotensin converting enzyme (ACE) present in the pulmonary capillary endothelium.

4. Inactivation partly or completely

of many vasoactive substances present in the blood is done by capillary endothelial cells as they pass through pulmonary circulation. These substances include bradykinin, serotonin, some prostaglandins, norepinephrine, acetylcholine, etc. Amount of serotonin and norepinephrine reaching the systemic circulation is decreased by lungs. Vasoactive substances that pass through the lungs without being

metabolized include epinephrine, dopamine, oxytocin, vasopressin and angiotensin I.

5. Fibrinolytic mechanism

present in the lung lyses clot in the pulmonary vessels.

6. Storage of hormones and certain biologically active peptides

is done in the APUD cells and nerve fibres present in the alveoli. These substances include VIP, substance P, opioid peptides, cholecystinin-pancreozymin (CCK-PZ) and somatostatin. These substances are later released into the systemic circulation.

D. Functions subserved by respiratory muscles

Respiratory muscles are also used during laughing and singing.

 - Factors Affecting Total Work of Breathing

Introduction

As we know, respiration, to be more precise the *external respiration* (supply of O₂ from atmosphere to body tissues and removal of CO₂ from the body to atmosphere), involves three major processes:

- *Pulmonary ventilation*, i.e. exchange of gases between the environment and lungs,
- *Pulmonary diffusion*, i.e. transfer of gases from the alveoli to capillary blood across the respiratory membrane and
- *Transport of gases* from the blood to tissue cells and back.

In this chapter, following aspects and concepts related to pulmonary ventilation are discussed:

- Mechanics of pulmonary ventilation,

- Lung volumes and capacities,
- Pulmonary elastance and compliance and
- Work of breathing.

Mechanics of pulmonary ventilation

Mechanism of breathing

- *Pulmonary ventilation* is accomplished by two processes: inspiration and expiration.
- *Inspiration* refers to inflow of atmospheric air into the lungs. This obviously occurs when the intrapulmonary pressure falls below the atmospheric air pressure.
- *Expiration* refers to outflow of air from the lungs into the atmosphere. This obviously occurs when the intrapulmonary pressure rises above the atmospheric air pressure.
- *Changes in the intrapulmonary pressure* which govern the respiratory cycle of inspiration and expiration are related to changes in the intrapleural pressure.
- *Changes in the intrapleural pressure* are brought about by changes in the size of the thoracic cavity. Expansion of the thoracic cage leads to fall in intrapleural pressure and decrease in the size of the thoracic cavity leads to rise in the intrapleural pressure.
- *Changes in the size of the thoracic cavity* are brought about by the actions of respiratory muscles:
- Muscles of normal tidal inspiration are diaphragm and external intercostal muscles.
- Accessory muscles of inspiration are scaleni, sternomastoid and serratus anterior, and alae nasi.

- Muscles of expiration are internal intercostal muscles and abdominal muscles (abdominal recti muscles, transverse abdominis muscles and internal oblique muscles).

Mechanism of tidal respiration

Inspiration

Inspiration is an active process, normally produced by contraction of the *inspiratory muscles* (*negative-pressure breathing*). Use of a respirator to inflate the respiratory system produces positive pressure (*positive-pressure breathing*). During tidal inspiration (quiet breathing), the diaphragm and external intercostal muscles contract and cause an increase in all the three dimensions of the thoracic cavity.

Role of a diaphragm.

In tidal inspiration (quiet breathing), 70–75% of the expansion of chest is caused due to the contraction of diaphragm. The diaphragm is a dome-shaped, musculotendinous partition between the thorax and abdomen. The convexity of this dome is directed towards the thorax. When the diaphragm contracts, the following changes occur:

- The dome becomes flattened, and the level of diaphragm is lowered *increasing the vertical diameter* of the thoracic cavity (Fig. 5.2-1A). During quiet breathing, the descent of diaphragm is about 1.5 cm, and during forced inspiration it increases to 7 cm.
- The descent of diaphragm causes the rise in intra-abdominal pressure which is accommodated by the reciprocal relaxation of the abdominal wall musculature.
- The contraction of diaphragm also lifts the lower ribs causing thoracic expansion laterally and anteriorly (the bucket handle and pump handle effect, respectively) (Figs 5.2-1B and C). The abdominal organs support the diaphragmatic dome and act as a fulcrum, while the diaphragmatic contraction raises the lower ribs.

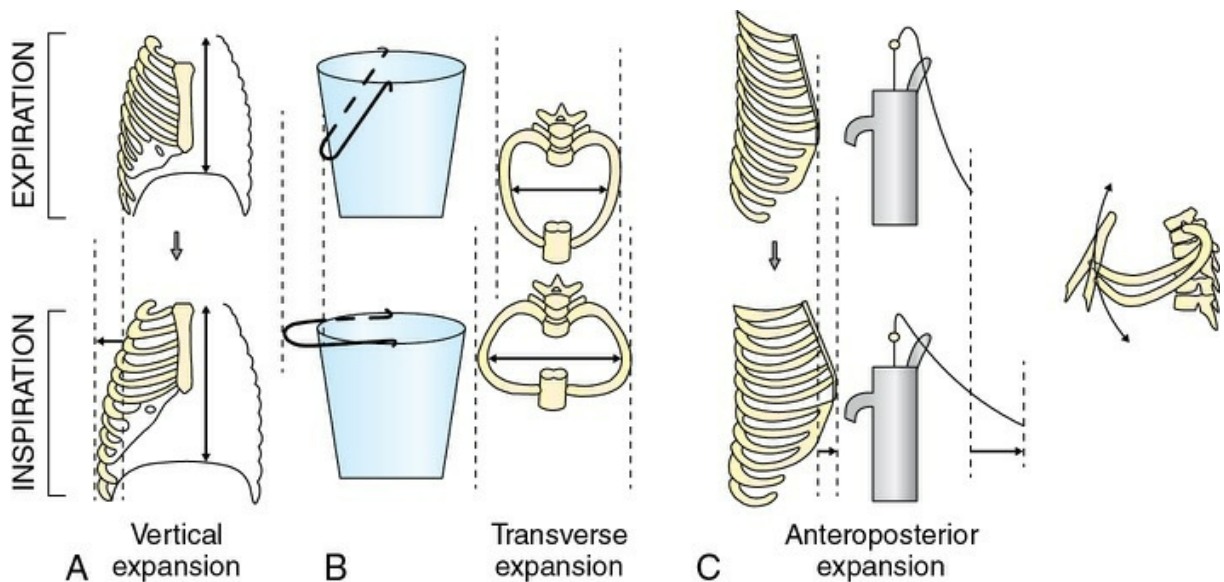

FIGURE 5.2-1 Mechanism of increase in diameter of thoracic cavity: **(A)** increase in vertical diameter (descent of diaphragm); **(B)** increase in transverse diameter (bucket handle effect) and **(C)** increase in anteroposterior diameter (pump handle effect).

Role of external intercostal muscles.

The fibres of external intercostal muscles slope downwards and forwards. They are attached close to the vertebral ends of the upper ribs than the lower ribs (Fig. 5.2-2). From pivot-like joint with the vertebrae, the ribs slope obliquely downwards and forwards. So, when the external intercostal muscles contract (because of the lever effect), the ribs are elevated causing the lateral and anteroposterior enlargement of the thoracic cavity due to the so-called bucket- and pump-handle effects, respectively (Figs. 5.2-1B and C).

FIGURE 5.2-2 Contraction of external intercostal muscle favours elevation of ribs due to mechanical leverage effect of the attachments of its fibres close to the pivot on the upper ribs as compared to lower ribs.

Role of laryngeal muscles.

The abductor muscles of the larynx contract during inspiration pulling the vocal cords apart.

Expiration

Expiration in quiet breathing is largely a passive phenomenon and is brought about by the following:

- Elastic recoil of the lungs,
- Decrease in the size of the thoracic cavity due to the relaxation of diaphragm and external intercostal muscles,
- An increase in the tone of muscle of the anterior abdominal wall which forces the relaxing diaphragm upwards and
- The serratus posterior inferior muscles that play a minor role in pulling down the ribs.

Applied Aspects

- *Hiccup* is a spasmodic contraction of diaphragm and other inspiratory muscles, resulting in inspiration in which there is a sudden closure of glottis, producing sound and a characteristic sensation. Its physiological significance is not yet clear. Usually, hiccup is of short duration, but when it becomes debilitating, then use of dopamine antagonist and centrally acting analgesics may help.
- In bilateral phrenic nerve palsy, adequate ventilation at rest can be maintained by the external intercostal muscles alone but respiration is somewhat laboured to maintain life.
- Spinal cord transaction above the level of the third cervical segment is fatal without artificial respiration, whereas in transaction below the fifth cervical segment, respiration remains normal as the phrenic nerve

(C₃, C₄, C₅) that innervates the diaphragm remains intact.

Mechanism of forced respiration

Forced inspiration

Forced inspiration is characterized by:

1. *Forceful contraction of diaphragm* leading to the descent of diaphragm by 7–10 cm as compared to 1–1.5 cm during quiet inspiration.
2. *Forceful contraction of external intercostal muscles* causing more elevation of ribs leading to more increase in transverse and anteroposterior diameter of the thoracic cavity.
3. *Contraction of accessory muscles of inspiration* which causes the following effects:
 - Sternomastoid muscles contract and lift the sternum upwards.
 - Anterior serrati muscles contract and lift many of the ribs upwards.
 - Scaleni muscles contract and lift the first two ribs.

Forced expiration

Forced expiration is required when respiration is increased during exercise or in the presence of severe respiratory disease. It is an active process that gives rise to the following:

1. *Contraction of abdominal muscles:*
 - Compression of the abdominal contents which increases the intra-abdominal pressure and forces the diaphragm upwards, thereby reducing the vertical diameter of the thoracic cavity.
 - Downward pull on the lower ribs, thus decreasing the

anteroposterior diameter of the thoracic cavity.

- Fixation of the lower ribs so that internal intercostal muscles act more effectively.

2. **Contraction of the internal intercostal:** It causes the effect which is just opposite to that of external intercostal muscles. This is because of the leverage mechanism of the direction of the muscle fibres which slope downwards and backwards, creating a longer force arm for the upper ribs (Fig. 5.2-3). Hence, their contraction tends to pull all the ribs downwards, thereby reducing the anteroposterior diameter (because of the falling of the pump-handle effect) as well as the transverse diameter (because of the action of ribs like the falling of the bucket-handle effect) of the thoracic cavity.

FIGURE 5.2-3 Contraction of internal intercostal muscle pulls the ribs down due to mechanical leverage effect of its fibres close to the pivot on the lower ribs as compared to upper ribs.

Note.

Besides their role in deep breathing, the expiratory muscles are also involved in other forced expiratory efforts, e.g. in coughing, vomiting,

defaecation and Valsalva manoeuvre, etc.

Pressure and volume changes during the respiratory cycle

Pressure changes

Intrapulmonary pressure changes during the respiratory cycle (fig. 5.2-4).

The movement of air in and out of the lungs depends primarily on the pressure gradient between the alveoli and the atmosphere (i.e. *transairway pressure*). The intrapulmonary or alveolar pressure is the air pressure inside the lung alveoli.

At end-expiration and end-inspiration,

i.e. when the glottis is open and there is no movement of air, the pressures in all parts of the respiratory tree are equal to the atmospheric pressure, and the intrapulmonary pressure is considered to be *zero* mm of Hg.

During inspiration in quiet breathing, the pressure in the alveoli decreases to about -1 mmHg, which is sufficient to suck in about 500 ml of air into the lungs within 2 sec of inspiration. At the end-inspiration, the intrapulmonary pressure again becomes zero.

During forced inspiration against a closed glottis (Muller's manoeuvre), the intrapulmonary pressure may be as low as -80 mmHg, i.e. below the atmospheric pressure.

During expiration in quiet breathing, the elastic recoil of the lungs causes the intrapulmonary pressure to swing slightly to the positive side ($+1$ mmHg) which forces the 500 ml of inspired air out of the lungs during 2–3 sec of expiration. At the end-expiration, once again the alveolar pressure regains the atmospheric pressure (zero mm of Hg).

Forceful expiration against closed glottis (Valsalva's manoeuvre) may produce the intrapulmonary pressure of as much as 100 mmHg.

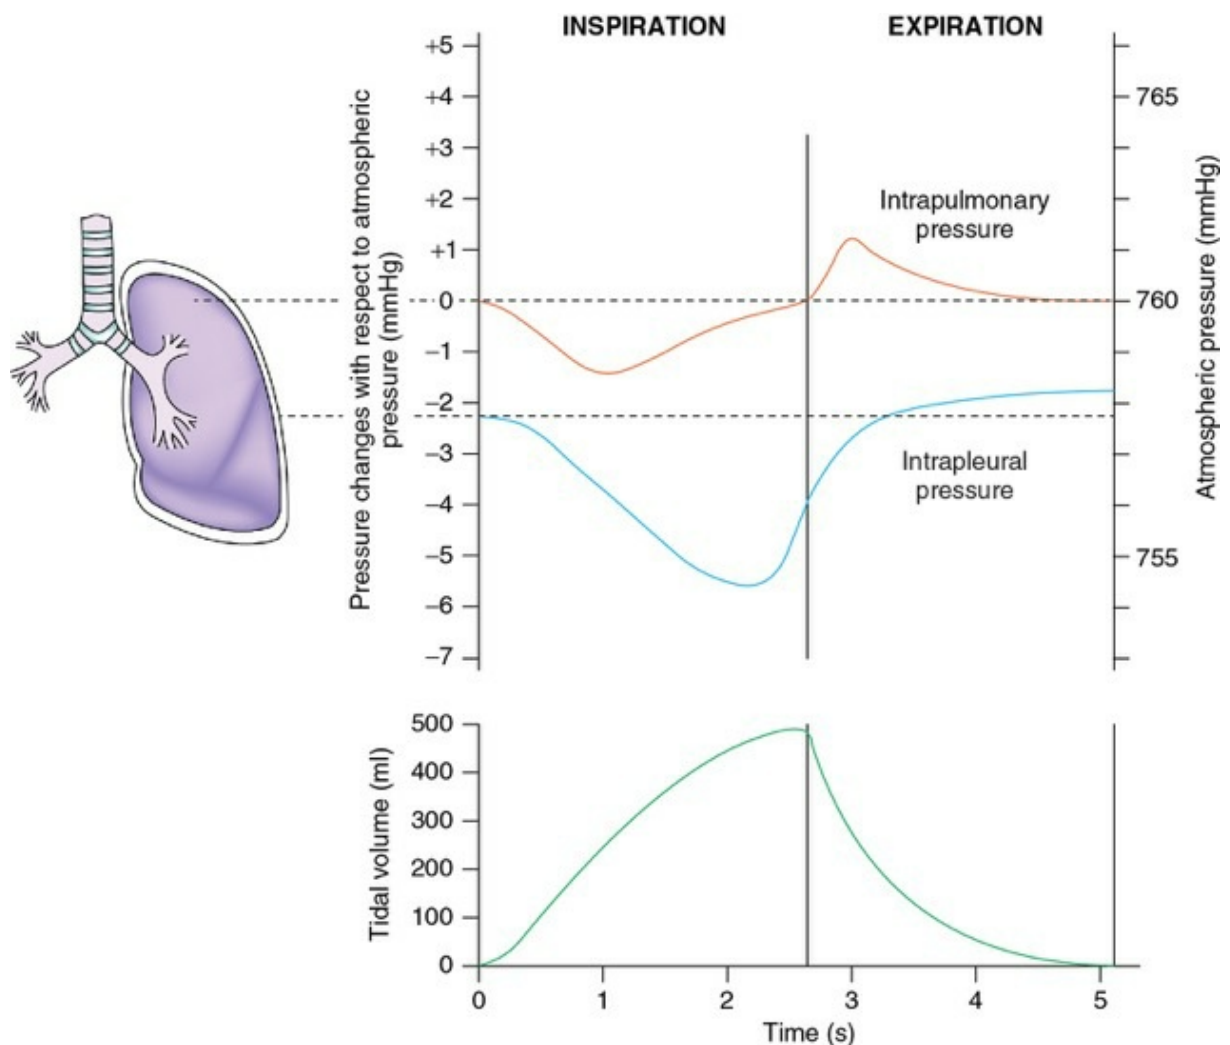

FIGURE 5.2-4 Pressure and volume changes during the respiratory cycle.

Intrapleural (pleural) pressure changes during the respiratory cycle (fig. 5.2-4)

Pleural pressure is the pressure of fluid in the space between the visceral pleura and parietal pleura.

- **Normal pleural pressure**

when the respiratory muscles are completely relaxed and the airways are open is about -2.5 mmHg.

- The negative pleural pressure (-2.5 mmHg) is the amount of suction required to hold the lungs at their equilibrium volume or the functional residual capacity (FRC). FRC is the lung volume at the end of normal (eupnoic), relaxed expiration and is about 2–2.5 L of gas.
- The negative pleural pressure (-2.5 mmHg) is the result of balance of

two opposite forces: the recoil tendency of the lungs and the recoil tendency of the thoracic cage.

- Recoil tendency of the lungs (continuous tendency to collapse) is caused by:
- The presence of many elastic fibres in the alveolar walls which are under constant stretch in the inflated lungs and
- Surface tension of the fluid lining the alveoli due to which the alveoli tend to become progressively smaller and collapse.
- Recoil tendency of the thoracic cage, i.e. a constant tendency to expand (to pop outwards), is because of the fact that the chest wall is an elastic structure which is normally partially pulled inwards. The elastic property of the thoracic cage is because of the elastic nature of ribs, muscles and tendons.
- *During Inspiration* due to the expansion of the chest wall, the pleural pressure becomes more negative (-6 mm of Hg) and pulls the surface of lungs with greater force creating negative intrapulmonary pressure.
- *During Expiration.* At the end of inspiration, the inspiratory muscles relax and the recoiling force of lungs begins to pull the chest wall back to expiratory position. At end-expiratory position, where the recoil force of the lungs and recoil force of thoracic cage balance, the pleural pressure returns back to -2.5 mmHg.

Factors affecting pleural pressure

1. *Deep inspirations.* The pleural pressure may become as low as -30 mmHg during deep inspiration.
2. *Valsalva manoeuvre* or when expiratory muscles work against closed glottis, there occurs a marked decrease in the thoracic volume causing deflation of lungs. Under such circumstances, the intrapleural pressure can become positive by $60-70$ mmHg (greater than atmospheric pressure), e.g. during defaecation and coughing.

3. **Gravity.** The pleural pressure in standing position is more negative (-7 mmHg) at the apices of the lungs as compared to the bases (-2 mmHg). Because of this, lungs are less expanded at the base and even the airway at the base may become closed at the end of expiration. This is why during the first part of inspiration, more of the inspired gas goes to the apices than bases of lungs.

4. **Injury to the chest wall** causing exposure of the pleural cavity to the exterior causes air to enter the pleural cavity (pneumothorax) and the pleural pressure rises from the subatmospheric level to the atmospheric level. Since there is no opposing force to the elastic recoil of the lung, so in pneumothorax the lung is collapsed.

5. **Emphysema** is a disease of the lungs in which lung elasticity is decreased or lost. Due to the decrease in the recoiling force of lungs, the intrapleural pressure becomes less negative (i.e. increases). Because of this reason, in this disease, the lung alveoli expands and chest also expands and becomes barrel shaped.

Effects of pleural pressure on the cardiovascular system

1. **During inspiration,** when the pleural pressure becomes more negative, the mediastinal pressure also becomes more negative, leading to the expansion of the walled structures in the thorax, especially large veins (superior and inferior vena cavae) and thereby decreasing pressure on them. This causes blood to be sucked into these veins from extrathoracic regions. Thus, there is *increased venous return* to the heart during inspiration due to suction action of the respiratory pump. The descent of diaphragm during inspiration causes a slight rise in intra-abdominal pressure, thereby increasing the pressure gradient between abdomen and thorax further. The increase in the venous return during inspiration *increases the cardiac output*. This respiratory pump action is especially marked during exercise.

2. **During Valsalva manoeuvre** or when expiratory muscles are working violently against closed glottis, e.g. while severe bouts of cough, the pleural pressure becomes positive leading to a decrease in the venous return. So the cardiac output is markedly decreased and there may occur cerebral ischaemia, visual blackouts and unconsciousness, especially in old persons.

Measurement of pleural pressure

1. *Manometric measurement* can be made by inserting a needle into the intrapleural space whose other end is attached to a water manometer with the help of a rubber tubing.
2. *Intraoesophageal* pressure can be recorded with the help of an air-containing rubber balloon sealed over a catheter placed in the lower part of thoracic part of oesophagus. Intraoesophageal pressure in the thoracic part is equivalent to the intrapleural pressure because this part of oesophagus becomes a closed cavity due to the closure of its lower end by the cardiac sphincter and upper end by the closure of glottis.

Lung volume changes during the respiratory cycle

- *During Tidal Inspiration*, the volume of air in the lungs increases by 500 ml (tidal volume).
- *During Tidal Expiration*, the elastic forces compress the gas in the lungs which starts flowing out and at the end of expiration the volume of air in the lungs decreases by 500 ml (Fig. 5.2-4).

Pressure–volume curve of respiratory system

The transrespiratory pressure (TRP) refers to the transmural pressure across the entire respiratory system. It equals alveolar pressure (PA) minus pressure at the body surface (PBs), i.e. $TRP = PA - PBs$. The pressure at the body surface is usually atmospheric pressure.

Pressure–volume curve of the respiratory system (Fig. 5.2-5) shows that:

- It is a sigmoid-shaped curve which is steepest in the middle and almost flat at both high- and low-lung volumes.
- FRC is determined by the volume at which the transrespiratory pressure (TRP) is zero.
- Residual volume (RV) and total lung capacity (TLC) are limited by the decreased compliance of the system, as indicated by the reduced slope of the curve at both extreme of volumes.

FIGURE 5.2-5 Pressure–volume curve of the respiratory system. RV= residual volume, FRC= functional residual capacity and TLC= total lung capacity.

Lung volumes and capacities

Static lung volumes and capacities

Lung volumes

The maximum volume to which a lung can be expanded has been divided into four nonoverlapping volumes (Fig. 5.2-6).

FIGURE 5.2-6 A spirogram showing various lung volumes and capacities: RV = residual volume; TV= tidal volume; IRV= inspiratory reserve volume; ERV = expiratory reserve volume; FRC= functional residual capacity; TLC= total lung capacity; IC= inspiratory capacity; VC= vital capacity and EC = expiratory capacity.

1. Tidal volume (TV).

It is the volume of air inspired or expired with each breath during normal quiet breathing. It is approximately 500 ml in a normal adult male.

2. Inspiratory reserve volume (IRV).

It is the extra volume of air that can be inhaled by a maximum inspiratory effort over and beyond the normal tidal volume. It is about 3000 ml in a normal adult male.

3. Expiratory reserve volume (ERV).

It is the extra volume of air that can be exhaled by maximum forceful expiration over and beyond the normal tidal volume, (i.e. after the end of normal passive expiration). It is approximately 1100 ml in a normal adult male.

4. Residual volume (RV).

It is the volume of the air that still remains in the lungs after the most forceful expiration. It is about 1200 ml in a normal adult male.

Lung capacities

Lung capacities are combination of two or more pulmonary volumes and include (Fig. 5.2-6):

1. Inspiratory capacity (IC).

This is the maximum volume of the air that can be inspired after normal tidal expiration. Therefore, it equals the tidal volume plus inspiratory reserve volume (TV + IRV) and is approximately 3500 ml in a normal adult male.

2. Expiratory capacity.

It is the maximum volume of air that can be expired after normal tidal inspiration. It equals tidal volume plus expiratory reserve volume (TV + ERV) and is approximately about 1600 ml in a normal adult male.

3. Functional residual capacity (FRC).

It is the volume of the air remaining in the lungs after normal tidal expiration. Therefore, it equals the expiratory reserve volume plus the residual volume (ERV + RV) and is about 2300 ml in a normal adult male.

• Significance of FRC.

The FRC (RV + ERV) of about 2300 ml represents the air that remains in the lungs most of the times. Even after the most forceful expiration about 1200 ml (residual volume) air is always present in the lungs. This has several advantages:

i. *Continuous exchange of gases* is possible due to presence of some air always in the lungs, and thereby concentration of O₂ and CO₂ in blood are maintained constant. Without FRC, pO₂ would have risen to 150 mmHg during inspiration, and reduced nearly to zero during expiration, which is maintained at about 100 mm of Hg due to the FRC.

ii. *Breath holding* is made possible due to the FRC.

iii. *Dilution of toxic inhaled gases* occurs due to the reserve of 2300 ml of air in the lungs (FRC) most of the times.

iv. *Load on respiratory mechanism and left ventricle would* have been much more if there was no FRC, since:

- Without FRC, lungs would have collapsed at the end of each expiration, and re-expansion would have required tremendous breathing effort, and
- The collapsed lungs would have increased pulmonary vascular resistance and imposed a heavy load on left ventricle.

- **Factors affecting FRC.**

Hyperinflation of the lungs seen in following conditions may be associated with increased FRC:

- Old age due to loss of elasticity of lungs,
- Emphysema, and
- Bronchial asthma.

- **Measurement of FRC.**

Functional residual capacity can be measured by the nitrogen wash-out method or the helium dilution method.

Nitrogen wash-out method for measuring FRC. This method is based on the assumption that the alveolar air has 80% nitrogen. In this method, the subject is made to wash out nitrogen from the lungs completely by inhaling pure O₂ for 5 min and expiring into a large gas bag called the Douglas bag (washed with pure O₂ and, hence, made nitrogen free). The volume of gas collected in the *Douglas bag* and its nitrogen content are measured and the value of FRC is calculated as follows.

- Suppose that the expired gas collected at the end of 5 min is 40 L and its nitrogen concentration is 5%.
- Then the volume of nitrogen (V_n) in the expired gas will be

$$\frac{40 \times 5}{100} = 2 \text{ L or } 2000 \text{ ml}$$

- Since the nitrogen content of the expired gas is solely from the subject's lungs where it forms 80% of the gas present in the lungs (FRC); therefore,

$$\begin{aligned} \text{FRC} &= \frac{2000 \times 100}{80} \text{ ml} \\ &= 2500 \text{ ml or } 2.5 \text{ L} \end{aligned}$$

Helium dilution method for FRC estimation. This method is based on the basic principle that the amount (A) of a substance present is equal to its volume (V) multiplied by its concentration (C), i.e.

$$A = V \times C.$$

- In this method, a closed circuit system is prepared with a mixture of helium, oxygen and air. The amount of helium is added in the mixture such as to achieve a helium concentration of 10%.
- The subject is then made to breathe in the closed system till the concentration of helium in the lungs and the bag becomes equal. The helium concentration is measured at the end of a normal expiration (because the FRC is the volume of air remaining in the lungs at the end of normal expiration).

Since no helium was present in the lungs to start with, The same amount of helium which was added in the mixture in the close circuit system gets distributed between the bag and the lungs (Figs 5.2-7A and

B).

- The FRC can be calculated as follows:
- Suppose that the volume of helium added in the mixture to make its concentration to 10% is 560 ml,
- Volume of the bag is 5000 ml and
- Concentration of helium (He) in the bag and lungs after breathing in the close circuit system is 8%.

Then, the

$$\text{volume of He} = \frac{(\text{Volume of lungs} + \text{bag})}{\text{Concentration of helium}} \times \left(\frac{8}{100} \right)$$

$$\text{i.e.} \quad 560 = (\text{volume of lungs} + 5000) \times \frac{8}{100}$$

or

$$\text{volume of lungs} + 5000 = \frac{560 \times 100}{8}$$

or

$$\text{Volume of lungs} = 7000 - 5000$$

$$\text{Hence,} \quad \text{FRC} = 2000 \text{ ml.}$$

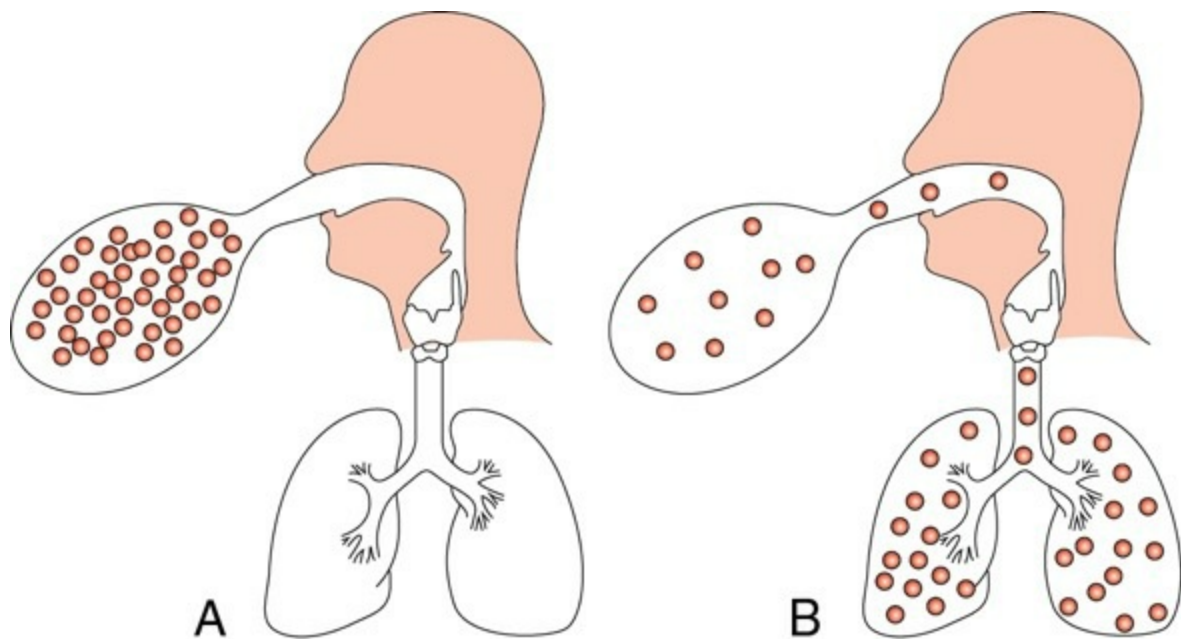

FIGURE 5.2-7 Helium dilution method for estimation of functional residual capacity (FRC): **(A)** in the beginning no helium present in the lungs and **(B)** The helium present in close circuit distributed equally between bag and the lungs.

4. Vital capacity (VC).

This is the maximum amount of air a person can expel from the lungs after the deepest possible inspiration. Therefore, it equals the tidal volume plus the inspiratory reserve volume plus the expiratory reserve volume ($TV + IRV + ERV$) and is about 4600 ml in a normal adult male.

Significance of vital capacity

- Estimation of VC allows the assessment of maximum inspiratory and expiratory efforts and, thus, gives useful information about the strength of respiratory muscles.
- VC also provides useful information about other aspects of pulmonary functions through FEV (see page 407).

Factors affecting vital capacity

- Size of the thoracic cavity.* VC is more in males (2.6 L/m^2 body surface area) because of large chest size and more muscle power than females.
- Age.* In old age, VC decreases due to the decrease in the elasticity of the lungs.

iii. *Strength of respiratory muscles.* In swimmers and divers, VC is more because of the increased strength of the respiratory muscles.

iv. *Gravity.* In standing position, VC is more than in sitting and lying position because of:

- Increased size of the thoracic cavity in standing (diaphragm moves down), and
- Reduced pulmonary blood flow due to decreased venous return.

v. *In pregnancy,* VC is reduced due to pushing up of the diaphragm and the reduced capacity of the thoracic cavity.

vi. *In ascites* (accumulation of fluid in the abdominal cavity), VC is reduced due to the same reason as in pregnancy.

vii. *Pulmonary diseases* such as pulmonary fibrosis, emphysema, respiratory obstruction, pulmonary oedema, pleural effusion and pneumothorax are associated with decreased VC.

5. Total lung capacity (TLC).

It is the volume of air present in the lungs after the maximal inspiration. It equals the vital capacity plus the residual volume (VC + RV) and is about 5800 ml in a normal adult male.

Measurement of static lung volumes and capacities.

All volumes and capacities except residual volume, functional residual capacity and TLC are recorded by a *spirometer*. Functional residual capacity is determined by the nitrogen wash-out method or the helium dilution method, and then residual volume and TLC are calculated.

Recording of lung volumes and capacities are the important lung function tests (for details see page 473).

Dynamic lung volumes and capacities

Timed vital capacity (TVC) or forced vital capacities

Forced vital capacity is the volume of the air that can be expired rapidly

with a maximum force following a maximum inspiration. The volume of air expired can be timed by recording the vital capacity on a spiograph moving at the known speed.

Components of TVC or FVC (fig. 5.2-8)

i. Forced expiratory volume in 1 sec (FEV₁).

It represents the volume expired in the first second of an FVC.

- Estimation of FEV₁ is the most commonly used screening test for airway diseases.
- The FEV₁ is actually a flow rate: its unit is L/sec.
- FEV₁% is the per cent of FVC expired in 1 sec (i.e. $FEV_1\% = FEV_1/FVC \times 100$); normally, FEV₁% is about 80% of the FVC (Fig. 5.2-9A).

Clinical application. Useful in distinguishing between restrictive and obstructive lung diseases:

- Patients with *restrictive lung disease* (RLD), e.g. kyphoscoliosis and ankylosing spondylitis, have a reduced FVC; but they are able to achieve relatively high flow rates; therefore, their FEV₁% exceeds 80% (Fig. 5.2-9B).
- Patients with *obstructive lung disease* (OLD), e.g. bronchial asthma, have low flow rates as a result of high airway resistance; therefore, their FEV₁% is abnormally low (Fig. 5.2-9C).

FIGURE 5.2-9 Forced expiratory volume in first second (FEV₁) component of timed vital capacity: **(A)** in normal subject; **(B)** in a patient with restrictive lung disease (RLD); and **(C)** in a patient with obstructive lung disease (OLD).

ii. Forced expiratory volume in 2 sec (FEV₂).

It represents the volume of air expired in the first 2 sec of FVC; FEV₂% is about 90% of FVC under the normal condition.

iii. Forced expiratory volume in 3 sec (FEV₃).

It represents the volume of air expired in the first 3 sec. Normally FEV₃% is 98%–100% of FVC.

FIGURE 5.2-8 Components of timed vital capacity.

Forced expiratory flow during 25%–75% of expiration (FEF 25%–75%)

- It is the mean expiratory flow rate during middle 50% of FVC (Fig. 5.2-10A).
- Normal FEF 25%–75% is 300 L/min.
- Mid expiratory time (MET) refers to the time taken for FEF 25%–75%. Its normal value is 0.5 sec which is increased in obstructive lung disorders.

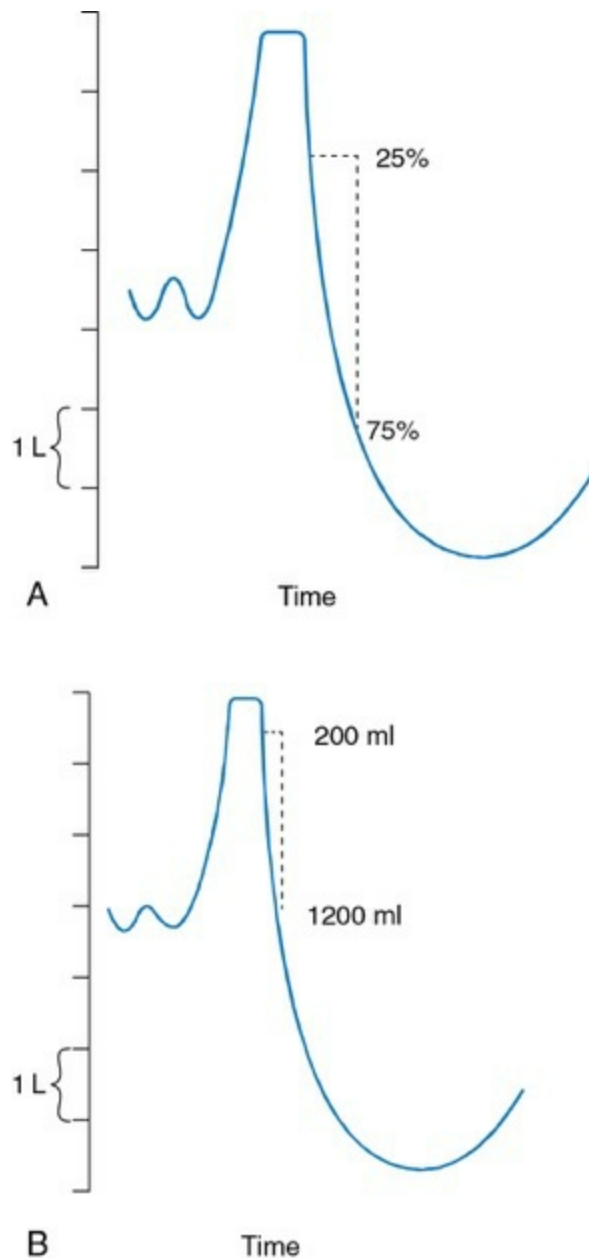

FIGURE 5.2-10 Forced expiratory flow: **(A)** during 25–75% of expiration (FEF 25–75%); and **(B)** during 200–1200 ml of expiration (FEF 200–1200 ml).

Forced expiratory flow during 200–1200 ml of expiration (FEF 200–1200)

- FEF 200–1200 refers to the mean expiratory flow rate between the 200 and 1200 ml segment of FVC (Fig. 5.2-10B).
- Normal values of FEF 200–1200 is 350 L/min.

Minute ventilation (MV) or pulmonary ventilation (PV)

It is the volume of air inspired or expired per minute. It equals the tidal volume multiplied by the respiratory rate ($TV \times RR$). The TV at rest averages 500 ml (0.5 L), and the normal respiratory rate is 12–15 breaths/min; therefore, normal minute volume is 6–7.5 L/min.

Maximum breathing capacity (MBC) or maximum voluntary ventilation or maximum ventilation volume (MVV)

- It is the maximum volume of air that can be ventilated on command during a given interval.
- This index of ventilatory function depends upon the complete cooperation of the subject, who is asked to breathe as rapidly and deeply as he/she can for a 15-sec interval. The volume of the air moved is either recorded by a spirometer fitted with a writing point or is collected in a Douglas bag; the result is expressed in L/min.
- A normal adult male can attain an MVV of 80–170 L/min (average 100 L/min).
- MVV is profoundly reduced in patients with emphysema, airway obstruction and very poor respiratory muscle strength.

Important Note

Hyperventilation causes CO_2 washout which leads to respiratory depression. This may result in fainting; therefore, voluntary hyperventilation should be done for the brief periods (15 sec only).

Pulmonary reserve or breathing reserve

- Pulmonary reserve (PR) refers to the maximum amount of the air above the pulmonary ventilation that can be inspired or expired in 1 min.
- It equals the maximum ventilation volume minus pulmonary ventilation (minute ventilation), i.e.

$$PR = MVV - PV/\text{min}.$$

- Pulmonary reserve is usually expressed as the percentage of MVV and is known as the percentage pulmonary reserve or the *dyspnoeic index (DI)*, *i.e.*

$$DI = \frac{MVV - PV}{MVV} \times 100$$

- Normal values of DI or per cent PR range from 60% to 90% with an average of 75%.
- Dyspnoea is usually present when the value of DI becomes less than 60%.

Pulmonary elastance and compliance

Pulmonary elastance

Elastance refers to the *recoil* (retractive) tendency of a structure. Both the thoracic cage and lungs have elastance.

Elastance of thoracic cage

Elastance or the recoil tendency of the thoracic cage refers to the constant tendency of the thoracic cage to expand (to pop outward). The elastance of the thoracic cage is because of the fact that the chest wall is an elastic structure which is normally kept partially pulled inward. The elastic property of the thoracic cage is because of the elastic nature of ribs, muscles and tendons.

Elastance of lungs

Elastance or recoil tendency of the lungs refer to the constant tendency of the lungs to collapse. The recoil forces in the lungs are generated by:

1. Tissue forces.

These are due to the presence of many elastic tissues such as smooth muscle, elastic and collagen in the lung parenchyma which are kept under constant stretch in the inflated lungs. However, the role of these connective tissue fibres in generating elastic (retractile) forces in the

lungs is not fully elucidated.

2. Surface forces.

These are generated at the alveolar surface lined by fluid (*alveolar surface tension*) due to which the alveoli tend to become progressively smaller and tend to collapse. The alveolar surface tension needs further discussion since it is responsible for about two-third of total elastic forces in the lungs.

Alveolar surface tension

Alveolar surface tension is generated because of the unbalanced attraction of the liquid molecules at the surface of alveolar membrane. A phase change occurs between the alveolar gas and the surface of the alveolar membrane. Alveolar surface tension has a tendency to reduce the size of each alveolus, thus resulting into recoil tendency of the lung, i.e. surface tension increases the tendency of the lungs to deflate. An increased transmural pressure is necessary to counteract the effects of surface tension. According to the *law of Laplace*, in a spherical structure like alveoli the transmural pressure generated equals two times the (surface) tension divided by radius, i.e. $P = 2T/r$. In other words, the pressure in the alveoli is directly proportionate to the surface tension and inversely proportionate to the radii. Therefore, small alveoli tend to become still smaller whereas large alveoli tend to become still larger (Fig. 5.2-11). Thus, surface tension tends to produce collapse of the alveoli.

FIGURE 5.2-11 Pressure in the alveoli (**P**) is directly proportionate to the surface tension (**T**) and inversely proportionate to the radii (*r*). Therefore, small alveoli tend to become still smaller and large alveoli tend to become still larger.

Alveolar surface tension playing a major role in generating elastance forces in the lungs can be demonstrated by an experiment (see page 408).

Pulmonary surfactant

The alveolar surface tension opposes the expansion of the lungs during inspiration. The surface tension of pure water and air interface is so high that every inspiration would require an exhausting muscular effort. However, the presence of pulmonary surfactant in the fluid lining the alveoli reduces the surface tension markedly.

Source.

Pulmonary surfactant is secreted by type II alveolar epithelial cells (granular pneumocytes). In the cells, it is stored in lamellar bodies. It comes to the surface of alveoli by the process of exocytosis and mixes with the water molecules present there.

Composition.

Pulmonary surfactant is a complex mixture of several phospholipids, proteins and ions. Four unique proteins have been identified in

surfactant: SP-A, SP-B, SP-C and SP-D. SP-A and SP-D are hydrophilic proteins, and SP-B and SP-C are strongly hydrophobic proteins. Dipalmitoylphosphatidylcholine (DPPC) along with several other phospholipids is responsible for reducing surface tension.

Mechanism of action.

One portion of each phospholipid molecule is hydrophilic and dissolves in the water lining the alveoli. Lipid hydrophobic portion of the molecule is oriented towards the air. This causes spreading of surfactant molecules over the surface of fluid lining the alveoli. Apoproteins and calcium ions are responsible for uniform and quick spreading of surfactant molecules over the surface. Such a hydrophobic surface exposed to air has one-twelfth to one-half of the surface tension of a pure water surface depending upon the concentrations and orientation of surfactant molecules on the surface.

Surface tension with normal alveolar fluid lining without surfactant is about 50 dynes/cm² and with surfactant it varies between 5 and 30 dynes/cm², depending upon the concentration of surfactant.

Functions of pulmonary surfactant

1. Reduces the tendency of alveoli to collapse.

The surface tension in a thin-walled sphere like alveolus tends to make the sphere smaller to collapse. Surfactant, by reducing surface tension decreases the tendency to collapse.

2. Reduces work of breathing.

According to Laplace's law, due to reduction in the surface tension, the mean alveolar radius is increased. This reduces the transmural pressure required for expanding the alveoli. As alveoli are easily expanded, so work of breathing is reduced. The low surface tension also facilitates the reopening of collapsed airway and alveoli.

3. Prevents pulmonary oedema.

Surface tension is retracting force which not only pulls alveolar wall to the centre of alveolus but also pulls fluid from capillaries into the interstitial space surrounding the alveoli and into the alveoli leading to pulmonary oedema. Surfactant prevents this phenomenon by lowering the surface tension.

4. Alveolar stabilization.

Surfactant causes stability of alveoli, i.e. it maintains almost uniform size of alveoli. Due to pulmonary surfactant pulling pressure in the alveoli is reduced from 18 cm of H₂O to 4 cm of H₂O. The mechanism of alveolar instability and how the pulmonary surfactant causes alveolar stabilization is explained.

Alveolar instability due to surface tension effect is produced as follows:

- In the two alveoli (with unequal size) connected to each other the amount of pressure generated in each according to Laplace's law will be:

$$\text{Pressure} = \frac{2 \times \text{surface tension}}{\text{radius}}$$

- Thus, when the surface tension is constant, the pressure developed in the smaller alveolus will be more than the larger alveolus. This will cause pushing of air from smaller alveolus (with higher pressure) to large alveolus (with lower pressure). As a result, the smaller alveolar sac will become more smaller and larger alveolar sac will become more larger (Fig. 5.2-11).
- The above cycle of pushing air from smaller to larger sac will continue till the smaller sac totally collapses leading to large distension of the other sac, thereby producing instability of the alveoli.

Pulmonary surfactant causes alveolar stabilization by following mechanisms:

- In the presence of surfactant, the surface tension developed in the alveoli is inversely proportionate to the concentration of surfactant per unit area.
- In the smaller alveolus, the surfactant molecules form a thick layer, while in a larger alveolus the surfactant molecules are scattered on the larger surface (as number of molecules is limited) (Fig. 5.2-12).
- Thus, in a smaller alveolus the tendency to develop more pressure due

to smaller radius will be neutralized by the tendency to develop less pressure due to more concentration of surfactant per unit area; and the reverse will occur in larger alveolus. In this way, there will not be much pressure gradient between the two alveoli helping to maintain the size of alveolar sac constant. Thus, due to the presence of surfactant stability of alveoli is maintained.

FIGURE 5.2-12 Distribution of surfactant in a (A) large and (B) small alveoli.

Other factors which help in alveolar stabilization along with surfactant are interdependence and fibrous tissue.

- **Interdependence** is a mechanical method of alveolar stabilization. The alveolar septa form a continuous network that is under tension because of lung inflation. Alveoli are tethered together by their

adjoining walls and cannot change volume independently of the neighbouring lung tissue.

- **Fibrous tissue.** The lung is constructed of about 50,000 functional units, each of which contains one or a few alveolar ducts and their associated alveoli. All of these are surrounded by fibrous septa that act as additional splints and stabilize the alveoli.

Factors affecting pulmonary surfactant

Factors which decrease the pulmonary surfactant

- Long-term inhalation of 100% O₂,
- Occlusion of main bronchus,
- Occlusion of one pulmonary artery,
- Cigarette smoking, and
- Cutting both the vagii.

Factors which increase surfactant production

- Thyroid hormones increase the secretion of pulmonary surfactant by increasing the size and number of inclusion bodies in type II alveolar lining epithelial cells.
- Glucocorticoids accelerate the maturation of pulmonary surfactant.

Applied Aspects

Clinical significance of pulmonary surfactant

1. **Respiratory distress syndrome of newborn** or the *hyaline membrane disease* occurs in the newborn babies (especially premature) due to inadequate formation of surfactant, resulting in an elevated alveolar surface tension. Retention of fluid in the lung is an additional factor in respiratory distress syndrome (RDS). During fetal life pulmonary epithelium secretes Cl⁻ in the fluid but at birth epithelial cells start absorbing Na⁺ through epithelial Na⁺ channels (ENaCs) and fluid gets absorbed along with Na⁺. Immaturity of EnaCs is responsible for

pulmonary oedema in RDS. Under this condition it is extremely difficult to expand the lungs.

Dysfunction/overproduction of surfactant proteins is the cause of pulmonary alveolar proteinosis and can lead to respiratory distress. Under this condition it is extremely difficult to expand the lungs.

Sign and symptoms – Respiratory work is greatly increased and there is inadequate exchange of gases due to alveolar instability, pulmonary oedema and collapse of alveoli (atelectasis) in many areas. This results in severe respiratory insufficiency, and the infant may die.

Diagnosis – Plasma levels of thyroid hormones and cortisol are low in infants with RDS.

Treatment – Therapy of RDS includes administration of exogenous surfactant and application of positive-end expiratory pressure (PEEP).

2. *Adult respiratory distress syndrome* occurs due to abnormal surfactant function caused by a variety of severe pulmonary injuries. Clinical trials are now underway using exogenous surfactant in an attempt to improve the outcome in adults.
3. *Patchy atelectasis* occurs due to surfactant abnormality in patients who have undergone cardiac surgery during which a pump oxygenator is used and the pulmonary circulation is interrupted.

Pulmonary compliance

Definition and normal value

- Compliance (C) refers to change in lung volume (ΔV) per unit change in transpulmonary pressure (ΔP), i.e.

$$C = \frac{\Delta V}{\Delta P}$$

Transpulmonary pressure is the difference in the pressure between alveolar pressure and pleural pressure.

- Compliance expresses the distensibility (expansibility) of the lung and chest wall.
- Normal value of compliance for the lungs and chest wall combined is 0.13 L/cm of H₂O and for the lung alone it is 0.22 L/cm of H₂O.

Measurement of total compliance

Total respiratory compliance (combined compliance of chest wall and lungs) can be measured by the pressure–volume curve of the respiratory system. The pressure–volume curve of the respiratory system can be obtained in living subjects by using a spirometer as below:

Procedure

The subject is connected to the spirometer and asked to breathe air through mouth (with nostrils closed). The manometer attached with the spirometer measures airway pressure (transpulmonary pressure). The subject inhales known volume of air from end-expiratory position, and the valve of the spirometer is then shut off to close the airway. The subject holds the breath and then releases the respiratory muscles and change in the airway pressure is measured. The procedure is repeated with actively inhaling or exhaling different air volumes up to the maximum.

The change in the airway pressure is plotted against each air volume and a curve obtained is called the pressure–volume curve of the respiratory system (Fig. 5.2-13).

FIGURE 5.2-13 Pressure–volume curve of the respiratory system.

Observations and inferences

1. The pressure–volume curve of the respiratory system is a sigmoid shape curve which is steepest at the middle and almost flat at both ends (i.e. high and low lung volumes).
2. The volume at which air pressure is 0 mmHg (atmospheric pressure) is called *relaxation volume* which is equal to FRC. At relaxation volume, the recoil of chest wall and recoil of lung balance each other.
3. Above relaxation volume, on increasing lung volumes there is increase in the airway pressure and at maximum inspiration pressure rises up to 30 mmHg. On the other hand, decrease in the lung volumes below relaxation volume airway pressure decreases and at maximum expiration point it decreases up to –30 mmHg.
4. The RV and TLC are limited by decrease compliance of the system as indicated by the reduced slope at both extreme volumes.

Factors affecting compliance of lungs and chest wall

Downward and right shift of the pressure–volume curve indicates decreased total respiratory compliance. The causes of decreased compliance are:

- Pulmonary congestion
- Interstitial pulmonary fibrosis
- Pulmonary oedema

Upward and left shift of the pressure–volume curve indicates increases total respiratory compliance. The causes of increased compliance are:

- Emphysema
- Old age

Measurement of pulmonary compliance

- The compliance of lung alone can be measured by measuring the intrapleural pressure at different lung volumes.
- The intrapleural pressure (being similar to intra-oesophageal pressure) is measured with the help of an intraoesophageal balloon connected to a manometer.
- The subject is made to inspire air from a spirometer in steps of 100 ml and each time the intrapleural pressure is recorded.
- The relationship of lung volume to intrapleural pressure is plotted on a graph, which gives the *inspiratory compliance curve* (Fig. 5.2-14).
- Similarly expiration is also done in steps and *expiratory compliance curve* is obtained (Fig. 5.2-14).
- The inspiratory and expiratory compliance curves do not coincide but form a loop called *hysteresis loop*.
- So, Figure 5.2-14 shows that the lung volume at any given pressure is greater during expiration than during inspiration. This is due to difference in the distensibility (stretchability) of the lungs between inspiratory and expiratory phases. The volume midway between the hysteresis loop (dashed linear line (Fig. 5.2-14) gives the average compliance of the lungs. Had the lungs been a perfectly elastic structure like a spring the pressure–volume relation line would have been linear (Hook's law).

- The curved lines obtained during inspiration and expiration are because of two resistances:
- Viscous resistance due to nonelastic tissues in the lungs, and
- Airway resistance.
- Therefore, to calculate the compliance of the lung, the point on the graph at the end of inspiration, i.e. when there is no air flow should be considered. At this point, there is no airway resistance and no viscous resistance. The compliance calculated from pressure and volume changes at this point indicates the compliance of lung alone due to elastic tissue only.

FIGURE 5.2-14 Change in volume per unit change in intrapleural pressure during quiet respiration. The dotted line represents the pulmonary compliance.

Static versus specific lung compliance

Static compliance.

The compliance measured as described above is the *static compliance*. The static compliance of any system is dependent on its size. Thus, the lung compliance depends upon the amount of functional lung tissue. Thus,

static compliance is not a good measure of absolute distensibility, as is clear from the following example:

For example, if a patient's lung compliance is 0.22 L/cm H₂O, then both lungs together are able to expand 0.22 L for each cm H₂O change in pleural pressure. Assuming equal compliance in both lungs, each lung will take up 0.11 L of gas. If the patient undergoes a pneumonectomy, the compliance measured will be only 0.11 L/cm H₂O, in spite of the fact that distensibility of the remaining lung is normal. Therefore, clinically term specific compliance is used.

Specific compliance

is the compliance of the lung at relaxation volume (the point at the end of a tidal expiration), i.e. the functional residual capacity. The specific compliance is expressed per litre of functional residual capacity (FRC). It is a measure of the absolute distensibility of a structure. For instance, in the above cited example if the FRC is 2.2 L then:

- Specific compliance with both intact lungs will be:

$$= \frac{0.22}{2.2} = 0.1 \text{ L /cm H}_2\text{O}$$

- Specific compliance after pneumonectomy of one lung will be

$$\frac{0.11}{1.1} = 0.1 \text{ L/cm H}_2\text{O}.$$

Factors affecting lung compliance

Lung compliance is inversely proportionate to the lung elastance (elastic recoil force). Therefore, lung compliance is determined on the basis of following elastic forces:

Elastic forces of the lung Tissues due to elastic and collagen fibres contribute smaller amount of elasticity.

Elastic forces caused by surface tension within the alveoli account for about two-thirds of total elastic forces in the lungs.

Alveolar surface tension plays a major role in generating elastance

forces in the lungs and thus is very important factor affecting lung compliance. It can be demonstrated experimentally by recording the compliance of an isolated lung of an animal by first distending it with air and then with saline. Filling the lungs with saline theoretically eliminates the force of surface tension so that only the elastic forces of the lung tissue produce recoil. [Figure 5.2-15](#) shows the results of such an experiment. Compared with air-filled lungs ([Fig. 5.2-15A](#)), the saline-filled lungs ([Fig. 5.2-15B](#)) markedly reduce recoil forces, leading to the conclusion that the elastic forces caused by alveolar surface tension play a major role in generating elastance forces in the lungs.

FIGURE 5.2-15 Pressure–volume relationship of an isolated lung filled (A) with air and (B) with saline. The saline filled lung has far greater compliance due to absence of surface tension at water–air interface seen with air filled lung.

Changes in the lung compliance

- **Decreased compliance**

of the lungs can be caused by lung diseases, (e.g. tuberculosis, silicosis) that produce scarring or fibrosis of the lungs, destruction of the functional lung tissue or both. Reduced compliance produces a condition termed RLD. Patients with RLD must generate greater than normal forces to expand the lungs.

- **Increased compliance**

is produced by the pathologic processes that occur in emphysema as well as from the aging process. Alveolar septa which provide some of the retractive forces in lungs are destroyed under both conditions, but emphysema causes a much more extensive loss of septa than the normal aging process.

Work of breathing

The contraction of respiratory muscles causes the expansion of the thoracic cage and thereby causes expansion of lungs and fall in intra-alveolar pressure and allows the atmospheric pressure to push air into the lungs during inspiration. Thus, to move the air into the lungs, the respiratory muscles have to do work to overcome the following *resistances*.

Resistance to breathing

Tissue resistance.

It is the resistance offered by the tissues as they expand or contract. Tissue resistance comprises:

1. **Elastic resistance.** It is the sum of forces of elastic recoil exerted by the lung and the chest wall. The elastic recoil of the lungs is due to the presence of elastic fibres in the lungs and due to the alveolar surface tension.
2. **Viscous resistance** is the resistance offered by the nonelastic tissues in the lungs.

Airway resistance.

It is the resistance caused by friction of gas molecules between themselves and the walls of the airways. Factors affecting airway

resistance are:

1. **Rate of gas flow.** Greater the rate of gas flow, greater is the resistance. The rate of gas flow is highest in the intermediate sized bronchi as they have highest cross-sectional area; so the highest resistance to flow occurs in this part of a tracheobronchial tree.

2. **Airway radius.** It is the most powerful determinant of resistance. Smaller the radius of airway, greater is the resistance. According to *Poiseuille-Hagen formula* (see page 302),

$$\text{resistance} \propto \frac{1}{r^4}.$$

In other words, if radius decreases by half (keeping the other factors constant), the resistance increases by 16 times.

Airway radius increases when lungs expand (during inspiration) and it decreases when lungs contract (during expiration). Therefore, airway resistance is high during expiration as compared to inspiration. Because of this reason in bronchial asthma patients (where broncho-constriction develops) inspiration is possible but there is extreme difficulty in expiration.

Control of airway diameter

- *Sympathetic adrenergic stimulation* to the airway causes bronchodilation. In human, direct sympathetic nerve activation causes only slight bronchodilation. Because these nerves do not actually innervate the bronchial smooth muscles. However, the bronchial smooth muscles contain a large number of β_2 receptors that respond to circulating adrenergic substances such as epinephrine, norepinephrine and isoproterenol.
- *Vagus nerve (cholinergic) stimulation* causes bronchoconstriction and increase in mucous formation. Cholinergic activity may be the cause of asthma in some individuals.
- *Nonadrenergic noncholinergic* control of bronchial smooth muscle is exerted through following substances:

- Noncholinergic excitatory compounds such as substance P and neurokinins A and B cause bronchoconstriction, mucous secretion and increased vascular permeability. These substances may be involved in pathogenesis of asthma in some individuals.
- Nonadrenergic inhibitory system consists of post-ganglionic neurons that release vasoactive intestinal polypeptide (VIP) and other mediators that cause smooth muscle relaxation and inhibit mucus production.

3. *Length of airway.* It does not change much during respiration or in lung diseases and therefore, is not an important factor.

4. *Type of air flow.* The airway resistance is more in turbulent flow (e.g. during rapid respiration) than in laminar flow or streamline flow in quiet breathing.

Components of work of breathing

The total work done by the respiratory muscles during quiet breathing may be divided into following components:

- Work done to overcome elastic resistance (65%),
- Work done to overcome viscous resistance (7%) and
- Work done to overcome airway resistance (28%).

Calculation of work of breathing

The work of breathing, i.e. the work of inflating the lungs can be calculated by plotting the change in lung volume (ΔV) versus the change in intrapleural pressure (ΔP) (Fig. 5.2-16). The total area represented by $\Delta P \times \Delta V$ in Figure 5.2-16 is proportional to the work that must be performed by the respiratory muscles and to the O_2 utilized by them. The work done by the respiratory muscles can be calculated separately for inspiration and expiration.

FIGURE 5.2-16 Calculation of work done during breathing by plotting the change in volume (ΔV) against change in intrapleural pressure (ΔP): **(A)** in normal quiet breathing; **(B)** in restrictive lung disease (RLD) and **(C)** in obstructive lung disease (OLD).

Work done during inspiration

In [Figure 5.2-16A](#), the area A×BC denotes the total work done during normal inspiration. The work of inspiration can be divided into three fractions:

- **Compliance work**

refers to the work done by respiratory muscles to inflate the lungs

against the *elastic resistance* of chest wall and lungs. It is represented by the grey triangular area AYBCA in [Figure 5.2-16A](#). Thus, most of the work done (65%) is used to overcome elastic resistance.

• **Nonelastic resistance work**

is done to overcome the nonelastic resistance. It includes the work done to overcome:

- Viscous resistance of lungs (7%) and
- Airway resistance (28%).

It is represented by pink area AXBYA in [Figure 5.2-16A](#). Thus, only a small amount (7%) of the work done is used to overcome the viscosity of the lungs and 28% of the work done is utilized to overcome the resistance of air flow through the respiratory passages.

Work done during expiration

Since in quiet breathing, expiration is a passive process so no work is done during expiration. The grey triangle AYBCA in [Figure 5.2-16 A](#) represents the stored elastic energy that is present at the end of inspiration. This stored energy can compress the alveolar gas and create expiratory flow. When the lungs are recoiling back some energy is required to overcome *nonelastic resistance*, i.e. the airway resistance plus viscous tissue resistance. This is represented by the area AYBZA which in normal quiet expiration falls within the triangle AYBCA (stored energy) and so no extra work is required to overcome this resistance.

Work of breathing done in restrictive lung disease

In the presence of RLD, the patient has to overcome significantly higher elastance forces for the normal tidal breathing. So, in RLD more work has to be performed by the respiratory muscles during inspiration to overcome the decreased compliance ([Fig. 5.2-16B](#)).

Minimal work of breathing

is a function of airway resistance and respiratory system compliance ([Fig. 5.2-17A](#)). All species of animals use the combination of tidal volume and respiratory rate that requires the minimal work of breathing. The increase in the elastance, work done in patients with RLD can be minimized by breathing rapidly and shallow ([Fig. 5.2-17B](#)). The tidal volume is decreased but the increased respiratory rate ensures adequate

ventilation of lungs.

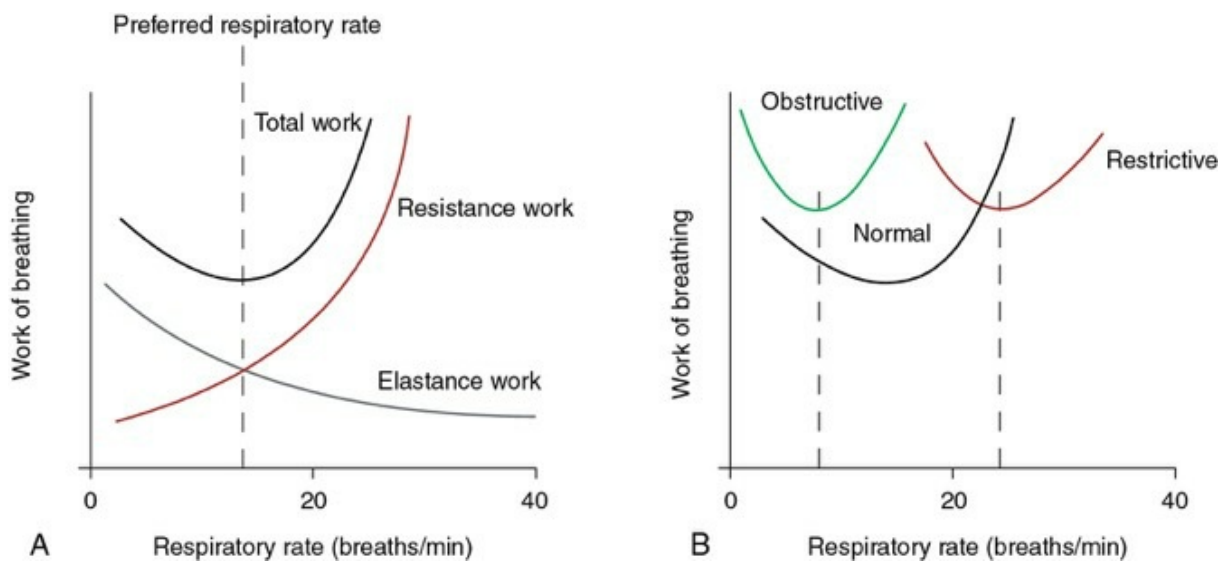

FIGURE 5.2-17 Determinants of an optimal breathing to do minimal work of breathing: **(A)** variations in different components of work of breathing—the preferred respiratory rate to do minimal work of breathing normally is 12–15 breaths/min, with tidal volume 0.5 L and **(B)** total work of breathing curve reflects that the patients with obstructive lung disease (OLD) minimizes their work of breathing by decreasing respiratory rate and increasing tidal volume and those with restrictive lung disease (RLD) do so by decreasing tidal volume and increasing respiratory rate.

Work of breathing done in obstructive lung diseases

In patient with OLD, the airway resistance is increased due to narrowing of passages. The patients must generate increased pressure gradients to produce adequate air flow. So, *during inspiration* more work by respiratory muscles is done to overcome the increased nonelastic resistance, as a result the work loop broadens significantly as is evident from the pink area AXBYA in [Figure 5.2-16C](#) vis-à-vis [5.2-14A](#). Under such circumstances when the work loop extends beyond Y-axis active contraction of expiratory muscles is required to accomplish the task of expiration, as the elastic recoil (stored energy represented by grey triangular area) is not sufficient for it. The extra work performed by expiratory muscles is represented by brown area in [Figure 5.2-16C](#).

Compensatory mechanism.

The resistance work can be minimized by breathing more slowly and

deeply (see [Fig. 5.2-17B](#)). This prolongs the time of expiration, which reduces the pressure gradient necessary to generate gas flow. The increased tidal volume compensates for the decreased respiratory rate so that normal alveolar ventilation is maintained.

Factors affecting total work of breathing

Total work of breathing during quiet respiration under normal circumstances ranges from 0.3 to 0.8 kg mt/min. Normally, the work of breathing represents 2–3% of the resting O₂ consumption.

- If either the respiratory resistance increases or the compliance decreases, the respiratory work will increase and therefore the respiratory muscles will use more O₂ to overcome the added load.
- The work of breathing is also increased markedly during muscular exercise (physiological).

- Chemical Control

Functional anatomy

The lungs have three circulations—pulmonary, bronchial and lymphatic.

Pulmonary circulation

Pulmonary trunk arises from the right ventricle and divides into right

and left pulmonary arteries which convey deoxygenated blood to the right and left lung, respectively. The blood circulates through a capillary plexus intimately related to the walls of alveoli and receives oxygen from the alveolar air. This blood which is now oxygenated is returned to the heart (left atrium) through the pulmonary veins. There are four pulmonary veins, two each (superior and inferior) on the right and left sides. The pulmonary veins have distensibility characteristics similar to those of veins in the systemic circulation.

Bronchial circulation

The lungs also receive oxygenated blood like other tissues in the body. This is conveyed through *bronchial arteries* (two left and one right) which are branches of the descending thoracic aorta. Bronchial blood flow amounts to about 1 to 2% of total cardiac output. The oxygenated blood in the bronchial arteries supplies the connective tissues, septa and large and small bronchi of the lungs. Because the bronchial blood empties into the pulmonary veins and bypasses the right heart, the bronchial circulation therefore constitutes a *physiological shunt*, i.e. a channel that bypasses oxygenation in the lungs. The other example of physiological shunt is coronary vessels that drain into the left side of the heart. These physiological shunts have two effects:

- They reduce the O₂ saturation of arterial blood slightly and
- They make the left ventricular output greater by about 1–2% than the right ventricular output.

Lymphatic circulation

Lungs are richly supplied by lymphatics. Lymphatics are present in the walls of the terminal bronchioles and in all the supportive tissues of the lungs. Particulate matter entering the alveoli during inspiration is removed by way of lymphatic channels. Lymphatics also remove the plasma proteins leaking from the lung capillaries and thus help to prevent the pulmonary oedema. The deep lymphatic vessels follow the bronchi and first drain into the *pulmonary nodes* (in the substance of the lungs) and then into *bronchopulmonary nodes*. The superficial lymph vessels lie near the surface of lungs and converge on to bronchopulmonary nodes. From bronchopulmonary node lymph drains into *tracheobronchial nodes* and from there into the *bronchomediastinal trunk*.

Characteristic features of pulmonary circulation

Introduction

- The pulmonary arteries and their branches are thin walled and distensible, giving the pulmonary arterial tree a large compliance. The distensibility of pulmonary vessels makes the pulmonary circulation a *low pressure, low-resistance and high-capacitance system*.
- The thickness of the right ventricle and pulmonary artery is approximately one-third of the thickness of left ventricle and aorta, respectively.
- The pulmonary arterioles have very little smooth muscles in their walls. The pulmonary capillaries are larger in diameter than systemic capillaries and have multiple anastomoses.
- The pulmonary capillaries surround the alveoli and are sandwiched between their walls, as a result each alveolus seems to be enclosed in a basket of capillaries (Fig. 5.3-1).

FIGURE 5.3-1 Organization of pulmonary circulation.

Pressures in the pulmonary system (fig. 5.3-2)

Right ventricular pressure

during each cardiac cycle reaches a peak value of 25 mmHg in systole (if 120 mmHg in the left ventricle) and falls to 0–1 mm in diastole (if 5 mmHg in left ventricle).

FIGURE 5.3-2 Blood pressure (mmHg) in pulmonary and systemic circulation. RA= right atrium, LA=left atrium, RV=right ventricle and LV=left ventricle

Pulmonary artery pressures

vis-à-vis aorta, respectively are:

- Systolic pressure 25 mmHg and 120 mmHg,

- Diastolic pressure 8 mmHg and 80 mmHg,
- Mean arterial pressure 15 mmHg and 100 mmHg, and
- Pulse pressure 17 mmHg and 40 mmHg.

Left atrial pressure

in major pulmonary veins averages about 5 mmHg in the recumbent human being. Therefore, the pressure gradient in the pulmonary system (mean pulmonary artery pressure–mean pulmonary vein pressure) is $15 - 5 = 10$ mmHg (if 120 mmHg in the systemic circulation).

Pulmonary capillary pressure,

the mean values estimated through indirect means is about 10 mmHg. Since this pressure is far below the colloid osmotic pressure (25 mmHg), so a net suction force of 15 mmHg tends to draw fluid from alveolar interstitial space into the pulmonary capillaries *which keeps the alveoli dry*. However, if the pulmonary capillary hydrostatic pressure rises above 25-mmHg fluid can escape into the interstitial space leading to *pulmonary oedema*. This can happen during exercise, particularly at high altitude, in left heart failure, mitral stenosis and pulmonary fibrosis. It is important to know that even a thin layer of interstitial fluid increases the distance between blood in pulmonary capillaries and gases in alveoli. Since the rate of diffusion is inversely proportional to the diffusion distance, increase in the distance would reduce the rate of gas exchange in the lungs. The resultant hypoxia may be fatal.

Pulmonary wedge pressure

is measured to give an estimate of left atrial pressure. Direct measurement of left atrial pressure is difficult because it requires passing a catheter through left ventricle. Pulmonary wedge pressure is measured by inserting a balloon tipped catheter through the right side of the heart and pulmonary artery until the catheter wedges tightly in a smaller branch of the artery and stops the blood flowing in it. Under such circumstances the ballooned tip of the catheter makes an almost direct connection through the pulmonary capillaries with the blood in pulmonary veins which have the pressure similar to left atrium. The wedge pressure so measured is usually only 2 to 3 mm greater than the left atrial pressure. Clinically, wedge pressure measurements are employed frequently for studying changes in left atrial pressure in

patients with congestive heart failure.

Pulmonary blood volume

- *Pulmonary vessels contain* about 600 ml of blood at rest. Since the pulmonary vessels act as capacitance vessels their blood content can vary from 200 ml to 900 ml.
- *Pulmonary blood volume decreases* under physiological conditions like standing and is shifted to systemic circulation to compensate for the blood pooled in the leg veins due to gravity. Under pathological conditions like haemorrhage the transfer of blood from pulmonary vessels to systemic circulation can partly compensate for the blood loss. Thus, the pulmonary vessels act as a reservoir of blood.
- *Pulmonary blood volume increases* when changing posture from standing to lying. Pathological conditions in which pulmonary blood volume is increased are mitral stenosis, mitral regurgitation and left heart failure.

Pulmonary blood flow: Regional distribution

Pulmonary blood flow

- **Pulmonary blood flow is nearly equal to cardiac output**

since the right ventricle also pushes the same amount of blood simultaneously into the pulmonary circulation as the left ventricle pushes in the systemic.

- **Blood flow through the lungs depends upon**

the relationship between pulmonary arterial pressure (Pa) pulmonary venous pressure (Pv) and alveolar pressure (PA) as:

- The difference between the pulmonary arterial pressure (Pa) and venous pressure (Pv) is the driving pressure and
- The pulmonary capillary pressure must be above the alveolar pressure for the blood flow to continue.

- **Effect of gravity on regional pulmonary blood flow.**

In normal adults in supine position the mean arterial pressure is same all

over the lung and so all regions of the lung are uniformly perfused. However, in erect posture the gravity affects the regional distribution of blood through the lung by altering the pulmonary vasculature pressure due to hydrostatic pressure effect. The hydrostatic pressure adds or subtracts from the pressure levels in supine position if levels are below or above the zero reference plane, respectively. The zero reference plane is at the level of the right atrium, which is approximately in the middle of lung in the region of hilum. Therefore, in standing posture the mean pulmonary arterial pressure in a 30-cm-long lung will be:

- In the middle of lung (zero reference level) 15 mmHg
- At the apex of lung it will be less by 15 cm H₂O or 11 mmHg, i.e. about 4 mmHg, and
- But at the base of lung it will be more by 11 mmHg, i.e. about 26 mmHg.

Perfusion zones of the lung.

Depending on the relationship between alveolar pressure (PA), pulmonary arterial pressure (Pa) and pulmonary venous pressure (Pv), the lung can be divided into three zones in erect posture:

- **Zone 1** refers to the area of zero flow, i.e. any region of the lung that does not receive blood flow. Zone 1 *does not exist in normal lungs*. Zone 1 occurs when the regional pulmonary arterial pressure becomes less than the alveolar pressure ($P_a < P_A$) under these conditions, the pulmonary capillaries collapse (Fig. 5.3-3) and blood flow becomes zero.

Zone 1 is present under following abnormal conditions:

- When the pulmonary arterial pressure is too low as in hypovolaemic shock, pulmonary embolism, or
- When the alveolar pressure is too high to allow flow as in severe obstructive lung disorder.
- **Zone 2** refers to region of lung that has intermittent blood flow. This

occurs during systole when the pulmonary arterial pressure exceeds the alveolar pressure which exceeds the pulmonary venous pressure $P_a > P_A > P_v$, but not during diastole when the arterial pressure is less than the alveolar pressure. Zone 2 blood flow is thus determined by the arterial–alveolar pressure gradient, and not the arteriovenous gradient. This condition is known as *waterfall effect*, because changes in the downstream pressure, or the venous pressure do not alter blood flow. Zone 2 condition normally occurs from the apex to hilum of the lung. At the middle of lung mean pulmonary artery pressure is 15 mmHg, but it varies from 25 mmHg (in the systole phase) to 8 mmHg (in diastole phase). These levels of arterial pressure keep on lowering by 1 cm H₂O (0.8 mmHg) for every 1 cm above the hilum level; therefore, at the apex of the lungs the mean arterial pressure becomes about 4 mmHg and varies from 14 mmHg in a systole to –3 mmHg in diastole. However, the alveolar pressure remains constant, and thus the blood flow (which depends in arterio-alveolar gradient) increases linearly from the top to the bottom of zone 2 (Fig. 5.3-3).

- **Zone 3** refers to region of high continuous blood flow where the capillary pressure remains greater than alveolar pressure during the entire cardiac cycle. So, Zone 3 occurs when the pulmonary artery pressure exceeds the pulmonary venous pressure which exceeds the alveolar pressure ($P_a > P_v > P_A$). This condition occurs near the bottom of the lung. Since the pulmonary vascular pressure increases as we go down from the middle of the lung to its bottom, so the blood flow increases down Zone 3 (Fig. 5.3-3).

FIGURE 5.3-3 Effect of gravity on regional distribution of pulmonary blood flow in standing posture.

Effect of exercise on regional pulmonary blood flow.

During exercise, the blood flow increases in all the regions of the lungs. During heavy exercise pulmonary blood flow increases 4 to 7 times. Near the base of the lung blood flow increases by 2 to 3 times, while in the upper regions it can increase to 8 times. Thus, the entire lung becomes equivalent to zone 3 during exercise. The marked increase in pulmonary blood flow occurs due to two effects:

- *Recruitment of capillaries*, i.e. increasing the number of open capillaries, and
- *Distension of the capillaries* increasing the rate of flow.

Both distension and recruitment of capillaries decrease the resistance to blood flow so much so that even during exercise the pulmonary artery pressure rises very little. This ability of the lungs to accommodate markedly increased flow during exercise has two advantages:

- Conserves the energy of right side of heart, and
- Prevents development of pulmonary oedema during the increased cardiac output.

Pulmonary capillary dynamics

Pulmonary transit time

The mean transit time in the pulmonary circulation from pulmonary valves to the left atrium is about 4 seconds. A red cell traverses the pulmonary capillary in approximately 0.8 seconds at rest (capillary transit time); and 0.3 seconds during exercise. Even in this brief duration, adequate gaseous exchange between red cells and the alveolar air can occur.

Capillary exchange of fluid in the lung, and pulmonary interstitial fluid dynamics

• Dynamics of fluid exchange through pulmonary capillaries

are qualitatively the same except for following quantitative differences from the peripheral tissues in systemic circulation:

- *Pulmonary capillary pressure* is low about 7 mmHg (c.f. 17 mmHg in peripheral tissues).
- *Interstitial fluid pressure* is slightly more negative (–5 to –8 mmHg) than in the peripheral subcutaneous tissue.
- *Capillary permeability* is high, so more proteins leak in the interstitial fluid; consequently the interstitial oncotic pressure is also high, averaging about 14 mmHg (c.f. 7 mmHg in peripheral tissues).
- *Alveolar walls are thin* and may rupture when the interstitial pressure becomes greater than atmospheric pressure, which allows dumping of fluid from the interstitial spaces into the alveoli.

• Mean filtration pressure at the pulmonary capillaries

is +1 mmHg. This value is derived from the balance of Starling forces at the capillary membrane as given:

- Outward forces are:
- Interstitial oncotic pressure = 14 mmHg (pulls fluid out)
- Interstitial hydrostatic pressure = –8 mmHg (pulls fluid out),

- Capillary hydrostatic pressure = 7 mmHg (pushes fluid out)
- Total outward force = 29 mmHg
- Inward force
- Plasma oncotic pressure = 28 mmHg
- Net mean filtration pressure = $29 - 28 = 1$ mmHg

- **Filtration of fluid**

from the pulmonary capillaries into the interstitial space caused by the net filtration pressure of +1 mmHg is very small in amount. Except for a meagre amount that evaporates in the alveoli, most of this fluid is pumped back to the circulation through the pulmonary lymphatic system. So practically a negligible amount of fluid is present in the interstitial space.

Pulmonary oedema

- Theoretically, pulmonary oedema can occur due to change in any of the four Starling forces resulting in increased capillary filtration in the same way as peripheral oedema can occur.
- *Increase in the capillary hydrostatic pressure* is by far the most common factor responsible for pulmonary oedema in conditions leading to left heart failure or mitral valvular disease. The pulmonary capillary pressure normally must rise equal to the plasma colloid osmotic pressure, i.e. above 28 mmHg. Thus, there is safety factor against pulmonary oedema of about 21 mmHg.
- *Increase in capillary permeability* due to damage to capillary membrane caused by infections or breathing of irritating gases produces rapid leakage of both plasma proteins and fluid out of the capillaries (exudation).
- *In acute left heart failure*, when capillary pressure rises above the safety level, lethal pulmonary oedema can occur within minutes to hours. When capillary pressure rises to 50 mmHg, death frequently ensues

within less than 30 minutes from acute pulmonary oedema.

- *In chronic cases of pulmonary oedema*, there occurs a compensatory increase in the lymphatic drainage as much as tenfold which prevents pulmonary oedema even at higher capillary pressure. In a patient with chronic mitral stenosis, pulmonary capillary pressure of 40 to 50 mmHg has been measured without the development of significant pulmonary oedema.

Functions of pulmonary circulation

- *Respiratory gas exchange* is the major function of pulmonary circulation. This function has been discussed in [Chapter 5.4](#) on Pulmonary Diffusion.
- *Other functions* of pulmonary circulation which have been described on page 394 are:
 - Reservoir for left ventricle,
 - Filter for removal of emboli and other particles from blood,
 - Removal of fluid from alveoli,
 - Role in absorption of drugs, and
 - Synthesis of angiotensin converting enzyme (ACE).

Regulation of pulmonary blood flow

The pulmonary blood flow is affected by autonomic innervation and large number of circulating humoral factors.

Neural control

Efferent sympathetic vasoconstrictor nerves

richly innervate the pulmonary blood vessels. But these nerves have *no resting discharge and tone*, which means they can only show an increase in activity when stimulated. These participate in the vasomotor reflexes, e.g.

- *Baroreceptor stimulation* produces reflex dilatation of pulmonary vessels, while
- *Chemoreceptor stimulation* causes pulmonary vasoconstriction.

However, the effect of vasodilatation and vasoconstriction is more on the capacity rather than the resistance of pulmonary vessels. The vasoconstriction produced in the lungs due to sympathetic discharge is considerable and results in transfer of pulmonary blood in systemic circulation, e.g. during acute haemorrhage.

Afferent control through vagus is mediated through following receptors:

- *Pulmonary baroreceptors* are present in the tunica adventitia of pulmonary trunk and its two major branches. These vagal mechanoreceptors detect rise in pressure in pulmonary artery and produce reflex bradycardia and hypotension.
- *Pulmonary volume receptors* are the vagal mechanoreceptors present at the junction of pulmonary vein with left atrium. Stimulation of these receptors produces tachycardia and diuresis which help in regulating blood volume. These vagal receptors could be afferent limb of the Bainbridge reflex.
- *J receptors* (juxtapulmonary receptors) are present adjacent to pulmonary capillaries in the alveolar interstitial space. These are stimulated by multiple microemboli in the small pulmonary vessels and also by the fluid entrapped in interstitial space specially after exercise and at high altitude. Stimulation of J receptors leads to *reflex tachypnoea* (increases in rate of breathing) and reduction of skeletal muscle tone. A.S. Paintal, an Indian physiologist who discovered J receptors postulated that stimulation of these receptors induces dyspnoea, which together with reduction of muscle tone would discourage exercise, thereby taking away the trigger for pulmonary congestion.

Conclusion. On the whole the neural control on the pulmonary circulation is not very strong, since all the cardiac output has to pass through the pulmonary circulation. Mostly pulmonary vessels act as passive distensible tubes that enlarge with increasing luminal pressure and become narrow with the decrease in pressure.

Chemical control

1. Local hypoxia

is responsible for most significant alterations in pulmonary blood flow by producing *vasoconstriction*. This is a local and direct action, since it can be demonstrated in isolated (denervated) perfused lungs. This is exactly opposite to what happens in systemic circulation where low pO_2 produces vasodilatation. Both of these opposite responses are very useful for the body:

- *In systemic circulation, low pO_2 in tissues indicates that oxygen supply is insufficient for the demands of the tissues. Therefore, low pO_2 induced vasodilation increases the blood flow and corrects the deficiency.*
- *In lungs low pO_2 in a region means that the alveoli in that region are not well ventilated. Therefore blood flow through that region is waste. Since it will not get adequately oxygenated, thus, the local low pO_2 induced vasoconstriction in the lungs is a phenomenon that diverts pulmonary blood flow from the alveoli that are poorly ventilated to better ventilated regions so that blood can be properly oxygenated.*

Mechanism. The smooth muscles of pulmonary arteries contain O_2 sensitive K^+ channels, which mediate the vasoconstriction caused by hypoxia. This is in contrast to systemic arteries, which contain adenosine triphosphate (ATP) dependent K^+ channels that permit more K^+ efflux with hypoxia and causes vasodilation rather than vasoconstriction.

2. Hypercapnia and acidosis

also produce vasoconstriction. The effects of pCO_2 and acidosis on pulmonary vessels are just opposite to those in the systemic vessels where these stimuli produce vasodilation. The functional significance of this response is same as in the case of local hypoxia.

3. Chronic hypoxia,

as occurs in high altitude dwellers, is associated with a marked increase in pulmonary arterial pressure (*pulmonary hypertension*), which imposes a heavy afterload on the right ventricle that results in right ventricular hypertrophy, right heart failure and pulmonary oedema. This is the reason that:

- Thick pulmonary precapillary vessels develop in high altitude dwellers and
- Children born and raised at high altitude show pulmonary hypertension.

Humoral control

The pulmonary vessels respond to circulating agents through their receptors located on smooth muscles of the vasculature (Table 5.3-1).

TABLE 5.3-1

Receptors on Smooth Muscles of Pulmonary Vasculature and Their Effects

Introduction

As discussed earlier, the external respiration (supply of O₂ from atmosphere to body tissues and removal of CO₂ from the body tissues to atmosphere) is accomplished by three major processes:

- *Pulmonary ventilation*, i.e. exchange of gases between the environment and lungs,
- *Pulmonary diffusion*, i.e. transfer of gases from alveoli to capillary blood across the respiratory membrane, and

- *Transport of gases* from the blood to the tissue cells and back.

To understand the *intricacies* of diffusion of gases across the respiratory membrane it is essential to have knowledge about the following related aspects and concepts, most of which form the contents of this chapter:

- *Pulmonary perfusion*, i.e. *pulmonary blood flow*. Special problems related to pulmonary haemodynamics have important implications for gas exchange in the lungs. Most of these have been discussed in [Chapter 5.3](#).
- *Physics of gas diffusion and gas partial pressures*. The rate at which the respiratory gases diffuse across the respiratory membrane is a much more complicated problem, requiring a deeper understanding of the physics of diffusion and gas exchange.
- *Alveolar ventilation*, i.e. the rate at which new air reaches the gas exchange area of the lungs. Alveolar ventilation governs the process of pulmonary diffusion in its own way.
- *Alveolar ventilation–perfusion ratio*. It is the ratio of alveolar ventilation and pulmonary blood flow. This is highly quantitative concept which was developed to help in understanding respiratory exchange when there is imbalance between alveolar ventilation and alveolar blood flow.
- *Diffusion of gases through the respiratory membrane* is the main process which transfers gases from the alveoli into the capillaries. Various important aspects of this process have also been discussed in this chapter.

Physics of gas diffusion and gas partial pressures

It is worthwhile to recapitulate some of the basic principles and laws governing the behaviour of gases, for a better understanding of the process of diffusion between alveolar air and pulmonary capillary blood. Consequently, the present discussion is on some of the important aspects concerning physics of gas diffusion and gas partial pressures.

Gas pressure

The gas molecules have a kinetic energy so they are in a continuous random motion. These molecules bounce against each other and/or against the walls of container and exert a pressure. The gas pressure (P) exerted depends upon following factors:

Concentration of molecules (n).

It is obvious that greater the concentration of the molecules of gas, the greater would be the force exerted by the molecules against the container walls at any given time. Therefore, the pressure of a gas is directly proportional to its concentration, i.e. (i)

$$P \propto n$$

Volume (V).

Unlike liquids, gases expand to fill the volume available to them. Therefore, it is obvious that the pressure exerted by a constant number of gas molecules will be more if the volume is less and vice versa. Therefore, at a constant temperature, the pressure (P) of a given mass of gas is inversely proportional to its volume (V), i.e.

$$p \propto \frac{1}{v}$$

This is called *Boyle's law* of gases.

Absolute temperature (T).

According to *Charles' law*, at a constant pressure the volume of gas is directly proportional to its absolute temperature, i.e. $V \propto T$, and as mentioned above according to Boyle's law

$$P \propto \frac{1}{v}.$$

Therefore, it can be derived that:

$$P \propto T$$

From equation (i), (ii) and (iii) it can be derived that:

$$P = \frac{nRT}{V} \text{ where}$$

P = Pressure of gas,

n = Number of molecules of gas,

T = Absolute temperature,

V = Volume of gas and

R = Gas constant.

Partial pressure

According to *Dalton's law* of partial pressure, the total pressure exerted by a mixture of gases is equal to the sum of the partial pressure of all gases present in the mixture. Thus, the partial pressure (p) refers to the pressure exerted by any one gas present in a mixture of gases. It is equal to the total pressure exerted by the mixture of gases times the fraction of the total amount of mixture of gases it represents. Hence, the partial pressure (p) of a gas can be calculated by multiplying its fractional concentration by the total pressure. For example, environmental air (which has atmospheric pressure (at sea level) of about 760 mmHg) is a mixture of 21% oxygen (O₂) and 79% nitrogen (N₂). Therefore, the partial pressure (p) of O₂ and N₂ respectively will be:

$$p_{O_2} = 760 \times \frac{21}{100} = 160 \text{ mmHg, and}$$
$$p_{N_2} = 760 \times \frac{79}{100} = 600 \text{ mmHg.}$$

Partial pressure of gases in water and tissues

It is important to have knowledge about the partial pressure of gases in water and tissues, because the respiratory gases to cross the respiratory membrane must first dissolve in the tissues and then diffuse into the plasma of pulmonary capillaries. The pressure (p) of a gas in a solution is determined not only by its concentration but also by its solubility coefficient. According to *Henry's law*, when temperature is kept constant, the content of gas (n) dissolved in any solution is directly proportional to the partial pressure of a gas, i.e.

$n = p.c.$, where

n = concentration (amount) of a gas in a solution,

p = partial pressure of gas, and

c = solubility coefficient of the gas.

Gas content, partial pressure and solubility

need further clarification. When a gas under pressure comes in contact with a liquid, some of the gas molecules get dissolved in it. As more and more molecules become dissolved, they diffuse all over the liquid medium and some of them start bouncing out of the liquid phase into the gas phase. Ultimately, an *equilibrium* is reached when the number of gas molecules entering the liquid phase equals the number of molecules leaving it.

Partial pressure

of a gas in a liquid represents the pressure it would exert in the gas phase. *At equilibrium*, the partial pressure in the liquid phase equals the partial pressure in the gas phase. *In the absence of equilibrium*, the partial pressure of a gas in liquid phase is less than in the gas phase.

Gas content

represents the volume of the gas per unit volume of liquid that is present. The units of gas content are volume of gas/volume of solvent (e.g. ml/L, ml, dl and so on).

Solubility

of a gas is a major determinant of the number of molecules present. A higher solubility increases the rate of diffusion, because this indicates the presence of an increased number of molecules.

Solubility coefficient

is a constant for each gas that equates gas content and partial pressure. Solubility coefficient of gases (important to respiratory physiology) is given in Table 5.4-1. Increasing the temperature reduces the solubility coefficient of gases (Table 5.4-1). It is important to note that *solubility coefficient of carbon dioxide (CO₂) is about 24 times more and that of nitrogen (N₂) is one half that of oxygen (O₂).*

TABLE 5.4-1

Solubility Coefficient of Important Gases to Respiratory Physiology

Temperature (°C)	Solubility coefficient (ml gas/ ml saline/ mmHg gas tension)			
	O ₂	N ₂	CO ₂	CO
0	0.049	0.024	1.71	0.035
20	0.032	0.016	0.90	0.023
37	0.024	0.012	0.58	0.019

Water vapour pressure

The atmospheric air entering the respiratory passages during inspiration is humidified by the water vapours from the conducting passages. By the time, the atmospheric air reaches the alveoli it is saturated with water vapours. Thus, in the alveolar air, besides O₂ and N₂, water vapours also exert its partial pressure. Vapour pressure of water is dependent upon its temperature. At body temperature (37°C) the vapour pressure of water in alveolar air is 47 mmHg.

Alveolar ventilation

Alveolar ventilation is the volume of the fresh air which reaches the gas exchange area of the lung each minute. During inspiration some of the air inhaled never reaches the gas exchange areas but instead fills the non-gas exchange areas (conducting zone) of the respiratory tract called the *dead space*, which is equal to about 150 ml. Thus, alveolar ventilation is not equal to pulmonary ventilation (PV) or the so-called minute respiratory volume (MV), which equals tidal volume (500 ml in quiet respiration) multiplied by the respiratory rate (12 breaths/min), i.e. about

6 L/min.

During expiration out of 500 ml of tidal volume 150 ml of the alveolar expired air remains in the conducting passages. Therefore, of 500 ml air entering the lungs only 350 ml/breath is the fresh air which contributes to alveolar ventilation. Thus, alveolar ventilation can be calculated as:

Alveolar ventilation (VA) = Respiratory rate \times (tidal volume – Dead space volume), with a normal tidal volume of 500 ml, a normal dead space of 150 ml, and a respiratory rate of 12 breaths per minute, alveolar ventilation equals $12 \times (500 - 350)$, or 4200 ml/min.

Physiological significance of alveolar ventilation

The physiological significance of alveolar ventilation can be understood by comparing the alveolar ventilation of two subjects with following parameters:

- **Subject A,**

having normal breathing with TV of 500 ml and respiratory rate (RR) of 12 breaths/min will have:

- Pulmonary ventilation = $12 \times 500 = 6$ L/min, and
- Alveolar ventilation = $12 \times 500 - 150 = 4.2$ L/min.

- **Subject B,**

having rapid shallow breathing with tidal volume of 200 ml and respiratory rate 30/min will have:

- Pulmonary ventilation = $30 \times 200 = 6$ L/min and
- Alveolar ventilation = $30 \times (200-150) = 1.5$ L/min.

- **On comparison,**

we see that both the subjects A and B have similar amounts of pulmonary ventilation (6 L/min), but the subject B has the alveolar ventilation (1.5 L/min) which is much less than that of subject A (4.2 L/min). Consequently, the subject B is likely to suffer from hypoxia and hypercapnia.

Dead space air

Dead space air is the portion of minute ventilation that does not take part

in exchange of gases. There are three types of dead spaces (Fig. 5.4-1):

FIGURE 5.4-1 Dead space: (A)Anatomical, (B+C+D+E+F) Alveolar and (A+B+C+D+E+F) Physiological.

1. Anatomical dead space

refers the volume of air present in the conducting zone of the respiratory passage, i.e. from nose to terminal bronchioles. The anatomical dead space ventilation (V_D) is a function of the anatomical dead space and respiratory rate. As mentioned earlier, the anatomical dead space contains approximately 150 ml of air, therefore, at a normal respiratory rate of 12 breaths/min, the anatomical dead space ventilation will be 150×12 , i.e. 1.8 L/min.

2. Alveolar dead spaceair

refers to the volume of air present in those alveoli which do not take part

in gas exchange. Normally, all the alveoli take part in gas exchange, but in some lung diseases, some alveoli do not take part in gas exchange because of following reasons:

- *When alveoli have zero blood flow* (Zone 1 condition), the volume of air ventilating such alveoli does not take part in gas exchange,
- *When alveoli are over ventilated*, some of the air which is in excess of the volume required to equilibrate with the blood is not able to take part in gas exchange. These alveoli form the alveolar dead space and the air present in them is called the alveolar dead space air.

3. Physiological dead space

refers to the total dead space which includes both the anatomical and alveolar dead spaces. In a normal healthy person, physiological dead space nearly equals the anatomical dead space. However, in certain respiratory disorders with many nonfunctioning alveoli the physiological dead space may be as much as 10 times the anatomical dead space; obviously, such patients would have very little effective alveolar ventilation which results in respiratory distress. Some of such common respiratory disorders include advanced stages of:

- Emphysema,
- Bronchiectasis and
- Pulmonary embolism.

Measurement of anatomical dead space

Single breath, oxygen technique.

This technique is also called Single breath Nitrogen washout test. In this test, nitrogen contents in the expired air are used as an indicator for determining the dead space.

Procedure. The subject is asked to take a deep breath of pure oxygen (100% O₂). Then steadily exhales into the nitrometer, which continuously measures N₂ contents in the expired air. The anatomical dead space can be measured by the analysis of single breath nitrogen curve (Fig. 5.4-2). The curve has four phases labelled by roman letters (I, II, III and IV).

- During inspiration, N₂ contents are nil (zero %) as subject has inspired

pure O₂.

- During initial phase of expiration (Phase I), N₂ contents are nill (zero %) as the expired air is from the dead space (which is filled with pure O₂).
- Subsequently (Phase II), there is rise in N₂ contents in expired air because exhaled air contains mixture of dead space air and alveolar air.
- In phase III, the N₂ contents reach to a plateau (60%) and phase III of single breath nitrogen curve ends at closing volume (CV) and followed by the phase IV. The CV is the lung volume at which the airways in lower (basal) part of the lung begin to close because of lesser transmural pressure in these regions. The CV is always above residual volume.
- Phase IV. In this phase N₂ contents of the expired air are further increase, because the upper parts of the lung are more distended at the beginning of inspiration, therefore N₂ in these regions get less diluted with oxygen.
- The volume of the anatomical dead space is measured by placing a vertical line on the record from mid-point of phase II of expiration (red area X = blue area Y).

FIGURE 5.4-2 Single breath curve for measuring dead space air. The changes in N₂ concentration of expired air during expiration are indicated by various phases (I-IV). (DS = dead space)

Measurement of physiological dead space

Bohr's equation

is used to measure the physiological (total) dead space by determining CO₂ tensions in the expired and alveolar gas. Bohr's equation is based on the fact that inspired air contains negligible quantity of CO₂ (almost zero). Therefore, all the CO₂ in expired air is derived from the functional alveoli. The equation is:

$$(V_T - V_D) \times p_{ACO_2} + (V_D \times p_{CO_2} \text{ in inspired air, i.e. zero}) = V_T \times p_{ECO_2}$$

$$\text{or } VT - VD = \frac{VT \times pECO_2}{pACO_2}$$

$$\text{or } VD = \frac{VT - VT \times pECO_2}{pACO_2}$$

$$\text{or } VD = VT \times (1 - pECO_2),$$

where

VD = Physiological (total) dead space air,

VT = Tidal volume,

pECO₂ = Carbon dioxide tension in mixed expired air and is represented by average pCO₂ and of the total expired air.

pACO₂ = Carbon dioxide tension in alveolar air and is theoretically represented by the pCO₂ of end-tidal samples of expired gases.

For example, if

$$pECO_2 = 28 \text{ mmHg}$$

$$pACO_2 = 40 \text{ mmHg}$$

$$VT = 500 \text{ ml}$$

$$\text{then, } VD = 150 \text{ ml}$$

Effect of gravity on alveolar ventilation

Alveolar ventilation is more or less evenly distributed in supine position, because hydrostatic effect on intrapleural pressure is reduced. However, in a vertical lung the alveolar ventilation is unevenly distributed because of variation in compliance in different regions of the lungs as explained (Fig. 5.4-3):

- The alveolar pressure is zero throughout the lung under static conditions.
- The intrapleural pressure shows a gradient of about 8 cm H₂O between

apex ($-10 \text{ cm H}_2\text{O}$) and base ($-2 \text{ cm H}_2\text{O}$).

- So, transpulmonary pressure (intrapleural pressure – alveolar pressure) also varies from $-10 \text{ cm H}_2\text{O}$ at apex to $-2 \text{ cm H}_2\text{O}$ at the base.
- Consequently, the lung compliance (change in lung volume per unit change in transpulmonary pressure) also shows corresponding gradient between apex and base.
- Because of more negative intrapleural pressure at apex ($-10 \text{ cm H}_2\text{O}$) the apical alveoli are larger but poorly ventilated. While the basal alveoli because of less negative ($-2 \text{ cm H}_2\text{O}$) intrapleural pressure is smaller but better ventilated.
- There is a linear reduction in regional alveolar ventilation from base to apex in erect position (Fig. 5.4-4).

FIGURE 5.4-3 Correlation of transpulmonary pressure ($PPL = PA - PL$) and lung inflation in different regions during erect

posture. PA = alveolar pressure, PL= intrapleural pressure, and PPL = transpulmonary pressure.

FIGURE 5.4-4 Distribution of alveolar ventilation and pulmonary blood flow in different regions of lung during standing.

Clinical significance of effect of gravity on alveolar ventilation.

Arterial oxygenation can be improved in patients with unilateral lung disease by making them lie on their sides so that the good lung is in the dependent position. Somehow, the situation is opposite in infants, who do better with the diseased lung in dependent position.

Alveolar ventilation–perfusion ratio

Alveolar ventilation–perfusion ratio (VA/Q) is the ratio of alveolar ventilation per minute to quantity of blood flow to alveoli per minute. Normally, alveolar ventilation (VA) is 4.2–5.0 L/min, and the pulmonary blood flow (equal to cardiac output) is approximately 5 L/min. So, the normal VA/Q is about 0.84 to 0.9. At this ratio maximum oxygenation occurs.

Effect of gravity on VA/Q

- Because of the effect of gravity the basal alveoli are over perfused and apical alveoli are under perfused (see details on page 414). There is almost of a linear reduction in the blood flow from base to apex (Fig. 5.4-4).
- The alveolar ventilation also reduces linearly from the base to apex (Fig. 5.4-4), and thus the basal alveoli are over ventilated and apical alveoli are under ventilated (For detailed mechanism see page 400).
- However, gravity affects perfusion much more than it affects ventilation. Hence, as shown in Fig. 5.4-4, the apical alveoli are more under perfused than under ventilated. Because of this relationship the VA/Q is more than 1. In the middle of lung the alveolar ventilation equilibrates the perfusion. As we go up from middle of the lung to apex the VA/Q ratio goes on increasing and is about 3 at the apices. Conversely, at the bases the alveoli are more over perfused than over ventilated, as a result the VA/Q is always less than normal. As we move down from the middle of the lungs to the bases, the VA/Q ratio goes on decreasing, at the bases it is about 0.6.

Applied Aspects

- Because of high VA/Q ratio, the apical alveolar air has low pCO₂ and high pO₂. Since high alveolar pO₂ provides favourable environment for the growth of *Mycobacterium tuberculosis* so the apices of lungs are more predisposed to tuberculosis.

Causes of alteration in the VA/Q ratio

Obviously, the factors altering alveolar ventilation or/and pulmonary perfusion will alter the VA/Q ratio.

Causes of uneven alveolar ventilation

include:

- Bronchial asthma,
- Emphysema,
- Pulmonary fibrosis,

- Pneumothorax, and
- Congestive heart failure.

Causes of uneven pulmonary perfusion

are:

- Anatomical shunts, e.g. Fallot's tetralogy,
- Pulmonary embolism,
- Regional decrease in pulmonary vascular bed in emphysema, and
- Increased pulmonary resistance in conditions like pulmonary fibrosis, pneumothorax and congestive heart failure.

Effects of alterations in the VA/Q ratio

1. Normal VA/Q ratio

implies that there is both normal alveolar ventilation and normal alveolar perfusion. The exchange of gases is optimal and the alveolar pO_2 is about 104 mmHg and pCO_2 is about 40 mmHg.

2. Increased VA/Q ratio

means that alveolar ventilation is more than the perfusion. As a result the whole of the alveolar air is not utilized for gaseous exchange. The extra air in the alveoli which goes waste forms the so-called *alveolar dead space air*. There will also be change in the composition of alveolar air (Fig. 5.4-5).

FIGURE 5.4-5 Relationship of alveolar ventilation–perfusion ratio (VA/Q) with alveolar air pO_2 and pCO_2 .

When VA/Q ratio increases to infinity, i.e. when alveolar perfusion becomes zero, no exchange of gases can occur. Under such circumstances the composition of alveolar air becomes equal to the humidified inspired air, which has a pO_2 of 149 mmHg and a pCO_2 of 0 mmHg (Fig. 5.4-5).

Thus, the effects of increased VA/Q are:

- Decreased exchange of gases at respiratory membrane,
- Alveolar dead space formation, leading to increase in physiological (total) dead space, and
- Change in alveolar air composition.

3. Decreased VA/Q ratio

occurs when the rate of blood flow is more than the rate of alveolar ventilation. Since the alveolar ventilation is not enough to provide oxygen, a fraction of venous blood passes through the pulmonary capillaries without becoming oxygenated. This fraction is called *shunted blood*. This shunted blood along with additional deoxygenated blood from bronchial veins to pulmonary vein (about 2% of cardiac output) forms the so-called *physiological shunt*. The greater the physiological shunt, the greater is the amount of blood that fails to be oxygenated as it

passes through the lungs.

When VA/Q becomes zero, there is no alveolar ventilation, so that the air in the alveolus comes to equilibrium with O_2 and CO_2 in the venous blood flowing through the pulmonary capillaries. So, alveolar air will have a pO_2 of 40 mmHg and pCO_2 of 45 mmHg.

Thus, the *effects of decreased VA/Q ratio are:*

- Decreased exchange of gases at the respiratory membrane,
- Shunting of part of venous blood, and
- Change in alveolar air composition (Fig. 5.4-5), under such circumstances an *anatomical shunt* is said to exist. The presence of an anatomical shunt means that true venous blood is mixing with oxygenated blood. The anatomical shunt may be intra- or extrapulmonary. An extrapulmonary anatomical shunt may result from congenital cardiac malformations such as atrial or ventricular septal defect with right to left blood flow.

Alveolar air

Volume of air which is available for exchange of gases in the alveoli per breath is called alveolar air, which is equivalent to tidal volume minus dead space, i.e. (500–150) or 350 ml.

Composition of alveolar air

Composition of alveolar air can be studied by *alveolar air sampling* that involves analysis of the last few millilitres of air that issues from the lungs during expiration. Alveolar air composition is considerably different than that of atmospheric air (Table 5.4-2) because of the following reasons:

TABLE 5.4-2

Composition and Partial Pressure of Gases in Atmospheric Air, Humidified Air, Alveolar Air and Expired Air

Partial pressure (mmHg) and concentration (percentage) of various gases				
Gas	Atmospheric air	Humidified air	Alveolar air	Expired air
N ₂	597.0 (78.62%)	563.4 (74.09%)	569.0 (74.9%)	566.0 (74.5%)
O ₂	159.0 (20.84%)	149.3 (19.67%)	104.0 (13.6%)	120.0 (15.7%)
CO ₂	0.3 (0.04%)	0.3 (0.04%)	40.0 (5.3%)	27.0 (3.6%)
H ₂ O	3.7 (0.5%)	47 (6.20%)	47.0 (6.2%)	47.0 (6.2%)
Total	760.0 100%	760 100%	760 100%	100%

1. Water vapours dilute the other gases in the inspired air.

As shown in Table 5.4-2, the atmospheric air is composed mostly of nitrogen (79%) and oxygen (21%). It contains almost no carbon dioxide or water vapour. The dry atmospheric air becomes totally humidified as it passes through the respiratory passages. Water vapour pressure rises to 47 mmHg at body temperature. As total pressure remains the same, so pO_2 decreases from 159 mmHg in atmospheric air to 149 mmHg in humidified air, and

- pN_2 decreases from 597 mmHg in atmospheric pressure to 563 mmHg in the humidified air.

2. Alveolar air is renewed very slowly by atmospheric air.

Since with each breath only 1/7th of the alveolar air is replaced by fresh air, so the composition of the two is different. This slow replacement of alveolar air prevents sudden changes in gas concentrations in the blood.

3. Oxygen is constantly being absorbed from the alveolar air

so its pO_2 is reduced to 104 mmHg. The alveolar O₂ concentration is controlled by a dynamic equilibrium between the rate of O₂ absorption into the blood and the rate of entry of new O₂ into the lungs.

4. Carbon dioxide is constantly diffusing from the pulmonary blood to alveoli

so the pCO_2 of alveolar air become 40 mmHg which is almost negligible in the atmospheric air.

Composition of expired air

As shown in Table 5.4-2, the composition of expired air is different than that of alveolar air. This is because of the fact that the expired air is a combination of dead space air and alveolar air. The expired air can be

split into three portions:

- **First portion** of the expired air represents the dead space air and its composition is similar to typical humidified air.
- **Middle portion** of the expired air is a mixture of more and more alveolar air with the dead space air until the dead space air is washed out.
- **Last portion** of the expired air represents the alveolar air and so is used to study the alveolar air composition (*alveolar air sampling*).

For alveolar air sampling last 10 ml of expired air, during quite breathing can be collected using modern apparatus with suitable automatic valve.

Alveolar gas equation

The alveolar pO_2 and pCO_2 are interrelated to each other, since both are related to alveolar ventilation and alveolar perfusion. The alveolar gas equation which gives the relationship between alveolar pO_2 and pCO_2 is as follows:

$$pAO_2 = pIO_2 - pACO_2 \times \left(FIO_2 + \frac{1 - FIO_2}{RQ} \right), \text{ where}$$

- pAO_2 = Alveolar air pO_2 (normally 104 mmHg)
- pIO_2 = Inspired air, i.e. atmospheric pO_2 (normally 159 mmHg)
- $pACO_2$ = Alveolar air pCO_2 (normally 40 mmHg)
- FIO_2 = Fraction of O_2 in dry air (normally 0.2)
- RQ = Respiratory quotient, i.e. the ratio of CO_2 output and O_2 intake by tissues per minute (normally 0.8).

The gas analysis for composition of gas mixture or in body fluids is done by the use of O_2 and CO_2 electrodes. These are small probes

sensitive to O_2 and CO_2 are inserted into the airway, or into blood vessels or tissues, and partial pressure of O_2 and CO_2 (pO_2 & pCO_2) can be recorded continuously.

Diffusion of gases through the respiratory membrane

Respiratory unit and respiratory membrane

Each respiratory unit

is composed of a respiratory bronchiole, alveolar ducts, atria and alveoli. There are about 300 million respiratory units in the two lungs. Gas exchange occurs through the membranes of all the structures forming a respiratory unit, not merely in the alveoli themselves.

Respiratory membrane

or pulmonary membrane or the alveolocapillary membrane is the name given to the tissues which separate the capillary blood from the alveolar air. The exchange of gases between the capillary blood and alveolar air requires diffusion through this membrane.

Structure of Respiratory Membrane. It consists of following layers (Fig. 5.4-6):

- Layer of pulmonary surfactant and fluid lining the alveolus,
- Layer of alveolar epithelial cells,
- Basement membrane of the alveolar epithelial cells,
- A very thin interstitial space between the epithelial and endothelial cells,
- Basement membrane of capillary endothelial cells, and
- Layer of capillary endothelial cells.

FIGURE 5.4-6 Layers of respiratory membrane.

Characteristic features

of respiratory membrane which optimize for the gas exchange are:

- *Thickness* of the respiratory membrane, despite the large number of layers forming it averages about $0.6 \mu\text{m}$.
- *Surface area* of the total respiratory membrane is about 70 square metres in the normal adult.

Factors affecting diffusion across respiratory membrane

The diffusion of gases across the respiratory membrane is affected by following factors:

1. Thickness of respiratory membrane.

As mentioned above the thickness of respiratory membrane (about 0.6 μm) has been optimized for gas exchange. The rate of diffusion through the membrane is inversely proportional to the membrane thickness (diffusion distance, denoted by d), i.e.

$$V_{\text{gas}}(\text{volume of gas diffused}) \propto 1/d$$

Any factor which increases thickness will therefore significantly decrease the gaseous exchange. Examples are:

- Pulmonary oedema, i.e. collection of fluid in the interstitial space and alveoli,
- Pulmonary fibrosis occurring in certain lung diseases increases the thickness of respiratory membrane.

2. Surface area of respiratory membrane.

Normally, the total surface area of the respiratory membrane is about 70 square metres. Rate of diffusion is directly proportional to the surface area (A), i.e. with the decrease in total surface area, the rate of diffusion of gases decreases, i.e.

$$V_{\text{gas}} \propto A$$

Some causes of decrease in surface area are:

- Pneumonectomy, i.e. removal of one complete diseased lung reduces surface area to half the normal.
- In emphysema, many of the alveoli coalesce, with dissolution of alveolar walls; this often causes the total surface to decrease by as much as five fold.

3. Diffusion coefficient.

The rate of diffusion is directly proportional to the diffusion coefficient (D) of the gas, i.e.

$$V_{\text{gas}} \propto D$$

- The diffusion coefficient of CO₂ is about 20 times that of O₂ through water (and therefore through fluid of respiratory membrane). Therefore, CO₂ diffuses much more easily through the respiratory membrane.
- The diffusion coefficient of a gas is a function of molecular weight (diffusion is inversely related to the square root of the molecular weight), solubility in a particular solvent, and absolute temperature (310 K, normal body temperature), i.e.

$$D = \frac{\text{Solubility of the gas}}{\sqrt{\text{Molecular weight of the gas}}}$$

4. Pressure gradient across respiratory membrane.

The rate of diffusion across the respiratory membrane is directly proportional to the pressure difference between the partial pressure of a gas in alveoli (P_A) and in pulmonary capillary (P_c), i.e.

$$V_{\text{gas}} \propto (P_c - P_A)$$

Further details about pressure gradient during diffusion of gases is discussed later.

From the equations (i), (ii), (iii) and (iv) it can be derived that:

$$V_{\text{gas}} = (P_c - P_A) \frac{D.A.}{d}$$

This is called *Fick's law of diffusion*. Thus, it can be concluded that the rate of pulmonary gas diffusion, i.e. the volume of gas that crosses the respiratory membrane per minute is determined by several factors as defined by Fick's law of diffusion.

Diffusion and equilibration of gases across the respiratory

membrane

Diffusion of O₂.

The normal alveolar pO₂ is 104 mmHg, whereas the blood entering the pulmonary capillary normally has a pO₂ of 40 mmHg. Pressure gradient therefore is 64 mmHg in the beginning. After dissolving in the respiratory membrane, the O₂ molecules diffuse into the blood. As O₂ diffuses from alveoli to blood the pO₂ of blood becomes the same as in alveolar air (104 mmHg), the gradient becomes zero, and no diffusion occurs (Fig. 5.4-7). By the time blood passes to one-third of distance in capillary the pO₂ of blood equals that of alveoli. This means the pressure gradient is there only for one-third of blood flow in capillary. As stated above, the pressure gradient which is 64 mmHg in the beginning becomes lesser and lesser with diffusion of O₂ into the blood. Average pressure gradient is therefore calculated considering the pressure gradients at various sites and the time for which particular pressure gradient was present. This time integrated average pressure gradient is about 11 mmHg.

FIGURE 5.4-7 (A) Diffusion of oxygen across respiratory membrane **(B)** leading to progressive increase in capillary blood pO_2 .

Equilibration time.

The blood remains for about 0.75 seconds in the capillary (*transit time*). As mentioned above, normally, enough O_2 diffuses across the respiratory membrane so that blood pO_2 and alveolar pO_2 equalize in one-third of the transit time, i.e. about 0.25 seconds (Fig. 5.4-8); then no further gas transfer normally takes place for the rest 0.50 seconds of transit time. This time provides a *safety margin* that ensures adequate O_2 uptake during periods of stress (e.g. exercise, exposure to high altitude) or impaired

diffusion. When the normal diffusing capacity of the lung for O₂ is diminished, the equilibrium time is prolonged or never reached.

FIGURE 5.4-8 Equilibration time of: oxygen (in normal DLO₂, moderately decreased DLO₂ and severely reduced DLO₂), nitrous oxide and carbon monoxide.

Diffusion of CO₂ occurs from blood to alveoli because pCO₂ is higher in blood than in alveolar air. The average pCO₂ in the pulmonary capillary blood is 46 mmHg, as opposed to 40 mmHg in the alveoli. Therefore, pressure gradient in the beginning is 6 mmHg and time integrated pressure gradient calculated for CO₂ (in a manner similar to O₂) across the respiratory membrane is only 1 mmHg. Although the pressure gradient for CO₂ is only one-tenth of the O₂ diffusion gradient, CO₂ diffuses almost 20 times more rapidly than O₂ because of higher diffusion coefficient.

Equilibration time.

It is estimated that the time required for the blood pCO₂ and alveolar air pCO₂ to equalize is also approximately 0.25 second.

Perfusion-limited versus diffusion limited gas exchange

Pulmonary gas exchange is determined by either perfusion or diffusion properties of the system (Fig. 5.4-9):

FIGURE 5.4-9 (A) In perfusion-limited gas exchange, the blood is equilibrated (as symbolized by full beakers), so that the only method of increasing gas uptake is to increase pulmonary blood flow (by moving more beakers through the system). **(B)** In diffusion-limited gas exchange the blood is not equilibrated (symbolized by partially filled beakers), so that diffusion rate must be increased to improve the exchange (so that available beaker in the above symbolization may become full). The diffusion rate can be increased by raising partial pressure of the alveolar air (pAO_2) and increasing the driving force for diffusion.

• Perfusion-limited gas exchange

occurs when equilibration takes place between the alveolar gas and the pulmonary capillary blood. Normally, O_2 and CO_2 are transferred by perfusion-limited gas exchange as they equilibrate in about 0.25 second (while transit time is 0.75 sec). Therefore, when pulmonary blood flow increases, the diffusion of O_2 and CO_2 across the respiratory membrane also increases.

Nitrous oxide (N_2O) an anesthetic gas reaches at equilibrium in about

0.1 second, therefore, N_2O taken up is not diffusion limited, but by the amount of blood flowing through pulmonary capillaries (i.e perfusion limited).

• Diffusion-limited gas exchange

occurs whenever equilibration does not take place between the alveolar and pulmonary gas tensions.

- Carbon monoxide (CO) which does not reach equilibrium in 0.75 second (transit time of blood in pulmonary capillary) has a diffusion limited transport, i.e. its transport across the respiratory membrane will increase only if the rate of diffusion increases. Increase in blood flow will not increase the transport of carbon monoxide.
- Since, CO exchange is diffusion limited, so measuring the diffusion capacity of CO is an effective means of evaluating the diffusion properties of respiratory system.
- In certain systemic diseases and at a significant increase in altitude pO_2 of alveolar air is reduced, which in turn reduces the diffusion rate. Raising the fraction of inspired O_2 (FIO_2) is one way to treat diffusion-limited gas exchange.

Effect of alveolar ventilation–perfusion ratio on pulmonary gas exchange

- Optimum gas exchange across the respiratory membrane occurs when the alveolar ventilation–perfusion ratio (VA/Q) is normal, i.e. between 0.8 and 1.
- Both, a decrease as well as an increase in VA/Q ratio reduces the gas exchange. For details see page 423.

Diffusion capacity of lung

Diffusion capacity (DL) of the lung is quantitative expression of the ability of the respiratory membrane to exchange a gas between the alveoli and the pulmonary blood. It is defined as the volume of gas (V_{gas}) that diffuses through the respiratory membrane of lung each minute for a pressure gradient of 1 mmHg.

Factors affecting diffusion capacity

All the factors discussed in detail that affect the rate of diffusion through the **respiratory membrane** (see page 425) will obviously affect the diffusing capacity of lung. To summarize once again the diffusion capacity of lung (DL) is

- Inversely proportional to thickness of the respiratory membrane, i.e. diffusion distance (d),
- Directly proportional to the surface area (A) of respiratory membrane,
- Directly proportional to the diffusion coefficient (D) of the particular gas. Diffusion coefficient in turn is directly proportional to the solubility (S) of the gas in respiratory membrane and inversely proportional to the square root of molecular weight (MW) of the gas.
- Directly proportional to the pressure gradient between the partial pressure of gas in alveolar air (pA) and capillary blood (pC), i.e. pA–pC.

Diffusion capacity of lung for different gases

Depending upon the above factors, the diffusion of lungs is bound to be different for different gases. Diffusion capacity of the lungs for common gases is (Table 5.4-3):

TABLE 5.4-3

Diffusion Capacity of Lungs for Different Gases

Gas	Diffusion Capacity (ml/min/mmHg)	
	Rest	Exercise
Oxygen (O ₂)	20-25	65
Carbon-dioxide (CO ₂)	400-500	1200-1300
Carbon monoxide (CO)	17	

Diffusion capacity of lungs for O₂

- **At rest** the diffusing capacity of lungs for O₂ is about 20–25 ml/min/mmHg. As the mean oxygen pressure gradient across the respiratory membrane is about 11 mmHg, so at rest about 250 ml of O₂ diffuses through the lungs per minute.
- **During exercise** the diffusing capacity of lungs for O₂ is increased. It may reach upto 65ml/min/mmHg during strenuous exercise (3 times of

diffusing capacity for O₂ at rest). It occurs due to:

- *Increase in surface area* of respiratory membrane caused by opening up of closed pulmonary capillaries and dilation of open capillaries, and
- *Improvement in ventilation–perfusion ratio.*

Diffusion capacity of lungs for CO₂

has never been measured because of technical difficulties. Carbon dioxide diffuses across the respiratory membrane so rapidly that the difference between the average pCO₂ of the capillary blood and pCO₂ of alveolar air is only 1 mmHg. Such a small difference cannot be detected by any available technique. However, from the available knowledge about diffusion coefficient of CO₂, the diffusion capacity of lungs for CO₂ is estimated.

- *At rest* the diffusing capacity of lungs for CO₂ is about 20 times that for O₂, i.e. about 400 ml to 500 ml/min/mmHg.
- *During strenuous exercise* the diffusing capacity for CO₂ is increased to 1200 ml to 1300 ml/min/mmHg.

Clinical significance of higher diffusion capacity of CO₂. When diffusing capacity of respiratory membrane is markedly decreased due to certain diseases, one expects retention of CO₂ and lack of O₂. But due to vast difference in the diffusing capacities for O₂ and CO₂, a serious impairment of diffusion of O₂ causes significant lack of O₂ with little signs of CO₂ retention.

Measurement of diffusion capacity of lungs

Diffusion capacity of lungs for different gases can be measured using *Fick's law*, according to which diffusion capacity is given by:

$$DL = \frac{V}{(pA - pC)}, \text{ where}$$

DL = Diffusion capacity of lungs for a given gas,

V = Volume of the gas uptake in one minute, and (increase in the gas content of blood in one minute),

pA-pC = Pressure gradient between alveolar air and pulmonary capillary blood.

- Thus, diffusion capacity for O₂ (DLO₂) is:

$$DLO_2 = \frac{O_2 \text{ consumption/min}}{pAO_2 - pO_2}$$

- It is easy to measure O₂ consumption/min and pAO₂, but it is difficult to measure pO₂ in pulmonary capillary blood (because collection of sample is extremely difficult).
- Therefore, diffusion capacity for O₂ is measured from the diffusion capacity for carbon monoxide.
- Carbon monoxide is preferred for measuring the diffusion capacity of lung because of two reasons:
- After entering the blood the CO very rapidly reacts with haemoglobin to form carboxyhaemoglobin and so do not allow the partial pressure of CO to build up in plasma. In this way, pCO in pulmonary capillary blood is almost zero (unless the subject is a smoker or exposed to atmospheric CO levels). Therefore, problem of collecting of CO in the pulmonary capillary blood is avoided.

- Diffusion of CO across respiratory membrane is diffusion limited. Therefore, the amount of CO transferred to blood is correct estimate of the diffusion capacity. Since diffusion of O₂ across the respiratory membrane is flow limited, so measuring the amount of O₂ transferred to blood will underestimate the true diffusion capacity.

Procedure of single-breath carbon monoxide technique of measuring diffusion capacity of lung

- The subject is made to take a single breath of gas mixture containing dilute concentration (0.01%) of carbon monoxide (CO). He is asked to hold the breath for 10 seconds to allow the diffusion.
- The CO uptake/min is calculated from the difference between the inspired air and expired air CO concentration, and FRC. The pCO of alveolar air is estimated from the end-expiratory sample. The pCO of pulmonary capillary blood is considered zero and so the diffusion capacity for CO (DL CO) is calculated as:

$$DL\ CO = \frac{\text{CO uptake/min}}{\text{pCO in alveolar in}}$$

- The diffusion capacity measured for CO at rest is about 17 ml/min/mmHg
- Diffusion capacity for O₂ is determined by multiplying the diffusion capacity for CO by 1.27, because diffusion coefficient of O₂ is about 1.2 times that of CO:

$$DLO_2 = 17 \times 1.2, \text{ or about } 20 \text{ ml/min/mmHg.}$$

- Respiratory Quotient

Introduction

It is being repeated, probably, for the fourth time in this section, but is essential as an introductory remark that *external respiration* refers to supply of O₂ from atmosphere to tissues and removal of CO₂ from the tissues into the atmosphere. It is accomplished by three major processes:

- *Pulmonary ventilation*, i.e. exchange of gases between the environment and lungs (discussed in [Chapter 5.2](#)),
- *Pulmonary diffusion*, i.e. transfer of gases from alveoli to capillary blood across the respiratory membrane (discussed in [Chapter 5.4](#)) and
- *Transport of gases* from blood to the tissue cells and back.

Transport of oxygen

Transport of oxygen from the lungs to tissues occurs due to constant *circulation of blood*, and *diffusion* of O₂ that occurs at various sites in the direction of concentration gradient which is represented by O₂ tension (pO₂) differences given:

- Alveolar air pO₂ : 104 mmHg

- Arterial blood pO_2 : 95 mmHg
- Venous blood pO_2 : 40 mmHg
- Tissue interstitial fluid pO_2 : 40 mmHg

From the above, it is clear that:

- Oxygen from the alveolar air is taken up by the pulmonary capillary blood along a pressure gradient of 104-40, or 64 mmHg, and
- Oxygen from the arterial blood is released into the tissues by a pressure gradient of 95–40, or 55 mmHg.

Transport of oxygen from the lungs to the tissues can be described as under:

- A. Uptake of oxygen in the lungs by pulmonary blood,
- B. Transport of oxygen in arterial blood, and
- C. Release (diffusion) of oxygen from blood to the interstitial fluid in tissues.

Uptake of oxygen by pulmonary blood

- As mentioned above, pO_2 of pulmonary arterial blood is about 40 mmHg and that of alveolar air is 104 mmHg. Therefore, due to this great concentration gradient, oxygen readily diffuses from the alveoli into the blood.
- The process of diffusion across the respiratory membrane has been described in [Chapter 5.4](#)
- It is important to note that this process is very rapid and even if the stay of blood in lungs is reduced (as occurs during strenuous exercise due to increased cardiac output) there occurs complete oxygenation.

Transport of oxygen in arterial blood

PO_2 in pulmonary venous blood is 104 mmHg, however, by the time

blood reaches the aorta pO_2 falls to about 100 mmHg. This happens due to *venous admixture*, i.e. mixing of venous blood to arterial blood. The venous blood which mixes with arterial blood is:

- Blood present in bronchial veins (which forms about 2% of cardiac output) mixes with the pulmonary capillary blood at the respiratory bronchioles which are supplied by systemic as well as pulmonary capillaries.
- Part of the coronary venous blood flows into the chambers of left side of heart through thebesian veins.

Arterial blood contains about 20 ml and venous blood about 15 ml of O_2 per 100 ml. Thus, about 5 ml of O_2 is transported per 100 ml of blood from lungs to the tissue cells.

Oxygen is transported in the blood in two forms: as dissolved form and in combination with haemoglobin.

Oxygen transport in dissolved form

- The solubility of O_2 in water (plasma) is so little that at pO_2 value of 100 mmHg, out of the 20 ml of O_2 present in 100 ml of blood, only 0.3 ml is in dissolved form and rest is combined with haemoglobin (as oxyhaemoglobin).
- The dissolved oxygen obeys Henry's law, i.e. amount dissolved is proportional to the pO_2 . Thus, there is no limit to the amount of O_2 that can be carried in dissolved form provided the pO_2 is sufficiently high. This is a distinct advantage over O_2 transport as oxyhaemoglobin which cannot exceed a certain limit.
- Therefore, dissolved O_2 at high pO_2 (hyperbaric oxygen) is utilized in clinical practice for the oxygenation of tissues when the haemoglobin gets denatured in certain types of poisoning, e.g. carbon monoxide poisoning.

Oxygen transport in combination with haemoglobin

Oxygenation of haemoglobin

After entering the blood from the alveolar air, most of the oxygen

combines with haemoglobin to form a *loose and reversible* combination. The iron present in heme molecule stays in the ferrous form; therefore, this process is called *oxygenation* (not oxidation) and converts deoxyhaemoglobin into oxyhaemoglobin. The reaction is very rapid requiring < 0.01 second. The *driving force* for this reaction is O₂ tension in the pulmonary capillaries.

One molecule of oxygen combines with one iron ion of the heme molecule. The O₂ molecule occupies the sixth *co-ordination* position of the iron atom. Since haemoglobin contains four molecules of heme, so each molecule of haemoglobin can combine with as many as *four* O₂ molecules. The reaction proceeds in four steps:

After the first step, affinity of haemoglobin for O₂ increases with each next step because in deoxyhemoglobin, the globin units are tightly bound (that is intense configuration), which reduces affinity for O₂. This happens so, because the insertion of O₂ molecule ruptures all the salt links and changes the quaternary structure of haemoglobin from the tense or *T-configuration* to relaxed or *R-configuration* which exposes more O₂ binding sites, which favours O₂ binding. Subsequent molecules of oxygen, therefore, find it easier to bind to haem moieties and there is 500 fold increase in O₂ affinity. This phenomenon is termed as *co-operative binding kinetics*. This is the reason for the sigmoid nature of oxygen haemoglobin association or dissociation curve. In tissues the reactions are reversed resulting in O₂ release.

Oxygen carrying capacity of haemoglobin

One gram of haemoglobin can bind with maximum of 1.34 ml of O₂. Thus, 100 ml of blood with haemoglobin level of 15 gm% can carry 1.34 × 15, or 20.1 ml of oxygen. However, due to the presence of various physiological shunts (venous admixture) only 97% of the haemoglobin is available for carrying the oxygen. Therefore, practically, 100 ml of the

arterial blood carries about 19.8 ml of oxygen out of which about 19.5 ml as oxyhaemoglobin and 0.3 ml as dissolved form in plasma.

Thus, under normal circumstances, the haemoglobin carries most of the bulk of oxygen present in the blood. The only *disadvantage* is that there is a ceiling on the amount of oxygen that can be carried by the haemoglobin (depending upon the concentration of haemoglobin in the blood). The limit can never be surpassed.

Haemoglobin saturation is the percentage of haemoglobin that is combined with oxygen. When all the four sites on haemoglobin are occupied by O₂ (1.34 ml), then that molecule of haemoglobin is 100% saturated. When one gram of haemoglobin is combined with 0.67 ml of O₂, it is said to be 50% saturated. The *percentage saturation* is the average saturation of the entire haemoglobin molecules in the blood and is calculated as:

$$\text{percentage saturation} = \frac{\text{O}_2 \text{ content of blood/100 ml}}{\text{O}_2 \text{ carrying capacity of blood}} \times 100$$

Oxygen–haemoglobin dissociation curve

The oxygen–haemoglobin curve

refers to the curve obtained when the relation between the pO₂ and the percentage of haemoglobin saturation is plotted (Fig. 5.5-1). The O₂–Hb dissociation curve shows that the percentage saturation of haemoglobin increases with the increase in pO₂ of arterial blood. However the relation is not linear but *sigmoid or S-shaped* (because of the reason explained above), but it has several physiological advantages (vide infra).

FIGURE 5.5-1 Normal oxygen–haemoglobin dissociation curve.

Two distinct zones of the O₂–Hb dissociation curve are recognized:

- **Loading (association) zone**

refers to upper flat part (plateau) of the curve, which is related to the process of O₂ uptake in the lungs. The curve shows that at pO₂ values of 100 mmHg or above, the haemoglobin is 100% saturated. More important to note is the fact that even if pO₂ falls to 60 mmHg, the Hb saturation is still 90%. Thus, the loading zone provides a margin of safety, because it ensures fairly high uptake of O₂ by pulmonary blood even when alveolar pO₂ is moderately decreased in situations like:

- Climbing mountains to moderate altitude, and
- Pulmonary diseases.

- **Unloading (dissociation) zone**

of the O₂–Hb dissociation curve refers to the *steep portion* of the curve that

occurs at pO_2 below 60 mmHg. The steep part of the curve is concerned with O_2 delivery in the tissues and shows that large amounts of oxygen can be liberated from the blood with relatively minor fall of O_2 tension. This property keeps the O_2 tension in the capillary blood relatively high so that the diffusion gradient for O_2 is maintained. At pO_2 value of 40 mmHg, Hb is 75% saturated with O_2 (Fig. 5.5-1). Thus, each 100 ml of blood can hold only 15ml of O_2 as compared to 20 ml at pO_2 of 100 mmHg (Fig. 5.5-2). Thus, 5 ml of O_2 is extracted by the tissues at rest. At values of pO_2 lower than 40 mmHg still larger volume of O_2 would be offloaded and become available to the tissue (e.g. during exercise). The greater release of O_2 with slight decrease in tissue pO_2 (due to increased O_2 consumption) minimizes decrease of tissue pO_2 that would otherwise take place. Thus, it will regulate tissue pO_2 (buffering effect).

FIGURE 5.5-2 The relationship between pO_2 and oxygen contents of the blood.

Physiological advantages of S-shaped O_2 -Hb dissociation curve,

which can be summarized from the above discussion are:

- It allows greater uptake of O_2 at lungs despite great variation in alveolar air pO_2 ,
- Tissues are supplied with O_2 according to their needs and
- Haemoglobin acts as a buffer and maintains tissue pO_2 at about 40 mmHg.

Shifts in O_2 -Hb dissociation curve

Several factors affect the affinity for haemoglobin for O_2 and thus shift the O_2 -Hb dissociation curve to either right or left.

Shift to right

Shift to the right of O_2 -Hb dissociation curve signifies decreased affinity of haemoglobin for O_2 (Fig. 5.5-3). Thus at every level of pO_2 , the oxygen saturation of haemoglobin is somewhat lower than the normal curve leading to more offloading of O_2 .

FIGURE 5.5-3 Right shift of oxygen-haemoglobin dissociation

curve which occurs due to increase in $p\text{CO}_2$, H^+ concentration, temperature or 2, 3-DPG. Note P_{50} is increased.

Causes.

The factors causing right shift are:

1. **Effect of $p\text{CO}_2$ and pH.** The description of O_2 -Hb dissociation curve given above (Fig. 5.5-1) holds true if the blood has $p\text{CO}_2$ value of 40 mmHg and a pH of 7.4 (pH of normal arterial blood).

- An increase in $p\text{CO}_2$ shifts the curve to right; this phenomenon is known as *Bohr's effect* (Fig. 5.5-3). When the arterial blood reaches the tissues, it is exposed to not only low tissue $p\text{O}_2$ (40 mmHg) but also higher $p\text{CO}_2$ (45 mmHg). So, normally in tissues the curve shifts to right and due to Bohr's effect for a given decrease in $p\text{O}_2$ larger volume of O_2 is shed off (about 2% more).
- A decrease in pH of blood, as occurs in the tissues, also shifts the O_2 -Hb dissociation curve to the right.

2. **Effect of temperature.** An increase in the temperature of blood shifts the curve to right (Fig. 5.5-4). During *exercise* the demand of O_2 is increased in skeletal muscles. The factors which facilitate the delivery of the required larger amounts of O_2 (by causing right shift in the curve) are:

- Increased temperature in skeletal muscles due to more heat production,
- Increased $p\text{CO}_2$ due to accumulation of CO_2 resulting from rapid metabolism,

- Decreased pO₂ due to rapid consumption, and
- Decreased pH due to accumulation of lactic acid produced in muscular exercise.

3. *Effect of diphosphoglycerate or biphosphoglycerate.* The red blood cells are rich in 2, 3 - diphosphoglycerate (2, 3-DPG) which is formed from 3-phosphoglyceraldehyde produced during glycolysis via *Embden-Meyerhof pathway*. The 2, 3-DPG is a highly charged anion that binds to β-chain of deoxygenated adult haemoglobin.

FIGURE 5.5-4 Effect of change of temperature of blood on the oxygen–haemoglobin dissociation curve. Note a right shift at increased temperature (43°C) and left shift at decreased temperature (10°C) as compared to the normal curve (37°C).

Thus, an increase in the concentration of 2, 3-DPG decreases the

affinity of Hb for O₂ and shifts the normal O₂-Hb dissociation curve to the right. Causes of increased levels of 2, 3 -DPG are : thyroid hormone, growth hormone, androgen, anaemia, exposure to chronic hypoxia at high altitude and certain pulmonary diseases.

Note:

- Acidosis inhibits red cell glycolysis, therefore, 2, 3-DPG concentration falls when pH is low.
- In stored blood (blood bank blood) level of 2, 3-DPG falls and ability to release oxygen in the tissues is reduced; therefore transfusion of stored blood especially in hypoxic patients has limited benefit.

Advantages versus disadvantages of right shift:

- Right shift is advantageous in the tissues where greater O₂ is released from haemoglobin (at the same pO₂).
- However, right shift is disadvantageous in the lungs because (at the same pO₂) blood takes up less oxygen.

Shift to left.

Shift to left of O₂-Hb dissociation curve signifies increased affinity of haemoglobin for O₂ (Fig. 5.5-5). Thus, at every pO₂ level the oxygen saturation of haemoglobin is somewhat greater than in a normal curve.

FIGURE 5.5-5 Left shift of oxygen–haemoglobin dissociation curve which occurs due to decrease in $p\text{CO}_2$, H^+ concentration, temperature and 2,3-DPG. Note— p_{50} value is decreased.

Causes

for left shift of the curve are:

- Decreased $p\text{CO}_2$ of blood,
- Increased pH of blood,
- Decreased temperature, and
- Fetal haemoglobin.

Advantages versus disadvantages of left shift. Left shift of the curve has limited advantage because though it allows greater uptake of O_2 at lungs (at same $p\text{O}_2$) but it decreases release of O_2 to the tissues (at same

pO₂).

Concept of p₅₀ and its significance

*p*₅₀ refers to the partial pressure of O₂ that produces a 50% saturation of the haemoglobin with O₂; Normal p₅₀ for arterial blood in an adult at 37°C body temperature and at pCO₂ of blood 40 mmHg is 25–27 mmHg (Fig. 5.5-1).

Haemoglobin affinity for O₂ is inversely related to the p₅₀ value, therefore:

- Decreased p₅₀ (Hb gets 50% saturated at lower pO₂) indicates increased affinity of haemoglobin for O₂. Thus, decreased p₅₀ is equivalent to shift of Hb–O₂ dissociation curve to left (Fig. 5.5-5). A decreased p₅₀ is an obvious benefit in the lungs because it enhances the haemoglobin saturation with O₂. Fetal haemoglobin and myoglobin have lower p₅₀ value than adult haemoglobin.
- Increased p₅₀ (Hb gets 50% saturated at higher pO₂) indicates decreased affinity of haemoglobin for O₂. Thus, increased p₅₀ is equivalent to right shift of O₂–Hb dissociation curve (Fig. 5.5-3). Increase in pCO₂, H⁺ concentration, temperature and 2, 3-DPG causes increased p₅₀.

O₂–Hb dissociation curve of fetal haemoglobin

- As shown in Figure 5.5-6, the O₂–Hb dissociation curve of fetal haemoglobin (HbF) is shifted to the left in comparison with O₂–Hb dissociation curve of adult haemoglobin (HbA).
- The O₂–Hb dissociation curve of HbF is shifted to left because its affinity for 2, 3-DPG is considerably less than that of HbA. This is because two gamma (γ) chains present in HbF have very little affinity for 2, 3-DPG as compared to the beta (β) chains of HbA.
- Thus, affinity of HbF to combine with O₂ is more than that of HbA. This property of HbF helps it to take up normal volumes of O₂ in spite of the fact that fetal blood is exposed to rather low pO₂ values of the maternal blood in placenta. As shown in Figure 5.5-6 at pO₂ 20 mmHg where HbA is only 35% saturated the HbF is 70% saturated, that is

why HbF can store more O₂.

FIGURE 5.5-6 Oxygen haemoglobin dissociation curves of adult haemoglobin (HbA) and fetal haemoglobin (HbF).

Effect of carbon monoxide on O₂ transport

- Carbon monoxide (CO) interferes with O₂ transport because it has about 200 times the affinity (of oxygen) for haemoglobin.
- CO combines with Hb at the same site on its molecule as O₂ and forms the carboxyhaemoglobin, and thus decreases the functional haemoglobin concentration.
- Because of the extreme affinity of CO for haemoglobin the carboxyhaemoglobin curve lies along the Y-axis and a CO tension of only 0.5 mmHg inactivates about 50% of the haemoglobin, i.e. p50 for

CO is only 0.5 mmHg (Fig. 5.5-7).

- CO lowers the tissue O₂ tension by decreasing the O₂ content and the p₅₀ for O₂.

FIGURE 5.5-7 Haemoglobin saturation curves for both O₂ (HbO₂) and carbon monoxide (HbCO). Note that HbCO curve lies along the Y axis which indicates extreme high affinity of haemoglobin for carbon monoxide. Note the p₅₀ for CO is only 0.5 mmHg.

Oxygen dissociation curve for myoglobin

Myoglobin is present in higher quantities in the muscles specialized for sustained contraction, e.g. muscles of legs and heart. The characteristic features of O₂ dissociation curve of myoglobin vis-à-vis haemoglobin are (Fig. 5.5-8):

- Dissociation curve of myoglobin is rectangular hyperbola rather than sigmoid in shape, because it takes up O₂ at low pressure much readily, i.e. rate of association of myoglobin with O₂ is very fast.

- Myoglobin does not show Bohr's effect.
- At pO_2 40 mmHg the myoglobin is 95% saturated while haemoglobin is 75% saturated. Even at pO_2 5mmHg myoglobin is saturated by slightly less than 60%. Thus, it acts as a temporary store house for O_2 in the muscles.

FIGURE 5.5-8 Oxygen dissociation curve of myoglobin versus haemoglobin.

Release of oxygen in tissues

Oxygen release at rest

Oxygen delivery.

represents the amount of O_2 that is presented to body cells per minute and is equal to the arterial O_2 content multiplied by cardiac output. Since 100 ml of arterial blood at pO_2 of about 100 mmHg contains about 20 ml of oxygen, thus with a cardiac output of about 5 L/min, the normal

oxygen delivery to the entire body is about 1L/min. The oxygen delivery to the tissues decreases with either decrease in arterial O₂ content or decrease in cardiac output.

Oxygen consumption.

When the arterial blood with approximate pO₂ 100 mmHg reaches the tissues with tissue fluid pO₂ 40 mmHg; because of pressure gradient, about 5 ml of O₂ diffuses from the tissue capillaries to the interstitial fluid out of 100 ml of blood (containing ~ 19 ml O₂) every minute. Thus, oxygen consumption of the whole body at rest with a cardiac output of 5 L/min is about or 250 ml of O₂ per minute.

Utilization coefficient.

Utilization coefficient refers to the percentage of oxygen consumed out of oxygen delivered to the tissue, i.e.

$$\text{Coefficient of utilization} = \frac{\text{Oxygen consumed/min}}{\text{Oxygen delivered/min}} \times 100$$

$$\begin{aligned} \text{So, at rest coefficient of} \\ \text{utilization of whole body} &= \frac{250 \text{ ml/min}}{1000 \text{ ml/min}} \times 100 \\ &= 25\% \end{aligned}$$

Oxygen release during exercise

Oxygen release during exercise or activity depending upon the severity of exercise the O₂ consumption is increased per min. The oxygen demand of the tissues is met with following changes:

Delivery of oxygen to the tissues

is *increased* by:

- Increase in blood flow to the tissues occurs due to:
- Increase in cardiac output,

- Local arteriolar dilatation, and
- Increase in the number of open capillaries.
- *Increase in RBC count* due to splenic contraction.

Release of oxygen in the tissue

is increased by:

- Right shift of oxygen dissociation curve occurs due to increase in $p\text{CO}_2$, H^+ concentration, temperature and 2, 3-DPG. As a result more O_2 is released to the tissues at the same $p\text{O}_2$. This can increase the oxygen uptake of tissues to 750 ml/min, i.e. 3 times the resting level.
- Fall in PO_2 of interstitial fluid. Depending upon the degree of activity, the O_2 tension in the interstitial fluid may fall to even zero. This leads to a very steep pressure gradient between blood and tissues increasing release of O_2 .

All the above factors combined can increase the oxygen released in the tissues by 15 times the resting levels.

Vehicles for transport of oxygen: A comparison of plasma, haemoglobin and whole blood

The oxygen dissociation curves of plasma, haemoglobin solution and whole blood (Fig. 5.5-9) and the amount of oxygen that can be loaded and unloaded by different transport vehicles reveal that:

FIGURE 5.5-9 Oxygen dissociation curves: (A) for plasma;

(B) for haemoglobin solution and (C) for whole blood.

From the lungs at pO_2

of about 100 mmHg, the amount of O_2 loaded by 100 ml of transport vehicle is:

• Whole blood	:	19.8 ml
• Haemoglobin solution	:	19.5 ml
• Plasma solution	:	0.3 ml only
	:	

In the tissue at pO_2

of 40 mmHg, the amount of oxygen released by 100 ml of transport vehicle is:

• Whole blood	:	5 ml,
• Haemoglobin solution	:	1.5 ml and
• Plasma	:	0.18 ml
	:	

At maximum haemoglobin saturation

the whole blood can release:

- 5 ml of O_2 at rest when tissue pO_2 is about 40 mmHg,
- 13 ml of O_2 during moderate exercise when tissue pO_2 is about 25 mmHg, and
- 15–16 ml of O_2 during severe exercise, when tissue pO_2 is about 15 mmHg.

From the above, it is quite clear that whole blood is an ideal vehicle for transport of O_2 , to load itself in lungs with O_2 and to release O_2 in tissues as per requirement.

Transport of carbon dioxide

Transport of carbon dioxide from tissue cells to the lungs occurs due to *constant circulation* of blood and diffusion of CO_2 that occurs at various sites in the direction of concentration gradient which is represented by

CO₂ tension differences as given:

• Intracellular pCO ₂	:	46 mmHg,
• Interstitial fluid pCO ₂	:	45 mmHg
• Arterial blood pCO ₂ (in tissue capillaries)	:	40 mmHg
• Venous blood pCO ₂	:	45 mmHg
• Alveolar air pCO ₂	:	40 mmHg
	:	

From the above pCO₂ levels, it is clear that:

- CO₂ from the cells diffuses into the interstitial fluid against a tension gradient of 1 mmHg,
- From the interstitial fluid the CO₂ diffuses into the capillaries at a tension gradient of 5 mmHg, and
- From the venous blood that is supplied to pulmonary capillaries the CO₂ diffuses across the respiratory membrane into the alveoli against a tension gradient of 5 mmHg.

Transport of carbon dioxide from the tissue cells to the lungs can be described as under:

A. Diffusion of CO₂ in the blood,

B. Transport of CO₂ in the blood and

C. Release of CO₂ in the lungs.

Diffusion of CO₂ in the blood

Tissue cells constantly form CO₂ inside the cells due to metabolism. As mentioned above intracellular pCO₂ is 46 mmHg and that of interstitial fluid surrounding the cells is 45 mmHg. Though the cells are continuously forming CO₂ but still the CO₂ tension gradient between inside and outside of the cells is only 1 mmHg. This is owing to the rapid diffusion of CO₂ (20 times that of O₂) out of the cells into the interstitial fluid. Since pCO₂ of the arterial blood flowing in tissue capillaries is lower (40 mmHg) than that of interstitial fluid, so CO₂ diffuses inside the capillary blood which flows in the systemic venous system.

Transport of CO₂ in blood

Venous blood contains about 52 ml and arterial blood about 48 ml of CO₂ per 100 ml. Thus, 4 ml of CO₂ is transported per 100 ml of blood from tissue cells to the lungs. Thus, total CO₂ transported from the whole body tissue cells at rest with a cardiac output of 5 L/min is about $4 \times 5000/100$, or 200 ml/min.

Carbon dioxide is transported in the blood in three forms (Fig. 5.5-10):

- In dissolved state (7%)
- In bicarbonate form (70%), and
- In carbamino compound form (23%).

FIGURE 5.5-10 (A) Transport of carbon dioxide (CO₂) in blood demonstrating formation of HCO₃⁻ and chloride shift phenomenon; (B) H⁺ buffering by haemoglobin; and (C)

formation of carbaminohaemoglobin.

Carbon dioxide transport in dissolved form

- The venous blood, with $p\text{CO}_2$ 45 mmHg contains about 2.7 ml/100 ml of CO_2 in the dissolved state.
- The arterial blood with $p\text{CO}_2$ 40 mmHg contains about 2.4 ml/100 ml of CO_2 in the dissolved state.
- Thus only 0.3 ml of CO_2 is transported in dissolved state per 100 ml of blood from tissues to the lungs. This represents about 7% of all CO_2 that is transported.

Carbon dioxide transport in bicarbonate form

Approximately 70% of the carbon dioxide is transported in the form of *plasma bicarbonate ions*. However, these bicarbonate ions are formed in the RBCs and then diffuse into plasma as explained:

- After entering the blood, most of the CO_2 enters the RBCs, wherein the presence of carbonic anhydrase, it rapidly reacts with water to form carbonic acid (H_2CO_3).
- Carbonic acid (H_2CO_3) dissociates into bicarbonate ions (HCO_3^-) and hydrogen ions (H^+).
- The bicarbonate ions diffuse out of the RBCs into plasma and are transported as sodium bicarbonate (alkali reserve of blood). Thus, although HCO_3^- is formed within the RBCs, most of the CO_2 is carried in the plasma as HCO_3^- and some in the RBCs as well.
- The H^+ are buffered by deoxygenated haemoglobin, which is a weaker acid than oxyhaemoglobin. This enables the reaction to proceed unabated in the forward direction.
- Chloride shift (*Hamburger phenomenon*) the HCO_3^- diffuses out of the RBCs into the plasma, the inside of the cells become less negatively charged. Because the RBC membrane is relatively impermeable to cations, so in order to neutralize this effect, negatively charged

chloride ions (Cl^-) diffuse from the plasma into the RBCs to replace the HCO_3^- . The movement of chloride ions into the RBCs is called chloride shift or Hamburger phenomenon. This process is mediated by Band 3, a major ion exchange membrane protein also called Anion Exchange-I (AE-I). The chloride shift occurs very rapidly and essentially completed within 1 second.

- As a result of chloride shift, the total number of ions inside the RBCs increase, so the osmotic pressure inside the RBCs becomes higher than that of plasma. This causes osmotic absorption of fluid into the RBCs. Thus, venous RBCs contain the greater quantity of fluid as compared to the arterial blood RBCs. Because of this:
- Packed cell volume (PCV) of venous blood is slightly higher ($\sim 3\%$) than that of arterial blood, and
- Venous RBCs are more fragile than the arterial RBCs.

Transport of carbon dioxide in carbamino form

Approximately 23% of the total CO_2 is transported in the blood in the form of carbamino compounds. After entering the blood, some of the CO_2 combines with the amino group ($-\text{NH}_2$) of proteins to form carbamino compounds:

• In the plasma,

CO_2 combines with amino group of plasma proteins to (Pr NH_2) form carbamino proteins:

- This reaction is much less significant because quantity of these proteins is one-fourth that of haemoglobin.

• In the RBCs,

CO_2 combines with amino group of haemoglobin (HbNH_2) to form a compound called carbamino haemoglobin.

- This combination of CO_2 with haemoglobin is a reversible reaction that occurs with a loose bond, so that the CO_2 is easily released into the alveoli where pCO_2 is lower than that in the tissue capillaries.
- This reaction of CO_2 with Hb is much slower than the reaction of CO_2 with water in RBCs. This is because, more CO_2 (70%) is transported as bicarbonates and less as carbamino compounds (23%).
- This reaction of CO_2 with Hb is further decreased to a great extent when 2, 3-DPG concentration is more, because both 2, 3-DPG and CO_2 compete for the same sites on Hb.

Carbon dioxide dissociation curve

- Carbon dioxide dissociation curve is obtained by plotting the relationship between pCO_2 and total CO_2 content of the blood (Fig. 5.5-11).
- The graph shows that relationship between the two is nearly linear over wider range of pCO_2 (if compared with O_2 -Hb, dissociation curve, which is sigmoid shaped).
- It is important to note that practically in the body the pCO_2 value of arterial and venous blood varies within a narrow range of 40 to 45 mmHg (in contrast the corresponding values of pO_2 vary from 100 to 40 mmHg). Therefore, the full range of CO_2 dissociation curve shown in Figure 5.5-11 is an experimental theoretical phenomenon and does not operate in the body practically. Physiologically the curve operates only within A-V range (Fig. 5.5-11).

FIGURE 5.5-11 Carbon dioxide dissociation curve for oxygenated (solid line) and for deoxygenated blood (dotted line) to demonstrate Haldane's effect.

Factors affecting CO₂ dissociation curve

1. Oxygen.

Deoxyhaemoglobin present in the tissue capillaries is capable of loading more CO₂ than the oxyhaemoglobin. And also the oxygenation of haemoglobin in the lungs increases the CO₂ unloading. This effect is called *Haldane's effect*. Haldane's effect on the transport of CO₂ depicts that:

- Blood with pCO₂ 40 mmHg reaching the tissues is capable of drawing CO₂ from the tissues more at pO₂ 40 mmHg (point A) than at pO₂ of 100 mmHg (point B). Thus, because of Haldane's effect, the CO₂ dissociation curve shifts to the left when blood flows to the tissues.
- Blood with pCO₂ 45 mmHg reaching the lungs is capable of retaining less or in other words releasing more CO₂ in the lungs at pO₂ 100 mmHg (point C) than at pO₂ 40 (point D). Thus, because of Haldane's effect, the CO₂ dissociation curve shifts to the right when blood flows

in the pulmonary capillaries.

- [Figure 5.5-11](#) also depicts that Haldane's effect is beneficial because it almost doubles the quantity of CO₂ to be carried from the tissues to lungs and also doubles the amount of CO₂ to be excreted by the lungs.

2. 2,3-DPG.

decreases the formation of carbamino haemoglobin because it competes with CO₂ for the same sites on Hb especially in case of reduced Hb. Thus, 2, 3-DPG shifts the CO₂ dissociation curve to the right meaning thereby that CO₂ carrying capacity is decreased.

3. Increase in body temperature.

causes release of O₂ from Hb, this causes left shift of the CO₂ dissociation curve, i.e. larger amount of CO₂ can be taken of at given pCO₂.

Release of CO₂ in the lungs

When the venous blood with pCO₂ of 45 mmHg, CO₂ content of 52 ml per 100 ml, and pO₂ of 40 mmHg reaches the pulmonary capillaries, it is separated by the respiratory membrane from the alveolar air having pCO₂ 40 mmHg. CO₂ content of 48 ml/100 ml and pO₂ 104 mmHg. Then following changes occur which lead to diffusion of 4 ml of CO₂ 100 ml of blood/min in the alveoli ([Fig. 5.5-12](#)):

FIGURE 5.5-12 (A) Release of carbon dioxide in the plasma from carbaminohaemoglobin and from bicarbonate ions and **(B)** diffusion of CO₂ from plasma into the alveoli through respiratory membrane.

Release of CO₂ from carbamino haemoglobin into plasma (fig. 5.5-12A)

- O₂ diffuses into the capillary blood with a concentration gradient of 104 mmHg – 40 mmHg or 64 mmHg.
- The O₂ enters the RBCs and converts the deoxyhaemoglobin into oxyhaemoglobin which has very low affinity for CO₂. In this CO₂ is released from the carbamino haemoglobin which diffuses into the plasma.

Release of CO₂ from carbonate into plasma (fig. 5.5-12B)

- The oxyhaemoglobin so formed is a strong acid. Increased acidity of the blood results in increased H^+ concentration. To neutralize it the bicarbonate (HCO_3^-) ions diffuse into the RBCs where H^+ and HCO_3^- react to form H_2CO_3 (carbonic acid) which dissociates to form H_2O and CO_2 . This whole reaction occurs in the presence of enzyme carbonic anhydrase. CO_2 so released diffuses into the plasma.
- With the movement of HCO_3^- inside the RBCs, inside of the cell becomes more negative. To neutralize them, either the positive charged cations should move in or -ve charge anions should flow out of the cell. Since RBC membrane is relatively impermeable to cations, so the Cl^- anions return in the plasma from the RBC. This whole reaction catalysed by carbonic anhydrase inhibitor is called *reversal of chloride shift*.

Diffusion of CO_2 from plasma to alveoli

The CO_2 dissolved in plasma plus that released from the carbamino haemoglobin and bicarbonates combinedly exerts pCO_2 of 45 mmHg. Since the pCO_2 of alveolar air is 40 mmHg, so because of pressure gradient CO_2 diffuses from blood to alveoli. Due to constant ventilation CO_2 from alveoli is transported to atmosphere.

Other facts about CO_2 transport

Comparison of different vehicles for CO_2 transport

The carbon dioxide dissociation curve of plasma, bicarbonate solution and whole blood (Fig. 5.5-13 and the amount of CO_2 that can be loaded and unloaded by different transport vehicles from the tissues at pCO_2 45 mmHg (Table 5.5-1) reveal that:

- *Plasma* is not a good transport vehicle as very small amount of CO_2 (only 0.2 ml) can be taken from tissues/100 ml of blood/min.
- *Bicarbonate solution* is also not a good transport vehicle because beyond pO_2 40 mmHg there is no further transport of CO_2 .
- *Whole blood* is an ideal vehicle for transport of CO_2 , to load itself in

tissues with CO₂ and to release CO₂ in the lung.

FIGURE 5.5-13 Carbon dioxide dissociation curve: **(A)** for plasma; **(B)** for bicarbonate solution and **(C)** for whole blood.

TABLE 5.5-1

Amount of CO₂ That can be Loaded and Unloaded by Different Transport Vehicles

Vehicle	Content of CO ₂ /100 ml/min		
	In venous blood at pCO ₂ 45 mmHg	In arterial blood at pCO ₂ 40 mmHg	Loaded by the blood
Plasma	1.8 ml	1.6 ml	0.2 ml
Bicarbonate solution	48 ml	48 ml	Nil
Whole blood	52 ml	48 ml	4 ml

Rate of total CO₂ transport

In resting conditions,

each 100 ml of blood transports about 4 ml of CO₂ from the tissues to the lungs. Thus, with an average cardiac output of 5L/min, a total of (4 × 5000)/100 or 200 ml of CO₂ is transported per min.

During exercise

the amount of CO₂ transported increases depending upon the severity of exercise. In severe exercise, as much as 4 L of CO₂ may be transported per minute. Because of greater solubility and transport in different forms, the transport of such a large amounts of CO₂ occurs without any difficulty. The conversion of most of CO₂ into bicarbonate ions prevents

any significant change in the pH of blood even when such a large volume of CO₂ enters the circulation.

Changes in blood pH during transport of CO₂

Normally, the pH of arterial blood is 7.4. As it passes through the tissues, it acquires CO₂ and the pH of blood falls due to formation of carbonic acid (H₂CO₃) in venous blood. The pH may fall by about 0.4. However, during exercise the fall in pH may become to the tune of 0.5 and even more. Nevertheless most of it is neutralized by the blood buffers.

Respiratory quotient

Definition.

Respiratory quotient (RQ) refers to the ratio of the rate of CO₂ excretion and rate of O₂ consumption per minute. It is also called the *respiratory exchange ratio*.

Normal value.

Normally, the rate of CO₂ excretion is 4 ml/100ml/min, and rate of O₂ consumption is 5 ml/100 ml/min. So, $RQ = 4/5$, or 0.8.

The RQ depends upon the type of fuel consumed

- In a person who is utilizing carbohydrates as the entire source of energy for the body metabolism, value of RQ is 1, because in metabolism of carbohydrates, one molecule of CO₂ is formed for each molecule of O₂ consumed.
- The RQ is <1.0 for proteins and fats. When only fats are metabolized, the value of RQ falls to 0.7, because 0.7 molecules of CO₂ are formed, for each molecule of O₂ consumed in the metabolism of fat.
- A lower RQ, thus suggests that a greater than usual proportion of proteins and fats are being catabolized in the body.
- RQ can be easily estimated by knowing the amount of O₂ removed from inspired air and the amount of CO₂ added to the expired air per minute.

Introduction

Respiration is regulated by a complex integration of neural control mechanisms which are modified by certain respiratory reflexes and chemical control mechanisms.

Neural control mechanisms include:

- *A system for automatic control* of respiration as an involuntary function. The involuntary control system of respiration is located in the medullary and pontine centres of the brain stem.
- *A system for voluntary control* of respiration is located in the cerebral

cortex.

Thus, respiration enjoys the distinction of being an involuntary function which can be influenced voluntarily. This *dual control* has great functional significance, i.e.

- Involuntary control which allows human to breathe without conscious efforts under all circumstances including sleep and is thus essential for life.
- The voluntary control system facilitates acts like talking, singing, swimming, breath holding and voluntary hyperventilation.

Respiratory reflexes which modify the effects of neural mechanisms are those initiated by stimulation of stretch receptors, irritant receptors, J-receptors and chest wall receptors.

Chemical control mechanisms are influenced by alterations in arterial pO_2 , pCO_2 and H^+ concentration. The chemical control mechanisms are initiated by stimulation of the chemoreceptors (central and peripheral).

Functions of respiratory regulatory mechanisms include:

- *Genesis of normal respiratory spontaneous rhythm.* This is the function of medullary and pontine centres of neural mechanism.
- *Control of rate and depth of respiration,* i.e. adjustment of total ventilation to match metabolic needs of the body so that arterial oxygen tension (pO_2), carbon dioxide tension (pCO_2) and H^+ concentration (pH) are almost maintained constant whether it be during quiet breathing, sleep or muscular exercise. This function is accomplished by all the respiratory control mechanisms acting in unison (Fig. 5.6-1):
- *Sensors,* i.e. chemoreceptors and other receptors (e.g. stretch, irritant, chest wall and J receptors) perceive the respiratory needs of the body and convey via afferent nerves to the central controller.
- *Central controller,* i.e. medullary, pontine and other parts of the brain adjust the efferent outputs as per the body needs and convey to the effectors.

- *Effectors* are the respiratory muscles which perform their activity as per the neural discharges received.

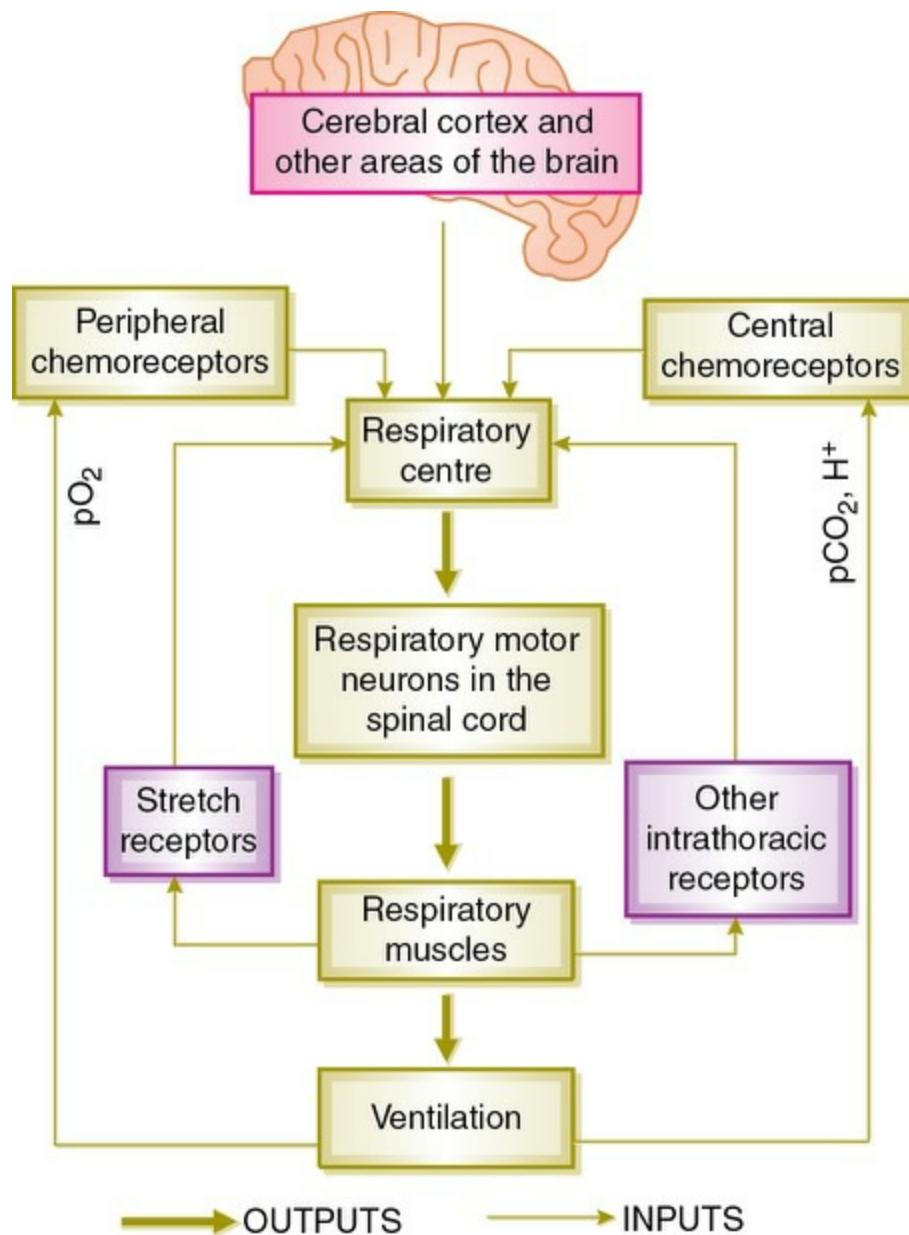

FIGURE 5.6-1 Diagrammatic representation of the inputs to respiratory centre that generate the output to the respiratory muscles.

Neural regulation of respiration

The neural mechanisms regulating respiration can be described under two headings:

- Automatic control system, and
- Afferent impulses to respiratory centres.

Automatic control system

Neural genesis of respiratory rhythm

The involuntary neural control system regulates respiration by several groups of neurons situated bilaterally in medulla and pons which include medullary respiratory centres, pontine respiratory centres and reticular activating system (RAS).

I. Medullary respiratory centres

The medullary respiratory centres include two groups of neurons: the dorsal respiratory group (DRG), and ventral respiratory group (VRG) which generate the basic respiratory rhythm.

The respiratory control pattern generator.

The respiratory control pattern generator, which is responsible for automatic respiration, is located in the medulla. A group of neurons called pacemaker cells from the pre-Botzinger complex, which are situated between nucleus ambiguus and lateral reticular nucleus. The rhythmic activity is initiated by these synaptically coupled neurons. These neurons discharge rhythmically and generate rhythmic motor activity in phrenic nerve, hypoglossal nerve and intercostal nerves.

Important Note

On the neurons of pre-Botzinger complex the receptors for substance P, Tachykinin (NK₁), 5HT₄ and μ -opioid are present. Opioids are used as analgesic, but at the same time it causes respiratory depression as a side effect. However, it is now known that 5HT₄ receptor agonists block the inhibitory effect of opioids on respiration without inhibiting analgesic effect.

1. Dorsal respiratory group neurons

Most of the neurons are located within the nucleus of tractus solitaries (NTS) and some in the adjacent reticular substance (Fig. 5.6-2). The neurons of DRG are of three types:

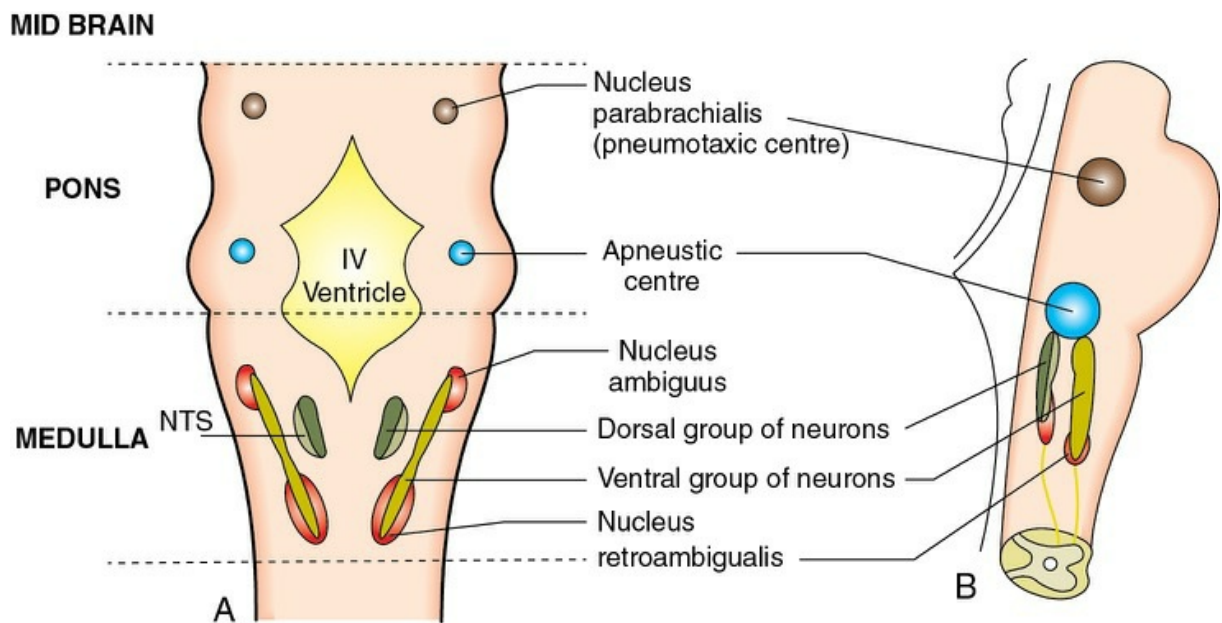

FIGURE 5.6-2 Medullary and pontine respiratory centres: **(A)** front view and **(B)** lateral view.

i. Inspiratory neurons.

The DRG mainly contains inspiratory cells called *I-neurons* that discharge during inspiration only. The axons of I-neurons cross the mid-line and descend on the contralateral side of spinal cord to make contact with the spinal motor neurons of inspiratory muscles, namely, the diaphragm (supplied by the phrenic nerve arising from C₃ to C₅ spinal segments) and the external intercostal muscles (supplied by the intercostal nerves). In other words, the neurons in the DRG are the upper motor neurons of respiratory muscles.

From I-neurons, nerve signals pass to the muscles of inspiration. The signal is not instantaneous but is a ramp signal, i.e. it is weak in the beginning and it steadily increases in a ramp manner for about 2 seconds and is thus called *inspiratory ramp*. This leads to a steady increase in the lung volume during inspiration rather than the respiratory gasps (abrupt distension). Ramp signal then abruptly ceases for approximately next 3 seconds.

ii. Inspiratory off-switch (IOS) neurons.

IOS neurons refer to a group of neurons that are responsible for terminating the activity of I-neurons and causes turning off of excitation of muscles of inspiration (diaphragm and external intercostal muscles). These muscles, therefore relax allowing elastic recoil of the chest wall and the lungs to cause expiration. After expiration again there is a signal

for starting another cycle.

iii. Integrator neurons.

Integrator neurons are other type of neurons of DRG present near the I-neurons and are stimulated by them. They subserve following integrating functions:

- The integrator neurons when depolarize to a critical level lead to firing of the so-called IOS neurons which are responsible for terminating the inspiratory ramp. The *I-neurons* trigger the IOS neurons indirectly through integrators and thereby bring about the termination of their own discharge. This forms the basic circuitry of an automatic respiratory rhythm (Fig. 5.6-3). In this way, the cycle of inspiration/expiration goes on continuously to cause tidal respiration.
- The *integrator neurons* receive both excitatory and inhibitory inputs (Fig. 5.6-3) and thus integrate the activity of *I-neurons* and IOS neurons accordingly.
- *The excitatory inputs* to integrator neurons come from:
 - Cerebral cortex
 - Pneumotaxic centre (PNC)
 - Vagal afferents from stretch receptors
- *The inhibitory inputs* to integrator neurons come from the medullary inhibitory neurons which from the so called *apneustic centre* (APN).

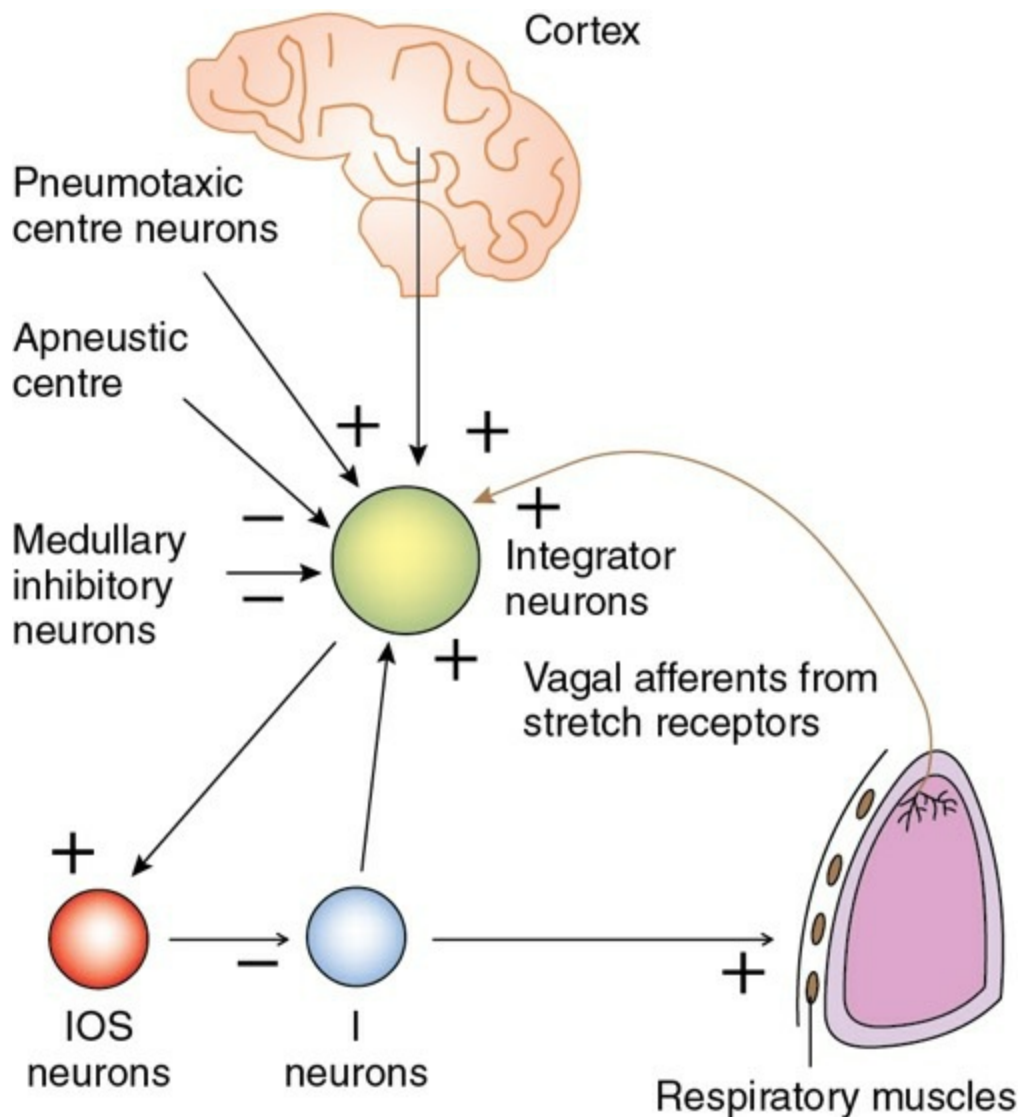

FIGURE 5.6-3 Basic circuitry for generation of respiratory rhythm.

iv. Other neurons.

Besides the above described, which form a part of DRG neurons are:

- *P-neurons or pump cells* are the second order pulmonary stretch receptor sensory neurons. These do not receive other respiratory inputs.
- *Propriobulbar inspiratory ramp interneurons, early inspiratory or early-burst neurons, late onset inspiratory neurons and post inspiration (PI)-related neurons* are other inspiratory neurons of the DRG.

Detailed functioning of these other neurons of the DRG is beyond the scope of this book.

2. Ventral respiratory group neurons

VRG neurons contain both inspiratory cells called I neurons and expiratory cells called E-neurons (c.f. DRG which contain only I-neurons).

Parts of VRG neurons.

The VRG neurons can be subdivided into three main parts (Fig. 5.6-2):

i. *Caudal part or nucleus retroambigualis (NRA)* contains mainly E-neurons which constitute the bulbospinal premotor neurons. Their axons cross the midline and descend on the contralateral side to make contact with the motor neuron pool for the muscles of expiration, i.e. internal intercostal muscles and abdominal muscles. In other words, these neurons in the VRG seem to form the *upper motor neurons of expiratory muscles*.

ii. *Intermediate part* of VRG neurons denote *nucleus parambigualis* because it parallels the ambiguus nucleus. This part mainly contains I-neurons called the bulbospinal inspiratory premotor neurons. These control the activity of inspiratory upper motor neurons.

iii. *Most rostral part of VRG* coincides with nucleus retrofacialis (NRF). It contains several types of E-neurons which form a complex called *Botzinger complex*. Some of these neurons control the pharyngeal and laryngeal musculature which must relax during expiration.

Interaction of I and E neurons.

The I and E neurons have inhibitory connections to each other, i.e. there exists *reciprocal innervation* between the two. Therefore, the motor neurons to the expiratory muscles are inhibited when those supplying the inspiratory muscles are active and vice versa. This reciprocal innervation is mediated via collaterals from excitatory pathway that synapse on inhibitory interneurons. Thus, an impulse that stimulates the one will inhibit the other and vice versa (Fig. 5.6-4):

FIGURE 5.6-4 Reciprocal innervation of I and E-neurons.

Role of VRG neurons.

The VRG neurons, normally remain totally inactive during quiet breathing. The VRG neurons become active during inspiration (role of I-neurons) as well as expiration (role of E-neurons) during forceful respiration. This area is especially important in providing powerful expiratory signals to expiratory muscles. Thus, VRG operates when high levels of pulmonary ventilation is required, for example, during exercise.

II. Pontine respiratory centres

The pontine centres include the apneustic (APN) and pneumotaxic (PNC), both of which modify the activity of medullary respiratory centres.

1. Apneustic centre

APN refers to a group of inhibitory neurons located bilaterally in the lower part of pons (Fig. 5.6-2). It sends signals to integrator neurons of DRG that affects the inspiratory off switch (IOS) neurons and prevent the switch-off of the inspiratory activity (Fig. 5.6-3). This increases the tidal volume and duration of inspiration, resulting in a deeper and more prolonged inspiratory effort termed as *apneusis*. However, normally the APN is inhibited by impulses carried by the vagus nerves and also by the activity of PNC. Either of these two influences, penumotaxic centre or the vagii, seems to be adequate to keep apneusis in check. The above-described facts are based on the experimental observations made in dogs and cats under general anaesthesia. The situation in conscious animals may be different. The existence and functions of APN are based on following experimental observations (Fig. 5.6-5):

- Sectioning of brain between the medulla and pons (level 1 in Fig. 5.6-5) leaves the basic rhythm intact indicating thereby that medullary respiratory centres are working normally.
- Sectioning the brain at mid-pontine level, i.e. between PNC and APN, (i.e. at level 2 in Figure 5.6-5) along with bilateral vagotomy leads to prolonged periods of inspiration, i.e. apneusis or apneustic breathing. This indicates that removal of two inhibitor influences (PNC and vagii) on the APN allows APN to exert its influence on medullary centres producing apneusis.

- Sectioning the brain rostral to the pons (level 3 in Fig. 5.6-5) leaves the respiratory rhythm intact even if combined with bilateral vagotomy. This indicates that mere presence of check by PNC is sufficient to control the apneustic effect of APN on medullary centres.

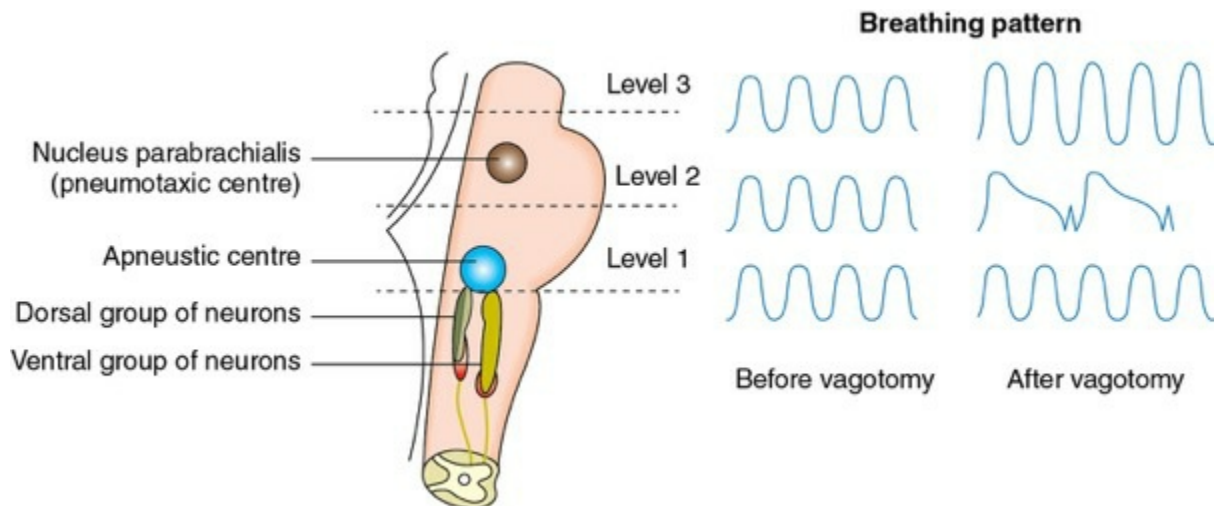

FIGURE 5.6-5 Sectioning of brain at different levels to demonstrate the activity of different respiratory centres.

2. Pneumotaxic centre

The PNCs are located bilaterally in *nucleus parabrachialis* of the upper pons.

Functions. As described above, the PNC inhibits the APN. Therefore, stimulation of PNC shortens inspiration, leading to shallow and more rapid respiratory pattern. In other words the PNC by inhibiting activity of APN indirectly controls the switch-off point of inspiratory ramp, thus controlling the duration of inspiration.

- Strong PNC discharge because of rapid switching-off of ramp signals may cut down the inspiratory phase to 0.5 second only; and as a result the rate of inspiration increases to 30–40 breaths per minute.
- Weak PNC discharge increases the duration of ramp signals and may reduce the rate of respiration to only a few breaths per minute.

Thus, though rhythm of respiration resides in DRG neurons in medulla, PNC and APN control these neurons to regulate the depth and rate of respiration.

III. Reticular activating system

The RAS stimulates the respiratory centres to increase respiratory drive. During sleep, RAS activity diminishes, decreasing respiratory drive, which diminishes alveolar ventilation and results in a slight elevation of arterial CO₂ tension.

Afferent impulses to respiratory centres

The respiratory centres generate the respiratory rhythm and execute their effects through the efferent nerves supplying the respiratory muscles. The activity of respiratory centres in turn is influenced by the afferent impulses from the lungs and various other parts of the body. These afferent impulses guide the respiratory centres to regulate their activity so as to serve a number of purposes in the body such as:

- To cope up with the O₂ demand of the body and get rid of CO₂ from the body,
- To help to regulate the H⁺ concentration of body,
- To maintain the appropriate O₂ tension of blood in certain conditions of anoxia or hypoxia.
- To help to maintain the normal body temperature, and so on.

Various afferent impulses to the respiratory centres can be grouped as (Fig. 5.6-6):

- Afferent impulses from higher centres,
- Afferent impulses from non-chemical receptors, which may constitute *non-chemical regulation of respiration* and
- Afferent impulses from the chemical receptors, which constitute the 'chemical regulation of respiration' and hence has been described separately.

FIGURE 5.6-6 Afferent impulses to respiratory centres.

Afferent impulses from higher centres

The afferent impulses from higher centres which influence the involuntary activity of respiratory centres mainly include voluntary control system and limbic control system.

1. Voluntary control system

As described above, normally, breathing is an involuntary effort and goes on automatically. However, the respiratory muscles are typical skeletal muscle and can also be controlled voluntarily. The voluntary control of respiration is mediated by a pathway which originates from the neocortex, bypasses the medullary respiratory centres to project directly on the spinal respiratory neurons. The voluntary control of breathing is exercised during: *activities like talking, singing, and*

swimming; and breath holding.

Breath holding or voluntary apnea.

Breathing can be stopped voluntarily for about 50–60 seconds (breath-holding time). But, after this time the chemical drive overrides the voluntary inhibition and the person has uncontrollable desire to breathe and ultimately breathing is resumed involuntarily. That is why it is impossible to commit suicide by holding the breath voluntarily. The decrease in arterial pO_2 and increase in arterial pCO_2 seem to be the chief causes for the end of breath-holding. Breath-holding can be prolonged by 15–20 seconds by an initial hyperventilation which lowers the arterial pCO_2 . As a result it takes longer duration of breath-holding to increase the arterial pCO_2 to the critical level. Breath-holding may also be increased by prior inhalation of pure O_2 . Some mechanical or reflex factors originating from the chest wall also seem to be involved in limiting the duration of breath-holding.

Voluntary hyperventilation,

i.e. voluntary overbreathing can be done for some time only similar to breath-holding. Effects of hyperventilation are discussed in chemical control of respiration (see page 452)

2. Limbic control system

Pain and emotional stimuli influence the rate and depth of breathing. It indicates the presence of afferents from limbic system to the pontomedullary respiratory neurons. Experimentally also marked changes in respiration are observed on electrical stimulation of various regions of hypothalamus. The influence of hypothalamus and the other parts of limbic system on respiration is only to be expected in view of respiratory changes being a part of emotional expression.

Important Note

Changes in the breathing pattern are the basis for part of polygraph test used as a lie detector.

Applied Aspects

As respiration has two separate controls, voluntary and automatic, sometimes automatic control is disrupted whereas voluntary control remains intact. Clinically, this condition is known as *Ondine curse*. In this

state person would stay alive only if he is awake and remembers to breathe. Ondine was a water nymph cursed by the king and all his automatic functions were withdrawn. Due to exhaustion he fell asleep and died because of stoppage of breathing. This condition usually occurs in the patients suffering with bulbar poliomyelitis or conditions which compress the medulla.

Afferent impulses from nonchemical receptors

Afferent impulses from the receptors other than the chemoreceptors, i.e. from nonchemical receptors include the following:

1. Afferent impulses from pulmonary stretch receptors (Hering–Breuer reflex)

Hering–Breuer reflex is one of the first examples of negative feedback. In 1868, Hering and Breuer found that lung inflation inhibits output of the phrenic motor neurons, thereby protecting lung from overinflation.

The Hering–Breuer inspiratory inhibitory reflex is initiated when the stretch receptors located in the smooth muscles of the bronchi and bronchioles are stimulated by inflation of the lungs. The impulses are then sent through *vagii nerves* to pontomedullary respiratory centres to inhibit respiration. This reflex has an important role in controlling tidal volume during eupnea in human infants. In adults this reflex, therefore, does not play any regulatory role in tidal respiration. This reflex is initiated only when the tidal volume is more than 1–1.5 L. Thus, the reflex tends to limit the tidal volume.

2. Afferent impulses from j-receptors

Afferent impulses from J-receptors constitute the J-reflex. The J-receptors were discovered by an Indian Physiologist AS Paintal in 1954. The name J-receptors (juxtapulmonary capillary receptors) was given to them because of their location very close to the pulmonary capillaries (Fig. 5.6-7). Important features of J-receptors are:

- J-receptors are basically un-myelinated vagal afferent nerve endings (type C fibres).
- These receptors are primarily sensitive to increase in the content of interstitial fluid between the capillary endothelium and alveolar epithelium, therefore they are stimulated in conditions like pulmonary congestion, pulmonary oedema, pneumonia, hyperinflation of lungs

and microembolism in pulmonary capillaries.

- J-receptors are also stimulated by some chemical substances like phenyl diguanide, capsaicin, halothane and bradykinin.
- The J-reflex response produced on stimulation of J-receptors is characterized by apnoea followed by hyperventilation, bradycardia, hypotension and weakness of skeletal muscles.
- Physiological role of J-receptors has been postulated by the discoverer Mr Paintal. He states that after exercise especially at high altitude some fluid is entrapped in the alveolar interstitial space which stimulates the J-receptors producing dyspnoea and reduction of skeletal muscle tone. Their combined effect would discourage exercise, thereby taking away the trigger for pulmonary congestion.

FIGURE 5.6-7 Location of J-receptors.

3. Afferent impulses from irritant receptors in the respiratory tract

Irritant receptors are located below the mucosa of whole respiratory tract. These are stimulated by smoke, noxious gases, particulate matter in the inspired air and in a number of other conditions. These receptors initiate a large number of reflexes some of which are:

i. Cough reflex.

This is a protective reflex caused by stimulation of irritant receptors in the pharynx, larynx, trachea and bronchi (conducting zone of respiratory tract). Cough begins with a deep inspiration followed by forced expiration with closed glottis. So, intrapleural pressure rises above 100 mmHg. The glottis is then suddenly opened producing an explosive outflow of air. The velocity of the air flow may reach 960 km per hour. By this endeavour the irritants may be expelled out of the respiratory tract.

ii. Sneezing reflex

is also a protective reflex produced on stimulation of irritant receptors of nasal mucosa. The sneezing begins with deep inspiration, followed by forceful expiration with opened glottis (in cough reflex where glottis is closed).

iii. Hering–Breuer deflation reflex

is produced on stimulation of irritant receptors located in bronchial epithelium due to distortion of bronchial epithelium caused by large deflations of the lungs as seen in pneumothorax and lung collapses (atelectasis). This reflex may also be responsible for the *sighs* or *yawning* in response to the increase in compliance that occurs periodically due to the collapse of smaller alveoli. The reflex helps in opening up the collapsed alveoli again.

- Yawning is a peculiar respiratory act. Its physiological basis is uncertain. However, one view suggests that deep inspiration and stretching help in opening up of alveoli and prevent them from collapsing. However, experimentally atelectasis preventing effect of yawning could not be demonstrated.
- Yawning increases venous return to the heart.

- In groups of certain animal (monkeys) yawning is used as signal for communication.

iv. Reflex tachypnoea and bronchoconstriction

is produced on stimulation of irritant receptors present in the respiratory zone of the respiratory tract. Rapid shallow breathing results from reflex stimulation of inspiratory motor neurons. Bronchoconstriction is produced by release of histamine and other chemical substances in the lungs, thereby preventing the irritants to reach the gas exchanging surface. For receptors see page 445.

v. Deglutition reflex

refers to temporary apnoea produced during pharyngeal phase of swallowing of food. It is a protective reflex which prevents the entry of food particles into the respiratory tract. The afferents travel in the glossopharyngeal nerve and produce *deglutition apnoea* by temporary inhibition of respiratory centres.

In the case of vomiting, the chest is fixed so that contraction of intra-abdominal muscle increases intra-abdominal pressure. See page 603.

4. Afferent impulses from proprioceptors

Proprioceptors are the receptors present in the muscles, tendons and joints and are stimulated during change in the position of different parts of the body. Afferent impulses from proprioceptors stimulate the inspiratory neurons to increase the rate and depth of respiration.

Important Note

This reflex helps in increasing ventilation during exercise. The paediatricians employ this reflex for initiating first breath in the newborn by slapping it.

5. Afferent impulses from chest wall stretch receptors

Chest wall stretch receptors are nothing but the *muscle spindles* present in the intercostal muscles. Stretching of the intercostal muscles produce a stretch reflex due to stimulation of muscle spindles that is characterized by contraction of intercostal muscles. The muscle spindles present in respiratory muscles help to co-ordinate breathing during change in posture or during speech. They play a special role in maintaining normal tidal volume when breathing is impeded by an increase in airway resistance or a decrease in pulmonary compliance.

When the mechanical load on the respiratory system is increased, intercostal muscles are stretched and their muscle spindles are stimulated leading to increased strength of contraction of intercostal muscle. It has been observed that increase in intercostal nerve afferent activity leads to contraction of neighbouring intercostal muscles. This reflex has been termed the *intercostal-to-intercostal reflex*.

Although diaphragm contains very few muscle spindles, but it also shows reflex contraction. This has been attributed to reflex contraction of diaphragm in response to afferent nerve impulses originating in lower intercostal nerves. This reflex has been termed the *intercostal-to-phrenic reflex*.

6. Afferent impulses from baroreceptors

Baroreceptors or pressure receptors located in the carotid sinus and aortic arch (see details on page 340) are stimulated by increase in the arterial blood pressure. Though they play primary role in regulation of blood pressure, but the impulses do travel to respiratory centres (via vagus from aortic arch and via glossopharyngeal nerve from carotid sinus) and cause inhibition of respiration, in physiological conditions the baroreceptors play an insignificant role in regulation of respiration. The *adrenaline apnoea* observed on injection of high doses of adrenaline has been explained due to the fact that the adrenaline causes a large rise in arterial pressure which in turn inhibits respiration by afferent impulses from the baroreceptors to respiratory centres. However, in small doses, adrenaline stimulates respiration by stimulating the peripheral chemoreceptors.

7. Afferent impulses from thermoreceptors

Thermoreceptors are those receptors which are stimulated by a change in the body temperature. Thermoreceptors are of two types: the cold receptors and the warmth receptors. When warm receptors are stimulated the impulses are conveyed to cerebral cortex via somatic afferent nerves. Cerebral cortex in turn stimulates the respiratory centres to produce hyperventilation.

Respiration helps to maintain body temperature, as some amount of heat is lost in the expired air. In dogs panting is one of the major mechanisms of thermoregulation.

Chemical regulation of respiration

The chemical factors regulating respiration are $p\text{CO}_2$, $p\text{O}_2$ and pH of blood. These factors influence respiration in such a way that their own blood levels are maintained constant. The chemical mechanism of regulation operates through chemoreceptors.

Chemoreceptors

Chemoreceptors are the sensory nerve endings, which are highly sensitive to changes in $p\text{CO}_2$, $p\text{O}_2$ and pH of blood. These are of three types:

- Peripheral chemoreceptors,
- Central chemoreceptors, and
- Pulmonary and myocardial chemoreceptors.

Peripheral chemoreceptors

Location.

Peripheral chemoreceptors include the carotid and aortic bodies (Fig. 5.6-8).

- *Carotid body* is located on either side near the bifurcation of common carotid artery.
- *Aortic bodies*, two or more in number, are located near the arch of aorta.

Structure. Each carotid and aortic body consists of:

FIGURE 5.6-8 Location of carotid and aortic bodies (peripheral chemoreceptors).

Capsule

surrounding each carotid and aortic body is very thin.

Sinusoidal

large capillaries present below the capsule surround the main mass of each body.

Epithelial cells.

The main mass of the body consists of islands of epithelial cells which are of two types: type I and type II (Fig. 5.6-9):

FIGURE 5.6-9 Histological structure of carotid body.

- **Type I or glomus cells**

are similar to chromaffin cells of the adrenal glands. These cells have dense-core granules containing catecholamines (probably dopamine). Unmyelinated nerve endings are closely applied to these cells, these nerve endings are cup shaped and have dopamine receptors (D_2) on them. When exposed to hypoxia, the type 1 cells release catecholamine which stimulates the D_2 receptors.

- **Type II cells**

which are probably glial cells are also closely applied to the type 1 cells.

- **Nerve fibres.**

Outside the capsule of each body, the nerve fibres acquire myelin sheath, they are only 2–5 μm in diameter and conduct at relatively low rate of 7–12 m/s. Afferent fibres from the carotid body join the sinus nerve, a branch of glossopharyngeal (IX) nerve and ultimately ascend to medulla. Those from the aortic body join the aortic nerve branch of vagus (Xth cranial) nerve and ascend to medulla.

Blood flow

to each carotid and aortic body is highest in the body (2000 ml/100 gm/min). Therefore, the O₂ needs of these cells can be met largely by dissolved O₂ only.

Functions.

The peripheral chemoreceptors respond to lowered pO₂ increased pCO₂ and increased H⁺ concentration in the arterial blood. The afferent impulses from the chemoreceptors stimulate the dorsal respiratory group (DRG) neurons, which lead to an increased rate and depth of respiration called *hyperventilation*. Increase in the rate or depth of respiration regardless of patients subjective sensation is called hyperpnoea. Salient points of their functions are:

- The peripheral chemoreceptors are the only sites that detect changes in pO₂.
- Carotid bodies are seven times more effective than aortic bodies in stimulating respiration.
- Carotid bodies increase both rate and depth of respiration, while aortic bodies increase only the frequency of respiration with small increase in ventilation.

Mechanism of chemoreceptors stimulation by hypoxia and oxygen transduction in glomus cells.

The peripheral chemoreceptors are stimulated by the release of neurotransmitter by glomus cells. Oxygen transduction is the process by which changes in the arterial pO₂ results in proportionate changes in the frequency of action potential discharge. The sequence of events is:

- Hypoxia leads to decrease in activity of oxygen-sensitive K⁺ channels present in the cell membrane of glomus cells leading to decrease in the K⁺ efflux depending upon the level of pO₂.
- Thus, the glomus cells get depolarized in proportion to the fall in arterial pO₂.
- Depolarization of the glomus cells opens up the L-type Ca²⁺ channels in the glomus cell membrane leading to increase in Ca²⁺ influx.

- The Ca^{2+} influx triggers the release of neurotransmitter which stimulates the afferent nerve endings.

Factors affecting peripheral chemoreceptors stimulation

i. O_2 tension versus O_2 content.

The peripheral chemoreceptors monitor the dissolved O_2 , i.e. pO_2 , rather than its total content. They are stimulated when pO_2 falls below 60 mmHg. Therefore, they respond to various types of hypoxia differently as:

- *Hypoxic hypoxia* in which arterial pO_2 is reduced stimulates peripheral chemoreceptors.
- *Histotoxic hypoxia* in which there is reduced utilization of O_2 by the tissue cells including glomus cells also stimulates chemoreceptors.
- *Anaemic hypoxia*, methaemoglobinemia or carbon monoxide poisoning do not stimulate the peripheral chemoreceptors, because under these conditions, though the total content of O_2 may be low, but the O_2 tension, which is determined by the amount of dissolved O_2 , remains normal.
- *Vascular stasis*, in which the amount of O_2 delivered to receptors per unit of time is decreased, which leads to chemoreceptor stimulation.
- *Drugs* such as cyanide, nicotine and lobeline, prevent O_2 utilization at the tissue level, stimulate peripheral chemoreceptors.

ii. Elevated pCO_2 .

Elevated pCO_2 (by 10 mmHg) also stimulates the peripheral chemoreceptors, but the major effect of CO_2 is on the central chemoreceptors.

iii. H^+ concentration

when increased in the blood (decreased pH by 0.1 unit) stimulates the peripheral chemoreceptors.

iv. Increase in plasma K^+ levels

may stimulate the peripheral chemoreceptors even in the absence of hypoxia. Increase in plasma K^+ levels during exercise contributes to exercise induced hyperventilation.

v. Asphyxia,

i.e. combination of O_2 lack plus CO_2 excess in blood stimulate peripheral chemoreceptors.

Effects of stimulation of peripheral chemoreceptors

- They regulate the respiration from breath to breath and their stimulation increases the rate and depth of respiration.
- They also cause increase in blood pressure and tachycardia.
- About 15–20% of resting respiratory drive is due to stimulatory effect of CO_2 on peripheral chemoreceptors.

Central chemoreceptors

Location.

Central chemoreceptors are the cells (neurons) that lie just beneath the ventral surface of the medulla oblongata and are therefore also called medullary receptors (Fig. 5.6-10).

FIGURE 5.6-10 Location of central chemoreceptors in medulla: **(A)** lateral view and **(B)** front view.

Innervation.

Nerves from the neurons forming central chemoreceptors project directly over to the respiratory centres which are located slightly deeper to central chemoreceptors.

Stimulation characteristics

of central chemoreceptors are:

- They respond to H^+ concentration in the surrounding interstitial fluid and CSF.
- The magnitude of stimulation is directly proportional to the local H^+ concentration, which in turn parallels arterial pCO_2 .
- *Mechanism by which increase in CO_2 concentration affects central*

chemoreceptors. CO_2 readily crosses the blood–brain barrier, because it is a small, very soluble, uncharged molecule. In the CSF, CO_2 combines with water to form H_2CO_3 which dissociates into H^+ and HCO_3^- ions. The increase in H^+ concentration of CSF and interstitial fluid stimulates the central chemo-receptors, whereas a decrease in the H^+ concentration inhibits respiration. It is important to note that the blood–brain barrier does not allow the charged ions (e.g. H^+ , HCO_3^- etc.) to cross through readily. Because of this reason if the arterial pCO_2 is kept constant experimentally a decrease in arterial pH (raised H^+ concentration) fails to stimulate central chemoreceptors.

- *Increase in pCO_2 of CSF is more effective in stimulating central chemoreceptors than increased pCO_2 in interstitial fluid of brain.* As mentioned above actual stimulus for central chemoreceptors is the increased H^+ concentration. In CSF, there are no buffers (proteins) to buffer the H^+ ions formed from H_2CO_3 . The interstitial fluid is surrounded by cells having proteins to act as buffers. Therefore, for the same change in CO_2 concentration, H^+ concentration of CSF is more than that of interstitial fluid; thus increased pCO_2 of CSF is more important stimulus.
- Central chemoreceptors are not stimulated by hypoxia, rather like any other cell, they are depressed by hypoxia.
- Central chemoreceptors are also inhibited by anaesthesia, cyanide and during sleep.

Effects of stimulation

of central chemoreceptors are:

- The central chemoreceptors regulate the respiration from minute to minute. Their stimulation leads to increase in the rate and depth of respiration.
- It is important to note that about 80–85% of the resting respiratory drive is due to stimulatory effect of CO_2 on the central chemoreceptors. While peripheral chemoreceptors provide only 15–20% of initial drive to increase respiration.

Pulmonary and myocardial chemoreceptors

Location.

Pulmonary and myocardial chemoreceptors are located in the pulmonary and coronary blood vessels, respectively.

Innervation.

These are innervated by the vagus (Xth cranial) nerve.

Stimulation characteristics and effects

of these receptors are:

• Pulmonary chemoreceptors

are stimulated by injection of veratridine or nicotine into pulmonary circulation and produce the so-called *pulmonary chemoreceptor reflex*, which is characterized by bradycardia, hypotension and apnoea followed by tachypnoea (rapid shallow breathing). Physiological role of this reflex is not established. It occurs in pathological states like pulmonary congestion or embolism.

• Myocardial chemoreceptors

are similarly stimulated when these agents are injected into coronaries supplying the left ventricle and produce the so-called *coronary chemoreflex* or *Bezold-Jarisch reflex* having features similar to pulmonary chemoreflex. *Physiological role* of this reflex is not established. It is known to occur after myocardial infarction (see page 345).

Effect of pO_2 , pCO_2 and H^+ concentration on respiration

- The pO_2 , pCO_2 and H^+ concentration influence the respiration by their effects on chemoreceptors.
- The peripheral and central chemoreceptors work in unison to bring about increased ventilation in response to a rise in pCO_2 , rise in H^+ concentration or a fall in arterial pO_2 . Of the three, hypercapnia provides the strongest respiratory drive.
- Chemical regulation of breathing ensures that the arterial pCO_2 is kept constant at normal value of 40 mmHg, arterial pO_2 is not allowed to fall below 60 mmHg and changes in blood pH are opposed.

- Denervation or removal of carotid chemoreceptors produces about 40% decrease in response to hypercapnia as well as H^+ concentration and complete abolition of response to drop in pO_2 . The predominant effect of hypoxia after denervation of the carotid bodies is a direct depression of the respiratory centre.

With these introductory remarks, effect of each chemical factor on respiration will be discussed followed by the interaction of chemical factors in regulation of respiration.

Effect of hypoxia on respiration

The normal arterial pO_2

is 100 mmHg, which may fall in many conditions (see page 459), producing the so-called hypoxic hypoxia.

A decrease in arterial pO_2

is the most potent stimulus for the peripheral chemoreceptors; consequently, the rate of discharge in the peripheral chemoreceptors begins to increase.

When the arterial pO_2 levels falls

between 100 and 60 mmHg not much effect is produced on ventilation. However, a marked increase in pulmonary ventilation occurs when the pO_2 falls below 60 mmHg (Fig. 5.6-11). This can be explained as:

FIGURE 5.6-11 Relationship of pO₂ with sinus nerve discharge rate (A) and pulmonary ventilation (B).

At pO₂ levels from 100 to 60 mmHg,

though there is significant increase in the afferent nerve discharge from the peripheral chemoreceptors, however, pulmonary ventilation does not increase significantly because of following two reasons:

- **Breaking effect of CO₂**

When decrease in pO₂ of arterial blood stimulates ventilation, increased ventilation causes washing out of CO₂. This leads to decrease in pCO₂ of blood which inhibits the respiration through its effect on central chemoreceptors. It opposes and neutralizes the effect of decreased pO₂ and thus there is no marked effect on ventilation. This phenomenon is called breaking effect of CO₂.

This fact can be confirmed experimentally by holding the pCO₂ constant at 40 mmHg and decreasing arterial pO₂ simultaneously. Under these conditions hyperventilation is observed even pO₂ between 100 and 60 mmHg.

- Due to hypoxia, the amount of deoxyhaemoglobin is increased which is

a weaker acid as compared to oxyhaemoglobin. This results in mild decrease in H^+ concentration of blood which tends to nullify the hypoxic drive on pulmonary ventilation.

At pO_2 levels below 60 mmHg,

the stimulation of peripheral chemoreceptors is so strong that it overrides the inhibitory effects of decreased arterial pCO_2 and decreased H^+ concentration and produces a marked increase in pulmonary ventilation.

- Hypoxia stimulating respiration through peripheral chemoreceptors can be proved experimentally by denervating them. Under such circumstances hypoxia cannot increase pulmonary ventilation, rather it causes direct depression of the respiratory centre.

Effect of hypercapnia on respiration

Normal pCO_2 is 40 mmHg,

which is kept constant by chemical regulation of respiration.

Hypercapnia,

i.e. rise in pCO_2 rarely occurs due to an increase in CO_2 production. Clinically, it may occur in restrictive lung disorders (see page 468).

An increase in arterial pCO_2 causes a prompt increase in pulmonary ventilation

resulting in CO_2 washout and a near restoration of arterial pCO_2 to normal level (40 mmHg). There exists a linear relation between increase in arterial pCO_2 and increase in pulmonary ventilation. This can be demonstrated experimentally by breathing from a bag of air with different concentration of CO_2 , varying from 4 to 7% (Fig. 5.6-12).

FIGURE 5.6-12 Effect of increase in (A) arterial pCO₂ and (B) decreased pH on pulmonary ventilation.

CO₂ increases pulmonary ventilation mainly by stimulating the central chemoreceptors.

This can be demonstrated experimentally by removing the peripheral chemoreceptors and then making the person to breathe from a bag of air with different concentration of CO₂. The same effect is obtained as above (Fig. 5.6-12).

Co₂ is capable of increasing the pulmonary ventilation by stimulating the peripheral chemoreceptors as well.

When central chemoreceptors are depressed by anaesthesia, CO₂ increases respiration through stimulation of peripheral chemoreceptors.

CO₂ acts as a main regulator of respiration

because of following facts:

- It has a direct effect on respiratory centre through the central chemoreceptors.
- It can cross the blood–brain or blood–CSF barrier easily; therefore, CO₂ concentration in CSF and in interstitial fluid of brain increases soon after the increase in concentration of CO₂ in the blood.
- CO₂ has a very strong breaking effect on the action of either decreased pO₂ or pH,
- pO₂ or pH does not have very strong breaking effect on the action of increased CO₂ on ventilation (Fig. 5.6-12).

Carbon dioxide narcosis.

It develops when arterial pCO₂ increases above 50 mmHg. Accumulation of such a large amount of CO₂ (hypercapnia) in the body depresses the CNS, including respiratory centres producing headache, confusion, convulsions and finally coma and death may occur.

Causes.

Carbon dioxide narcosis may occur in patients with prolonged severe emphysema or due to accidental inhalation of CO₂ (in breweries, refrigeration plants, etc). Experimentally, it can be produced by making the person to inhale the air containing more than 7% CO₂. When the inspired air pCO₂ approaches close to the alveolar pCO₂, as a result elimination of CO₂ becomes difficult which causes alveolar and arterial pCO₂ to rise abruptly in spite of the hyperventilation.

Important Note

Clinical significance. Whenever CO₂ is to be used to stimulate respiration in a comatose patient with respiratory depressions it is always advisable to estimate the CO₂ content of blood, to avoid occurrence of death from carbon dioxide narcosis.

Effect of arterial pH on respiration

i. Increased H^+ concentration

(metabolic acidosis) produces prolonged respiratory centre stimulation via peripheral chemoreceptors, leading to a decrease in the arterial pCO_2 by elimination of larger amounts of CO_2 , producing compensatory fall in blood H^+ concentration. The related aspects of renal correction of acid–base balance are discussed in [Chapter 12.3](#) page 1227.

Causes

of metabolic acidosis, i.e. decrease in HCO_3^- concentration in blood secondary to increase in H^+ concentration of blood are:

- Diabetic ketoacidosis (hyperventilation occurring in this condition is called *Kussmaul breathing*).
- Renal failure (when kidney fails to excrete their normal quota of H^+).
- Due to accumulation of lactic acid in severe muscular exercise.
- Ketoacidosis in starvation and
- Infantile diarrhoea associated with loss of $NaHCO_3$.

ii. Decreased H^+

concentration (metabolic alkalosis) depresses respiratory centre via peripheral chemoreceptors, leading to retention of CO_2 and an increase in arterial pCO_2 . The secondary changes in arterial pCO_2 compensate for the primary metabolic defects and help to restore H^+ concentration of blood.

Common causes

of metabolic alkalosis, i.e. increase in HCO_3^- concentration in blood secondary to decreased H^+ concentration in blood: excessive vomiting with loss of HCl from the body.

Respiratory acidosis and alkalosis. It may be added here that primary changes in the pulmonary ventilation also effect the pH of blood causing respiratory acidosis or alkalosis.

iii. Primary pulmonary hypoventilation

may lead to elevation of arterial pCO_2 (hypercapnia) producing the so-called *respiratory acidosis*.

Causes

of hypercapnia responsible for respiratory acidosis are:

- Respiratory depression due to narcotic poisoning or cerebral diseases.
- Neuromuscular disorders with impaired breathing.
- Chronic obstructive pulmonary disease such as emphysema in which effective alveolar ventilation is decreased due to ventilation–perfusion mismatch.

Compensatory mechanism

through chemoreceptors produces hyperventilation, washes out CO_2 and tries to restore arterial pCO_2 .

iv. Primary pulmonary hyperventilation

may cause a decrease in the arterial pCO_2 producing the so-called *respiratory alkalosis*.

Causes

of respiratory alkalosis are:

- Voluntary hyperventilation,
- Excessive artificial respiration,
- Compulsive hyperventilation in hysteric patients and
- Chronic O_2 lack (hypoxia) producing CO_2 wash due to hyperventilation, e.g. as seen in high altitude hypoxia.

Signs and symptoms

- *Hypocapnia* produced causes faintness and paraesthesias due to reduction of cerebral blood flow.
- *Respiratory alkalosis* produced causes lowering of ionized Ca^{2+} in plasma and the appearance of symptoms of tetany, e.g. carpopedal spasm.

Compensatory mechanism through chemoreceptors slows down the respiration, leading to retention of CO_2 , which in turn restores H^+

concentration of blood towards normal.

Interaction of pO_2 , pCO_2 and pH in regulation of respiration

In the above discussion, we have seen that each of hypoxia, increased pCO_2 and acidosis individually cause an increase in the respiration. In many physiological or clinical situations more than one factor may be present. Their interaction is summarized here:

1. Interaction of pCO_2 and pO_2

Hypoxia sensitizes the respiratory mechanism to excess of CO_2 or H^+ concentration, therefore increased pCO_2 and H^+ concentration produce a much greater effect (Fig. 5.6-13.).

FIGURE 5.6-13 Interaction of arterial pO_2 and pCO_2 depicting effect of pCO_2 on pulmonary ventilation at different levels of pO_2 .

When pCO_2 is held constant at a level 2–3 mm of Hg above normal (i.e. in the presence of hypercapnic drive) there is an inverse relationship between ventilation and alveolar pO_2 , even in the 90–110 mmHg range

(Fig. 5.6-14). When $p\text{CO}_2$ is held constant at a level 2–3 mmHg below normal, (i.e. in the absence of CO_2 related drive), a fall in $p\text{O}_2$ level between 110 and 60 mmHg does not produce any effect on ventilation. However, a marked increase in pulmonary ventilation occurs when $p\text{O}_2$ falls below 60 mmHg (Fig. 5.6-14).

FIGURE 5.6-14 Effect of hypoxia ($p\text{O}_2$) on pulmonary ventilation with arterial $p\text{CO}_2$ being kept **(A)** 2–3 mm above normal and **(B)** 2–3 mm below normal.

2. Interaction of pH and CO_2 response

The stimulatory effects of H^+ concentration and CO_2 on respiration are *additive*, i.e. a fall in pH (acidosis) shifts the CO_2 response curve to left without change in slope. In other words, the same amount of respiratory stimulation is produced by lower arterial $p\text{CO}_2$ levels (Fig. 5.6-15).

FIGURE 5.6-15 Effect on CO₂ response curve of varying amount of hypoxia and pH.

3. Interaction of CO₂ and body temperature

The effect of CO₂ on respiration increases with increase in body temperature (Fig. 5.6-16).

FIGURE 5.6-16 Effect of temperature on CO₂ response curve.

Some other aspects related to chemical regulation of respiration

Effects of hyperventilation

Effect of short lasting severe hyperventilation

Effects of hyperventilation on respiration can be demonstrated experimentally by making a person to breathe as rapidly and as deeply as possible for him for one to two minutes and then stop. The voluntary hyperventilation may show following effects (Fig. 5.6-17):

FIGURE 5.6-17 Effect of hyperventilation on arterial pO_2 , pCO_2 and respiration. Note correlation between pCO_2 , pO_2 and periods of hyperventilation, apnoea and periodic breathing and normal breathing.

i. Effects on respiration.

After a period of hyperventilation, any of the following pattern of respiration may be seen for a small period before normal respiration is restored:

- *Hypoventilation* for a prolonged period is seen in most of the individuals.
- *Apnoea*, i.e. complete cessation of breathing for 1–2 minutes may occur in some individuals.
- *Periodic breathing (Cheyne-Stokes breathing)*, i.e. alternate phases of apnoea and breathing may occur for sometime in a few individuals.

ii. Effects on arterial pCO₂ and pO₂ and their correlation with effect on respiration (fig. 5.6-17)

- Arterial pO₂ may go as high as 150 mmHg and pCO₂ as low as 15 mmHg after a period of voluntary hyperventilation.
- Apnoea occurring in some individuals at the end of hyperventilation seems to be related to lack of CO₂, because it does not occur if the person hyperventilates a gas mixture containing 5% CO₂ and 20% oxygen.
- During phase of apnoea, due to metabolism of body, there occurs a decline in arterial pO₂ and an increase in pCO₂. Depending upon the interaction between levels of pO₂ and pCO₂ attained following effects can occur on respiration.
- If the arterial pCO₂ is reached at threshold level (40 mmHg), then a normal breathing is resumed,
- If the hypoxic stimulus (decreased pO₂) becomes strong before the pCO₂ reaches a threshold level, then *periodic breathing* (Cheyne-Stokes breathing) may result, i.e. a few breaths eliminate hypoxic drive, then breathing stops and restarts when again hypoxic drive stimulates it. Such cycles are repeated till pCO₂ reaches threshold level to normalize breathing.

Effects of prolonged moderate hyperventilation

Prolonged moderate hyperventilation, i.e. two to fivefold increase in pulmonary ventilation may occur under following circumstances:

- In residents of high altitude,
- In clinically hypoxic patients due to some pulmonary disease or
- It may also be maintained even voluntarily.

The prolonged moderate hyperventilation is associated with decrease in alveolar and arterial $p\text{CO}_2$, since pulmonary ventilation is in excess of the metabolic requirements of the body. The low arterial $p\text{CO}_2$ which lasts for many days may result in following complication in the body:

- **Respiratory alkalosis.**

Low levels of $p\text{CO}_2$ reduce the formation of H^+ and HCO_3^- in the blood causing increase in its pH to 7.55 or even 7.6, a condition called respiratory alkalosis.

- **Renal changes.**

The respiratory alkalosis produced due to decreased arterial $p\text{CO}_2$ interferes with H^+ secretory mechanism in the kidney. There occurs failure of proximal tubular reabsorption of HCO_3^- , which results in excretion of alkaline urine containing HCO_3^- .

- **Neurological changes**

may occur due to:

- *Respiratory alkalosis induced hypocalcaemic tetany* which include numbness and tingling in the extremities, and carpopedal spasm.
- *Low arterial $p\text{CO}_2$ induced constriction of cerebral vessels* may produce symptoms like dizziness and light headache. The consciousness may be dulled or even lost.

- **Cardiovascular changes**

may occur due to moderately increased cardiac output owing to muscular efforts involved in the production of hyperventilation.

Effect of sleep on respiration

It has been reported that, due to inhibition of central chemoreceptors during sleep the sensitivity of respiratory centre neurons to arterial $p\text{CO}_2$ is decreased (Fig. 5.6-18). It may cause following effects:

- *Apnoea for brief period (10 second duration)* is of common occurrence during sleep in normal individuals.
- *Sleep apnoea syndrome* is a serious clinical problem which may occur

in some individuals. Such episodes of apnoea are more common in obese male snorers and children with enlarged tonsils and adenoids. The frequent episodes of more prolonged (30 to 90 seconds duration) apnoea many produce hypoxic damage to the brain leading to intellectual deterioration (see page 457).

FIGURE 5.6-18 Effect of sleep on the sensitivity of respiratory neurons. Note the amount of pulmonary ventilation of the same level of pCO₂ is less during sleep than during awakening.

Introduction

Applied respiratory physiology forms a link between the basics of respiration and clinical manifestations of respiratory diseases. The pulmonary function tests performed to diagnose respiratory disorders require an understanding of basic physiological principles of respiration and gas exchange. In fact, respiratory diseases cannot be managed

satisfactorily without a proper understanding of the basic and applied aspects of respiratory physiology. This chapter is concerned with some of the important applied aspects of respiration which include:

- Respiratory adjustments to stresses in health,
- Disturbances of respiration,
- Artificial respiration,
- Pulmonary function tests.

Respiratory adjustments to stresses in health

Respiratory adjustments to stresses in health illustrate the integrated operation of the respiratory regulatory mechanisms. The stresses faced by respiration requiring adjustments in day-to-day life include:

1. Respiratory adjustments during exercise.

Exercise is the most frequently faced stress in day-to-day life. Since during exercise, many complex adjustments of muscular blood flow, metabolism, respiration, circulation and temperature are required, so they have been comprehensively discussed in Chapter on '[Physiology of Exercise](#)' (page 1207).

2. Respiratory adjustments at high altitude.

At high altitude barometric pressure is low and so the partial pressure of O₂ is also low, however, the amount of O₂ in the atmosphere is same as it is at the sea level. When a person is exposed to high altitude particularly by rapid ascent, the different systems of the body cannot cope with the lowered O₂ tension and the effects of hypoxia start. Respiratory adjustments are thus a part of changes in the body at high altitude, so these have been discussed comprehensively under the title '*Physiology of high altitude*' (see page 1219).

3. Respiratory adjustments to high atmospheric pressure.

form a part of physiological problems faced by the body while going under the sea and have been discussed comprehensively under the title

Deep sea physiology (see page 1223).

4. Respiratory adjustments on exposure to cold and heat.

have been discussed under the title *Effects of exposure to heat and cold on the body* (see page 1246).

5. Respiratory adjustments at birth.

Birth is the most traumatic event that the respiratory system must withstand during the entire life span of an individual. These form a part of *Fetal physiology* and that have been discussed in the concerned chapter at page 1254.

Note. Students are advised to go through the respiratory changes occurring during the above-mentioned situations along with the study of respiratory system for better understanding.

Disturbances of respiration

From the physiological viewpoint, disturbances of respiration can be discussed under following headings:

- Abnormal respiratory patterns,
- Disturbances related to respiratory gases and
- Pulmonary diseases: pathophysiological aspects.

Abnormal respiratory patterns

Eupnoea refers to normal respiratory pattern, which implies a normal rate, rhythm and depth of respiration. Various abnormal respiratory patterns ([Fig. 5.7-1](#)) can be produced by changes in the environment or diseases affecting the respiratory system, cardiovascular system, or brain. The terms used for the altered pattern of respiration are:

- *Tachypnoea* refers to increase in the rate of respiration
- *Bradypnoea* means decrease in the rate of respiration.
- *Polypnoea* is used to denote the rapid but shallow breathing resembling panting in dogs. In this, the rate of respiration is increased but the force does not change significantly.

- *Apnoea* refers to temporary cessation of breathing.
- *Hypoventilation* term is used to describe a decrease in rate and force of respiration.
- *Hyperventilation* refers to increase in rate as well as force of respiration.
- *Hyperpnoea* signifies a marked increase in pulmonary ventilation due to increase in rate and/or force of respiration.
- *Dyspnoea*. When hyperpnoea involves 4–5 fold increase in pulmonary ventilation, an unpleasant sensation or discomfort is felt. This type of respiration is called dyspnoea.
- *Periodic breathing* refers to a respiratory pattern characterized by alternate periods of respiratory activity and apnoea. Some of the abnormal respiratory patterns are discussed in detail.

FIGURE 5.7-1 Various abnormal respiratory patterns.

Apnoea

Apnoea refers to temporary cessation of breathing. Depending upon the cause, apnoea may be of following types:

1. Voluntary apnoea

refers to temporary arrest of breathing due to voluntary control of respiration. It is also called breath-holding. The breath-holding time or apnoea time during which breathing can be withheld voluntarily is about 40–60 seconds in a normal person, after a deep inspiration (for details see page 445).

Breaking point is the point at which breathing can no longer be voluntarily inhibited. At this point, chemical regulation overcomes the neural regulation. The breaking point is due to an increased arterial $p\text{CO}_2$ and a decreased $p\text{O}_2$.

2. Apnoea after hyperventilation

occurs due to reduced stimulation of respiratory centre owing to CO_2 wash caused by hyperventilation (for details see page 454).

3. Deglutition apnoea

occurs reflexly during swallowing (about 0.5 second). During the pharyngeal stage of swallowing, the fluid or food stimulates the sensory nerve endings (5th, 9th and 10th cranial nerves) around the pharynx. Nerve impulses from these irritant receptors, via the swallowing centres specifically inhibit the respiratory centre, stopping the breathing at any point of the cycle (deglutition apnoea). Simultaneously, there is closure of glottis (the opening between vocal cords). Both these effects prevent aspiration of fluid or food into the lungs (also see page 585).

4. Breath-holding attacks

are attacks of brief period of apnoea which occur in infants and young children, and are generally precipitated by emotional distress, such as fright, frustration, pain or anxiety. The child starts to cry, and then suddenly holds his/her breath, becomes limp or stiff, and may become blue and lose consciousness. The attacks last briefly and recovery is rapid and complete. In some cases, there may be a rigid phase followed by tonic and clonic convulsions. These attacks are harmless and stop by the

age of three years; they are not considered epileptic in origin.

5. Vagal apnoea

can be produced experimentally in animals by stimulation of vagus nerve. Stimulation of vagus nerve produces apnoea by inhibiting the inspiratory centre.

6. Adrenaline apnoea

occurs after injection of high doses of adrenaline (see page 447).

7. Sleep apnoea

refers to cessation of breathing for a brief period (10 second) during sleep in normal individuals. It has been related to reduced sensitivity of respiratory centre neurons to arterial $p\text{CO}_2$ owing to inhibition of central chemoreceptors.

Sleep apnoea syndrome

has been recognized as a serious clinical problem or disorders of respiratory control that affects middle-aged and elderly men. It may occur in two forms:

- **Obstructive sleep apnoea** occurs when inspiration is prevented by transient blockage of the airway due to collapse of hypopharynx as a result of loss of tone of pharyngeal muscles which prevent airflow though strong contractions of inspiratory muscles occur (Fig. 5.7-2). Partial airway obstruction causes snoring. The association of sleep apnoea with extreme obesity is referred to as the *pickwickian syndrome*.
- **Nonobstructive (central) sleep apnoea** refers to complete stoppage of rhythmic activity from respiratory centres. Obviously, during apnoea there is no respiratory muscle contraction (Fig. 5.7-2). It is supposed to result from decreased chemoreceptor sensitivity to O_2 and CO_2 . Central sleep apnoea has been proposed as one of the many possible causes of *sudden infant death syndrome*.

FIGURE 5.7-2 Record of air flow and chest movements in patients with obstructive and central sleep apnoea.

Hypoventilation

Hypoventilation is used to describe a decrease in rate and force of respiration. Thus, in hypoventilation the amount of air moving in and out of lungs is reduced.

Causes of hypoventilation are:

- Depression of respiratory centres by some drugs
- Partial paralysis of respiratory muscles.

Effects. Hypoventilation leads on to hypoxia and hypercapnia which result in increase in rate and force of respiration and patient may develop dyspnoea.

Hyperventilation

Hyperventilation refers to increase in rate as well as force of respiration. Thus, in hyperventilation the amount of air moving in and out of lungs is increased; that is why it is also called increased pulmonary ventilation or overventilation.

Causes of hyperventilation are:

- During exercise due to stimulation of respiratory centres by increased $p\text{CO}_2$
- Voluntary hyperventilation
- Secondary to hypoxia.

Effects of hyperventilation on respiration and other systems of the body are described on page 452.

Dyspnoea

Dyspnoea literally means distressed breathing. Increased respiration without discomfort is called *hyperpnoea*. One is not aware of one's respiration till resting pulmonary ventilation becomes more than double. When hyperpnoea involves four-Fivefold increase in pulmonary ventilation, an unpleasant sensation or discomfort is felt. This type of respiration is called dyspnoea. The word 'air-hunger' is used as synonym to dyspnoea in general language. Thus, desire for air or mental anguish associated with inability to ventilate enough to satisfy the air demand is the essence of dyspnoea.

Dyspnoea point refers to the height of hyperpnoea at which dyspnoea appears.

Predisposing factors for dyspnoea include:

1. *Low vital capacity*. People with low vital capacity are more predisposed to get dyspnoea than those with normal or high vital capacity.
2. *Maximum ventilatory volume (MVV)*. Patients with reduced MVV (maximum volume of air that can be taken in or given out per minute, normal value is 120 L/min) are more predisposed to get dyspnoea.
3. *Breathing reserve (BR)* is the difference between MVV and respiratory

minute volume (RMV). RMV is the volume of air that is taken in or given out per minute (Normal $500 \times 12 = 6\text{L}/\text{min}$). Individuals with increased RMV (also called pulmonary ventilation) by 4–5 times get dyspnoea. Individuals with less breathing reserve are more prone to get dyspnoea.

$$\text{BR} = \text{MVV} - \text{RMV} = 114 \text{ L}/\text{min}$$

Dyspnoeic index (DI) refers to breathing reserve percentage of MVV, i.e.

$$\text{DI} = \frac{\text{BR} \times 100}{\text{MVV}} = \frac{110 \times 100}{120} = 95\%$$

- Normal value of DI range from 70–95%
- Dyspnoea occurs when DI is <60%.

Causes

of dyspnoea are:

- *Physiologically dyspnoea occurs* in severe muscular exercise
- *Pathological causes* include:
 - *Respiratory disorders* such as bronchial asthma, emphysema, pneumonia, pulmonary oedema and pneumothorax.
 - *Cardiac failure*: It causes dyspnoea by the mechanism explained in [Figure 5.7-3](#)).

Important Note

It is important to note that patients with cardiac failure prefer to sit rather than lie down, because in lying position pulmonary congestion is increased which causes dyspnoea. Dyspnoea occurring in lying down position is called *orthopnoea*.

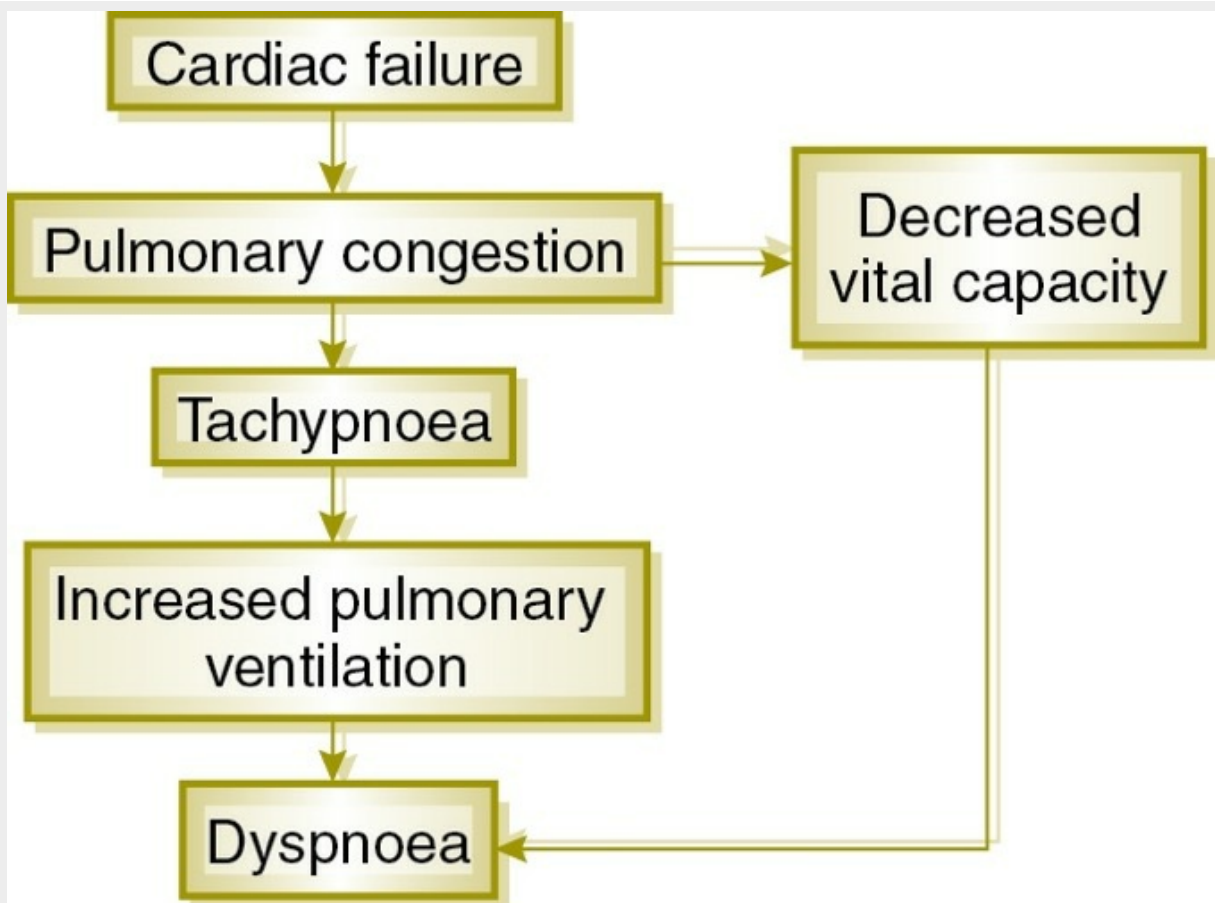

FIGURE 5.7-3 Cardiac failure causing dyspnoea: mechanism.

- *Metabolic disorders* causing dyspnoea are diabetic acidosis, uraemia, increased H^+ concentration. Metabolic acidosis causes dyspnoea by increasing pulmonary ventilation.

Periodic breathing

Periodic breathing is characterized by alternate periods of respiratory activity and apnoea. It is of two types:

- Cheyne-Stokes respiration and
- Biot's breathing.

Cheyne-stokes respiration

Cheyne-Stokes respiration is periodic type of breathing in which the alternate periods of respiratory activity and apnoea occur at regular intervals; and during the period of respiratory activity there is waxing and waning of tidal volume. The duration of one cycle is about one minute. The arterial pO_2 and pCO_2 fluctuate during each cycle. The pO_2

is lowest and the $p\text{CO}_2$ is highest at the end of apnoea (Fig. 5.7-4A).

FIGURE 5.7-4 Periodic breathing: **(A)** Cheyne-Stokes breathing; and **(B)** Biot's breathing.

Causes

of Cheyne-Stokes respiration are:

1. *Physiological causes* include:

- Voluntary hyperventilation,
- High altitude and
- During sleep in some normal individuals especially infants.

2. *Pathological causes* are:

- Chronic heart failure, due to increased circulation time from lungs to brain,
- Brain damage due to increased negative feedback gain in the respiratory centre,
- Uraemia and
- Poisoning by narcotics.

Mechanism of development of cheyne-stokes respiration in three most important conditions is described

Voluntary hyperventilation.

Mechanism of development of Cheyne-Stokes breathing in hyperventilation has been described on page 454.

Heart failure.

Mechanism of development of Cheyne-Stokes breathing is summarized as:

- Left ventricular failure → Pulmonary congestion → Hypoxia → Stimulation of respiratory centres → Increased ventilation → Increased alveolar pO_2 and decreased pCO_2 → Decreased arterial pCO_2 .
- As in heart failure *circulation time* is prolonged, so it takes longer than normal time for the blood with low pCO_2 to reach the brain and cause apnoea by inhibiting respiratory centre.
- Since in heart failure the pulmonary congestion continuously present, so hypoxia is maintained and the above-described cycle of apnoea followed respiratory activity keeps on repeating till the heart failure is treated or alveolar pCO_2 comes back to normal.

Brain damage.

In brain damage, when supramedullary inhibitory pathway is damaged

the medullary (central) chemoreceptors become more sensitive to the action of CO₂ and produces Cheyne-Stokes breathing as:

- Increased sensitivity of central chemoreceptors to CO₂ → Hyperventilation → CO₂ washout → Apnoea → Accumulation of CO₂ → Increased pCO₂ → Hyperventilation → Cycle of respiratory activity and apnoea continues.

Biot's breathing

Biot's breathing also known as *ataxic breathing* is a type of periodic breathing showing alternate periods of respiratory activity and apnoea (Fig. 5.7-4B). It differs from Cheyne-Stokes breathing in following aspects:

- It occurs at irregular intervals,
- There is no waxing and waning of tidal volume during the period of respiratory activity and
- It can never occur physiologically.

Causes.

Biot's breathing indicates a disruption of the normal medullary rhythmicity of respiration. It may occur when medulla is involved in disorders such as meningitis, head injury, medullary compressions like pontine haematomas or cerebellopontine herniation. *Central medullary lesions* are the most common cause of Biot's breathing. So, it is rare in cerebral ischaemia, which has to be bilateral to infarct the central medulla.

Disturbances related to respiratory gases

Respiratory disturbances related to respiratory gases include:

- Hypoxia,
- Hypercapnia,
- Hypocapnia,
- Asphyxia and

- Carbon monoxide poisoning.

Hypoxia

The term hypoxia is used to denote deficiency of oxygen supply at the tissue level. It has almost replaced the term anoxia (complete absence of oxygen), which rarely occurs practically.

Causes and types

Causes.

Hypoxia can occur because of any one or more of the following defects:

- Decreased oxygen tension (pO_2) of the arterial blood,
- Decreased oxygen carrying capacity of the blood,
- Decreased rate of blood flow to the tissue or
- Decreased utilization of oxygen by tissue cells.

Types.

Depending upon the mechanism of occurrence there are four types of hypoxia:

- Hypoxic hypoxia,
- Anaemic hypoxia,
- Stagnant hypoxia and
- Histotoxic hypoxia.

1. Hypoxic Hypoxia

Hypoxic hypoxia occurs due to decreased oxygen tension (pO_2) of the arterial blood, hence also called *arterial hypoxia*. Therefore, in this condition O_2 carrying capacity of blood, rate of blood flow to tissue and utilization of O_2 by tissues is normal.

Causes of hypoxic hypoxia are:

1. *Low oxygen tension (pO_2) in inspired air, e.g.*

- High altitude, where person is exposed to low atmospheric pO_2 ,
- Breathing artificial gas mixture with low pO_2 and
- Breathing in a closed space.

2. *Hypoventilation* due to any causes, e.g.

- Obstruction in respiratory passages as in asthma,
- Decreased lung compliance as in pneumothorax,
- Paresis or paralysis of respiratory muscles, as in poliomyelitis,
- Pump failure due to fatigue of respiratory muscles and
- Damage to respiratory centres by drugs like morphine (that causes depression of respiratory neurons in the medulla) or brain tumours.

Hypoventilation decreases alveolar pO_2 and hence arterial pO_2 .

3. *Reduced diffusion of oxygen across respiratory membrane* occurs due to:

- Marked reduction in area of respiratory membrane as in emphysema,
- Increased thickness of respiratory membrane as in pulmonary oedema and

- Nonfunctioning respiratory membrane as in fibrosis.

4. *Physiological shunt* formation due to abnormalities of ventilation–perfusion (VA/Q) ratio.

5. *Anatomical shunts*, i.e. when venous blood mixes with arterial blood lowering its pO_2 , as occurs in:

- Congenital heart diseases such as Fallot's tetralogy.

Characteristic features of hypoxic hypoxia are:

- *Low* – Arterial pO_2 , arterial O_2 content, percentage saturation of haemoglobin and low A-V pO_2 difference.
- *Normal* – O_2 carrying capacity of blood, blood flow to tissues and utilization of O_2 by tissue cells.

2. Anaemic Hypoxia

Anaemic hypoxia occurs due to the decreased O_2 carrying capacity of blood.

Causes of anaemic hypoxia are:

1. *Decreased RBC count* as occurs in:

- Bone marrow depression and

- Haemorrhage.

2. *Decreased haemoglobin content* of blood as occurs in:

- Anaemias of all types.

3. *Altered haemoglobin* which is not capable of carrying O₂,
e.g.

- Methaemoglobin, in which iron is present in ferric (Fe³⁺) form instead of ferrous (Fe²⁺) form
- Carboxyhaemoglobin, in which carbon monoxide combines with haemoglobin due to its 200 times more affinity than O₂.

Characteristic features of anaemic hypoxia are:

- Arterial pO₂ is normal (95–100 mmHg),
- Oxygen carrying capacity of blood is reduced due to anaemia or altered haemoglobin,
- Percentage saturation of haemoglobin is decreased,
- A–V pO₂ difference is normal (95–40 = 55 mmHg).

Pathophysiology of low O₂ supply to tissues in anaemic hypoxia

- Mild to moderate anaemia usually does not produce hypoxia at rest because there is compensatory increase in 2,3-DPG amount in the RBCs which combines with oxyhaemoglobin and results in increased liberation of O₂,

- However, during exercise the increased demand of O₂

by tissues is not met with and hence symptoms of hypoxia appear.

- Anaemic hypoxia in carbon monoxide poisoning is severe and needs emergency treatment. CO produces severe hypoxia by:

- Preventing the Hb to combine with O₂ and
- Shifting O₂-Hb dissociation curve to left (Fig. 5.7-5) thereby decreasing the amount of O₂ that can be released.

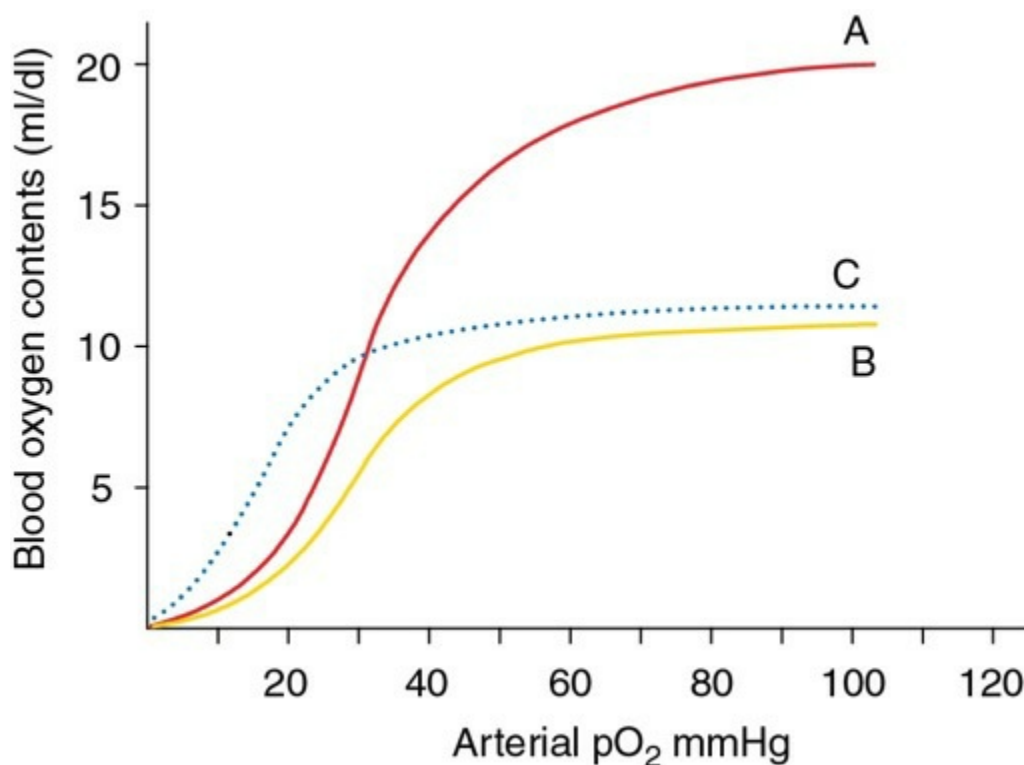

FIGURE 5.7-5 Oxygen–haemoglobin dissociation curves: **(A)** normal curve (when haemoglobin concentration is 15 gm/dl); **(B)** anaemic curve (when haemoglobin concentration is 7 gm/dl); and **(C)** carbon monoxide poisoning curve (when 50% carboxyhaemoglobin) shifted to left of the anaemic curve.

3. Stagnant Hypoxia

Stagnant hypoxia occurs due to decreased blood flow to the tissues so that in spite of normal pO_2 and haemoglobin, adequate O_2 is not delivered to the tissues.

Causes. Stagnant or ischaemic hypoxia may be generalized or localized.

Generalized stagnant hypoxia occurs in:

- *Shock* due to circulatory failure and haemorrhage. In this condition via baroreceptors there occurs reflex vasoconstriction and thus blood flow to the tissues is decreased. Worst affected are kidneys and heart which have very high O_2 demand.
- *Congestive heart failure* is associated with decreased venous return and hence decreased blood flow to the tissues causing hypoxia. Liver and brain are worst affected by venous congestion. Further, the associated pulmonary congestion produces defect in oxygenation and thus the patients also suffer from hypoxic hypoxia in addition to stagnant hypoxia.
- *Localized stagnant hypoxia* is caused by abnormalities in regional vessels such as:
 - Atherosclerosis,
 - Thrombosis and
 - Embolism.

Characteristic features of stagnant hypoxia are:

- Normal arterial pO_2 ,
- Normal arterial O_2 content,
- Normal arterial percentage oxygen saturation of haemoglobin,
- A-V pO_2 difference is more than normal because resting

O₂ uptake of tissues increases from 5 ml % to 10 ml % or the blood stays in the tissue for longer period. Thus in venous blood:

- pO₂ is reduced from ~ 40 mmHg to ~ 25 mmHg.
- O₂ content is reduced from 14 to 9 ml % and
- O₂ saturation of Hb is reduced from 75% to 45%.

4. Histotoxic Hypoxia

Histotoxic hypoxia occurs due to decreased ability of the tissues themselves to utilize the oxygen. So, strictly speaking, it is not a true hypoxia, because O₂ supply to the tissues is adequate.

Causes. Histotoxic hypoxia is caused by certain poisonous substances which destroy the cellular oxidative enzymes and completely paralyse the cytochrome oxidative system of the cells. These include:

- Cyanide poisoning and
- Sulphide poisoning.

Characteristic features. Since O₂ supply is adequate and the tissue cells are not able to utilize the O₂, so histotoxic hypoxia is characterized by:

- Normal arterial pO₂
- Normal arterial % O₂ saturation of haemoglobin
- No difference in the O₂ content of arterial and venous blood and
- A-V pO₂ difference is practically nil.

Characteristic features of four types of hypoxia are summarized in [Table 5.7-1](#).

TABLE 5.7-1

Characteristic Features of Different Types of Hypoxia

Features	Hypoxic hypoxia	Anaemic hypoxia	Stagnant hypoxia	Histotoxic hypoxia
Pathophysiology	Occurs due to decreased O ₂ tension (decreased arterial pO ₂)	Occurs due to low O ₂ carrying capacity of blood	Occurs due to decreased blood flow to tissue	Occurs due to decreased ability of the tissue to utilise O ₂
Causes	<ul style="list-style-type: none"> • Low O₂ tension (low pO₂ in inspired air) • Hypoventilation • ↓ Diffusion of O₂ across respiratory membrane • Physiological shunt • Anatomical shunt 	<ul style="list-style-type: none"> • ↓ RBC count • ↓ Hb content of blood • Altered Hb 	<ul style="list-style-type: none"> • Shock • Circulatory failure 	<ul style="list-style-type: none"> • Cyanide poisoning
Arterial pO ₂	Decreased	Normal	Normal	Normal
Arterial O ₂ contents	Decreased	Markedly Decreased	Normal	Normal
Arterial Hb contents	Normal	Reduced	Normal	Normal
% O ₂ saturation (in arterial blood)	Decreased	Decreased	Normal	Normal
O ₂ carrying capacity of arterial blood	Normal	Decreased	Normal	Normal
A-V (arterial–venous) pO ₂ difference	Decreased	Normal	More than normal	Less than normal (nil)
Cyanosis	Present	Absent	Present	Absent
Peripheral chemoreceptor stimulation	Present (because dissolved oxygen in plasma is reduced)	Absent (because dissolved oxygen in plasma is sufficient)	Present (because arterial pCO ₂ increases and pO ₂ decreases)	Present (cyanide decreases oxygen utilisation at tissue level)
Tachypnoea	Present	Absent	Present	Present

Symptoms of hypoxia

Symptoms of hypoxia depend upon:

- Rapidity of development of hypoxia,
- Severity of hypoxia and
- Effectiveness of the body's compensatory mechanisms.

Based on the above the hypoxia may be fulminant, acute or chronic.

1. Fulminant hypoxia

refers to severe hypoxia developing very fast, i.e. which occurs within seconds after exposure to an arterial O₂ tension of less than 20 mmHg.

Such a situation may occur if an aircraft loses cabin pressure (becomes depressurized) above 20,000 feet and no supplemental O₂ is available. It results in:

- *Unconsciousness* within 15 to 20 second due to lack of O₂ supply to brain and
- *Brain death* may follow in 4–5 minutes.

2. Acute hypoxia

is produced by exposure to arterial O₂ tensions of 25–40 mmHg (e.g. as would occur at altitudes of 18,000–25,000 feet). Symptoms of acute hypoxia are very similar to the effects of ethyl alcohol and include:

- Lack of co-ordination,
- Slowed reflexes,
- Slurring of speech,
- Overconfidence and eventually,
- Unconsciousness,
- Coma and death can occur in minutes to hours if the compensatory mechanisms of the body are inadequate.

3. Chronic hypoxia.

It occurs due to exposure to low pO₂(40–60 mmHg) for long periods (e.g. as would occur after stay for extended period of time at altitudes of approximately 10,000–18,000 feet). Most of the clinical cases of hypoxia are of this category. Patients with chronic hypoxia may be bedridden or limited to chair because respiratory and cardiac disease prevents them from increasing O₂ supply to tissues. Symptoms of chronic hypoxia are:

- Severe fatigue,
- Dyspnoea,
- Shortness of breath,
- Respiratory arrhythmias (e.g. Cheyne-Stokes breathing) can occur in patients with chronic hypoxia, especially during sleep, which can contribute to the hypoxic state.

Signs of hypoxia

1. Cyanosis

is the bluish discolouration of skin and mucous membrane caused by presence of more than 5 gm of deoxyhaemoglobin/100 ml of the capillary blood. There are two types of cyanosis:

Peripheral cyanosis is seen in the nailbeds and is suggestive of *stagnant hypoxia*. This is because perfusion in these distally located areas are worst affected in hypotensive states. Large amount of O₂ is extracted from haemoglobin and the concentration of deoxyhaemoglobin rises to produce cyanosis.

Central cyanosis is seen in the earlobes where skin is thin and in the mucous membrane of lips and tongue. These areas receive a good blood supply and become cyanotic only if the O₂ saturation of blood is low, as occurs in *hypoxic hypoxia*.

Cyanosis is not a reliable sign of hypoxia because:

- Anaemic patients may never develop cyanosis, even though they are extremely hypoxic because of an inadequate haemoglobin concentration,
- Cyanosis does not occur in histotoxic hypoxia either, because the O₂ saturation of haemoglobin is normal and
- In contrast, patients with polycythemia may be cyanotic as a result of high concentration of haemoglobin, even though their tissues are adequately oxygenated and further
- Methaemoglobin, with its slate-grey colour, can also impart a bluish colour to tissues.

2. Tachycardia.

It occurs as a peripheral chemoreceptor reflex response to the low arterial oxygen tension.

3. Tachypnoea,

(i.e. rapid breathing and *hyperpnoea* (i.e. deep breathing) are also reflex responses to hypoxia that are activated by arterial chemoreceptors.

Therefore, tachypnoea and hyperpnoea are:

- Present in hypoxic hypoxia where arterial pO₂ is low and are
- Absent in both anaemic hypoxia and stagnant hypoxia in which the arterial pO₂ is normal.

Physiological compensatory responses to chronic hypoxia

Two types of physiologic compensatory responses known to occur in hypoxia are *accommodation* and *acclimatization*.

I. Accommodation.

Accommodation, refers to immediate reflex adjustments of the respiratory and cardiovascular systems to hypoxia. These include:

- **Hyperventilation.** As mentioned above, hyperventilation occurs secondary to stimulation of peripheral chemoreceptors by low O_2 tension in the arterial blood. The increased ventilation is compensated by:
 - Increasing pO_2 and reducing pCO_2 ,
 - Reduced pCO_2 causes a respiratory alkalosis, which in turn, lowers the respiratory drive. The respiratory drive continues to increase during this time as the alkalosis is corrected.
- **Tachycardia,** as mentioned above, also occurs as a peripheral chemoreceptor response to the low arterial oxygen tension. It increases O_2 delivery to the tissues by increasing cardiac output. In the individuals who go to high altitudes, the cardiac output returns to normal after several weeks.
- **Increase in 2,3-diphosphoglycerate (2,3-DPG) concentration** in RBCs occurs in response to hypoxia and alkalosis. The increased 2,3-DPG concentration raises p_{50} of haemoglobin, which helps to maintain the tissue O_2 tension at slightly higher level than it would be otherwise.

II. Acclimatization.

Acclimatization refers to the changes in body tissues in response to long-term exposure to hypoxia, such as when a person living at sea level goes and stays at high altitude for a long time. With longer stay, the person gradually gets acclimatized to low pO_2 by following changes in the body tissues:

- **Increase in red blood cell count** or the polycythaemia secondary to tissue hypoxia results from the release of *renal erythropoietic factor*, which acts on a plasma globulin to form erythropoietin. Erythropoietin stimulates the production of RBCs by the bone marrow. This leads to:
- Increase in haemoglobin concentration from 15 gm% to about 20 gm%,
- Increase in haematocrit from normal value of 40–45% to 60% after full acclimatization and
- Increase in blood volume by 20–30% leading to total increase in circulating haemoglobin by 50%.

These changes allow each unit of blood to carry additional O₂, which compensates for the decreased O₂ tension.

Increase in haemoglobin and blood volume starts after 2 weeks, reaches half development in a month and is fully developed only after many months.

- **Increase in pulmonary ventilation.** When an individual stays at high altitude for many days, there is gradual increase in ventilation to an average of about five times the normal. This is because of loss of buffering effect of CO₂ due to renal correction of alkalosis, leading to decreased HCO₃⁻ ion concentration in CSF and brain tissues.
- **Cardiovascular changes** in the form of increased heart rate, force of contraction and increased cardiac output which occur in the initial accommodation period, later on decrease back to normal once the O₂ supply to tissues becomes normal due to changes in blood.
- **Pulmonary hypertension.** It occurs secondary to the generalized hypoxic pulmonary vasoconstriction. The increased pulmonary artery pressure causes a more even distribution of pulmonary blood flow, which can improve gas exchange. However, the elevated pulmonary artery pressure can induce cor pulmonale if the hypoxia is sufficiently severe.

- *Increase in total lung capacity and diffusing capacity of the lung* occur in high altitude natives as compared to their sea-level counterparts. The increase in total lung capacity is evidenced by the enlarged chest that high altitude natives develop.

Diffusing capacity of lungs increases due to increase in surface area of respiratory membrane. The greatly increased pulmonary capillary blood volume expands the capillaries thereby increasing surface area. Hypoxia increases pulmonary ventilation leading to increase in lung volume which expands surface area of alveolar membrane. Pulmonary hypertension forces blood into greater number of alveolar capillaries than normally, especially in upper parts of lungs which are poorly perfused.

- *Cellular and tissue acclimatization* occurs after a long stay at high altitude. These include:
- *Increase in oxidative enzyme concentrations* within the mitochondria of many tissues, which allows more rapid generation of ATP via oxidative phosphorylation.
- *Increase in mitochondrial density* within the cells, which reduces the diffusion distance and provides more sites for O₂ utilization.
- *Increase in capillary density* in skeletal and cardiac muscles, which reduces the diffusion distance from the blood into the cells.
- *Decreased respiratory drive* is caused by lifelong exposure to hypoxia, i.e. for very prolonged periods. The reduced respiratory drive leads to higher CO₂ tension and lower O₂ tension, but it diminishes the work of respiration, which reserves more O₂ for use by other skeletal muscles.

Oxygen therapy

Physiological basis of oxygen therapy in hypoxia

Oxygen therapy is of great value in certain types of hypoxia and at the same time of almost no value in other types. With the basic knowledge of physiological principles of different types of hypoxia, one can readily decide when oxygen therapy will be of value and, if so how valuable.

In general, simple O₂ therapy is not of much help in treatment of hypoxia because diffusion across respiratory membrane depends upon partial pressure of gases, therefore, alveolar pO₂ can be increased by:

- Inhalation of 100% pure oxygen, or
- Inhalation of 100% pure oxygen at high barometric pressure, called hyperbaric oxygen therapy.

Oxygen therapy with 100% pure oxygen at atmospheric pressure, i.e. at 760 mmHg.

1. Oxygen therapy is useful

in most types of hypoxic hypoxia. The way the oxygen therapy is useful in different causes of hypoxic hypoxia are highlighted:

- *In atmospheric hypoxia*, oxygen therapy can correct the depressed oxygen level in the inspired gases and therefore provide 100 per cent effective therapy.
- *In hypoventilation hypoxia*, a person breathing 100 per cent oxygen can move five times as much oxygen into the alveoli with each breath as when breathing normal air. Again, here oxygen therapy can be extremely beneficial.
- *In hypoxia due to impaired respiratory membrane diffusion*, oxygen therapy can increase the pO₂ in the lungs from a normal value of about 100 mmHg to as high as 160 mmHg thus raising the oxygen diffusion gradient.

2. Oxygen therapy is of limited value

in anaemic hypoxia, stagnant hypoxia and hypoxic hypoxia caused by physiological or anatomical shunts; because in all these conditions oxygen is already available in the alveoli. However, in these conditions

some extra oxygen can be transported in dissolved state in the blood when alveolar oxygen is increased to the maximum level; and this extra oxygen may some times be the difference between life and death.

Therefore, hyperbaric O₂ therapy is more useful in such conditions than O₂ therapy at atmospheric pressure.

3. Oxygen therapy is of no use

in histotoxic hypoxia, because in this type of hypoxia, the tissue metabolic enzyme system is simply incapable of utilizing the oxygen that is delivered.

4. Caution is required while giving oxygen therapy

to patients with severe pulmonary failure associated with hypercapnia (increased pCO₂), as it may cause death. The central chemoreceptors in these patients are inhibited following excessive overdrive by the pCO₂. In such a situation, whatever respiration is there, it is due to hypoxic stimulation of peripheral chemoreceptors. So, O₂ therapy at such a juncture may produce apnoea by taking away this hypoxic drive and soon death may occur due to direct depression of respiratory centre by severe hypoxia and hypercapnia.

Hyperbaric oxygen therapy (inhalation of 100% pure oxygen at high barometric pressure)

Advantage of hyperbaric O₂

therapy over O₂ therapy at atmospheric pressure is that the former increases the amount of dissolved O₂ in plasma, and is therefore unaffected by the haemoglobin concentration.

Amount of O₂ dissolved in plasma

depends upon its partial pressures:

- Normally, plasma can have 0.3 ml of dissolved oxygen per 100 ml per 100 mmHg pO₂, or 0.003 ml per 100 ml per mmHg pO₂.
- At 1 atmospheric pressure (760 mmHg). inhalation of 100% O₂ (in a patient with normal pCO₂ 40 mmHg and p_{H₂O} 47 mmHg) can raise the arterial pO₂ to a maximum of 760 – (40 + 47), or 673 mmHg.

- Therefore, the maximum amount of O₂ that can be dissolved in plasma will be:
- At 1 atmospheric pressure: 673×0.003 , or 2 ml/100 ml.
- At 2 atmospheric pressure: $673 \times 0.003 \times 2$, or 4 ml/100 ml and
- At 3 atmospheric pressure: $673 \times 0.003 \times 3$, or 6 ml/100 ml.
- The normal demand of the body tissues (5 ml/100ml/min), thus can be met only by dissolved O₂ in plasma, if administered at atmospheric pressure of 2.5 or more.

Indications of hyperbaric O₂ therapy,

thus include those types of hypoxias in which normal Hb is not available to carry the O₂ to the tissues, and so the main dependence is on dissolved O₂ in plasma. These conditions include:

- Carbon monoxide poisoning
- Anaemic hypoxia (due to severe anaemia)
- Decompression sickness and air embolism
- Wounds with poor blood supply
- Stagnant hypoxia (very limited value).

Caution. For therapeutic use, the hyperbaric 100% O₂ should not be used with pressures beyond 2–3 times atmospheric and should not be used more than five hours; because of high chances of developing O₂ toxicity.

Side effects of 100% O₂ (O₂ toxicity)

- **Mechanism of side effects.** Inhalation of 100% O₂ produces side effects (harmful effects) due to conversion of molecular oxygen into active

oxygen, i.e. superoxide anion (O_2^-), which is free radical and H_2O .

- *Side effects noted by inhalation of 100% O_2* include:
 - *Irritation of airways* in the form of nasal congestion, sore throat, substernal discomfort, sneezing and coughing and bronchoconstriction may occur after about 8 hours of inhalation.
 - *Bronchopneumonia* may be initiated when O_2 therapy is continued for more than 24 hours because of:
 - Inhibition of ability of lung macrophages to kill bacteria and
 - Decreased production of surfactant.
 - *Complications in newborn infants* are very common, as they are very sensitive to get O_2 toxicity. Therefore, special care is needed while treating newborns in incubators with O_2 therapy. It is cautioned that infants should never be given more than 40% O_2 . Special dangers of O_2 therapy in premature infants are occurrence of:
 - *Retinopathy of prematurity* (old name retrolental fibroplasia), which is characterized by retinal neovascularization and proliferation of fibrovascular tissue ultimately forming an opaque retrolental mass, leading to bilateral permanent blindness. Normally, the retinal receptors get matured from central part towards the peripheral part of the retina, and at the same time vascularization also occurs in an orderly manner (centre

towards periphery). A large amount of oxygen is being utilized in the process of maturation, therefore, if premature babies are treated with 100% oxygen, the normal pattern of maturation fails and consequently there is proliferation of fibrovascular tissue resulting in formation of opaque retrolental mass.

- *Bronchopulmonary dysplasia* is characterized by formation of lung cysts and opacities.
- *Nervous system complications*, i.e. derangement of cerebral activity is especially known to occur with administration of *hyperbaric O₂* therapy. At high pressures of O₂, dissolved O₂ in plasma is greatly increased, which in turn causes rise in tissue pO₂. As mentioned above, oxygen toxicity is caused by production of free oxygen radicals which oxidize polyunsaturated fatty acids (essential compounds of cells membrane) and also oxidize cellular enzymes (damaging cellular metabolic systems). Nervous tissues are especially susceptible because of their high lipid content. Nervous symptoms include muscular twitching, tinnitus (ringing of bells in ears), convulsions, coma and even death.

Hypercapnia

Hypercapnia refers to increase in arterial pCO₂ (normal value 40 mmHg). When hypercapnia is the primary problem, it is associated with respiratory acidosis (see page 451) since an increase in CO₂ promptly generates excess H⁺ through following reaction:

Causes of hypercapnia

Hypercapnia rarely occurs due to increased production of CO_2 , because an increase in arterial pCO_2 causes a prompt increase in pulmonary ventilation through stimulation of central chemoreceptors, resulting in CO_2 washout and a near restoration of arterial pCO_2 to normal levels of about 40 mmHg. There exists a linear relationship between increase in arterial pCO_2 and increase in pulmonary ventilation (see page 451).

Increased production of CO_2 without hypercapnia occurs in fever, following excess consumption of carbohydrate and in metabolic acidosis with respiratory compensation.

Hypercapnia occurs due to:

1. *Defective elimination of CO_2* as occurs in:
 - Reduced pulmonary ventilation due to restrictive lung disorder, or
 - Reduced effective alveolar ventilation due to ventilation-perfusion mismatch as seen in chronic obstructive pulmonary disease (COPD).
2. *Accidental inhalation of CO_2* in persons working in breweries and refrigeration plants.

Signs and symptoms of hypercapnia

1. *Hyperpnoea* occurs due to stimulation of respiratory centre through central chemoreceptors. Since, most of the times, clinically hypercapnia occurs due to restrictive lung disorders, so hyperpnoea fails to improve pulmonary ventilation.
2. *Carbon dioxide narcosis* develops when arterial pCO_2 increases above 50 mmHg. Retention of large amount of CO_2 causes depression of central nervous system leading to confusion, diminution of sensory acuity and eventually coma and death.

These patients present with severe respiratory acidosis, therefore, as a compensation for acidosis, large amount of HCO_3^- are excreted in urine (for details see page 451).

Hypocapnia

Hypocapnia, i.e. reduced pCO_2 is usually associated with *respiratory alkalosis*, since decrease in CO_2 promptly drives the following reaction in backward direction, resulting in a decrease in H^+ concentration.

Causes.

Hypocapnia occurs due to hyperventilation (see page 452). The effects of hypocapnia are-

- Vasoconstriction due to direct effect on cerebral blood vessels causes reduction in cerebral blood flow by 30%. The resulting ischemia causes headache, dizziness and parasthesia.
- Due to alkalosis pH increases to 7.5–7.6, and low plasma HCO_3^- level, the renal compensation results in absorption of HCO_3^- due to inhibition of acid secretion.
- Plasma ionic calcium level (Ca^{2+}) falls, therefore, hypocapnic patient develops signs of tetany i.e. *carpopedal spasm* and a *positive Chevostek's sign*.

Asphyxia

Asphyxia refers to a condition in which hypoxia (decreased pO_2) is associated with hypercapnia (increased pCO_2).

Causes.

Asphyxia can be general or local.

- *Local asphyxia* occurs following complete obstruction or ligation of blood vessel.

- *General asphyxia* can be chronic or acute.
- *Chronic asphyxia* may occur in patient with cor pulmonale, i.e. right ventricular failure due to lung diseases, and
- *Acute asphyxia* occurs due to sudden blockage in airways. Common causes are:
 - Strangulation,
 - Drowning,
 - Acute tracheal obstruction (due to entry of food or due to choking),
 - Paralysis of diaphragm, as in acute poliomyelitis.

Clinical stages of acute asphyxia.

There are three stages of acute asphyxia:

Stage 1: Stage of hyperpnoea.

This stage lasts for one minute and is characterized by:

- Increase in rate and depth of respiration, with more pronounced expiratory effort,
- Dyspnoea, cyanosis and sudden prominence of eyeballs.
- This stage occurs due to sudden and powerful stimulation of respiratory centres by acutely occurring rise in $p\text{CO}_2$. O_2 lack is not yet enough to stimulate ventilation.

Stage II: Stage of central excitation.

This stage occurs due to excess CO_2 stimulating the centres directly, and lack of O_2 stimulating the centres reflexly. It lasts for about 1 minute and is characterized by all signs of central excitation, such as:

- Expiration becomes more *violent*,

- Heart rate is increased,
- Systemic blood pressure rises due to widespread vasoconstriction,
- Pupils are constricted,
- All the reflexes are exaggerated,
- Convulsions occur due to excess of $p\text{CO}_2$ and
- Consciousness is lost.

Stage III: Stage of central depression.

This stage occurs due to direct effect of O_2 lack on vital centres causing their inhibition. It lasts for 2–3 minutes and its characteristic features are:

- Convulsions disappear,
- Respiration becomes slow and finally it becomes gasping (shallow and with low frequency),
- Heart rate is decreased,
- Blood pressure falls,
- Pupils are dilated,
- All the reflexes are abolished,
- The whole body lies still,
- Duration between the gasps is gradually increased and
- Finally the death occurs.

Drowning

There are two main mechanisms by which effects of drowning, ultimately causing death:

1. Asphyxia

is the cause of death in only 10% cases of drowning. Asphyxia occurs initially due to *breath-holding*, and after the breaking in effect due to the

severe *laryngospasm* induced by first gasp of water. The laryngospasm prevents entry of water into the lungs, but soon produces death due to asphyxia. Thus, the lungs remain dry in asphyxial deaths due to drowning.

2. Flooding of lungs with water

occurs in 90 per cent cases of drowning. The muscles of glottis relax and allow entry of water into the lungs. Further events depend upon the type of water:

- *Fresh water drowning* is associated with rapid absorption of water (since it is hypotonic) into the circulation, which causes plasma dilution and intravascular haemolysis.
- *Sea water drowning* is associated with hypovolaemia due to draining of water from the circulation into the lungs (since the sea water is hypertonic).

Note.

When the patients with drowning are timely rescued and resuscitated with artificial respiration, the above described circulatory effects must be taken care of depending upon the type of water.

Carbon monoxide poisoning

Carbon monoxide (CO) is a dangerous gas present in exhaust of gasoline engines, coal mines, gases from deep wells and underground drainage systems.

Toxic effects.

Carbon monoxide produces anaemic hypoxia and derangement of cellular metabolic system.

1. Anaemic hypoxia.

When CO inhaled accidentally from the abovementioned sources, carbon monoxide having 200 times more affinity than O₂ for haemoglobin combines with it to form *carboxyhaemoglobin*. The carboxyhaemoglobin produces severe anaemic hypoxia by following mechanisms:

- It does not allow the haemoglobin to take up oxygen from alveolar air and

- The presence of carboxyhaemoglobin decreases the release of oxygen from haemoglobin, i.e. the oxygenhaemoglobin dissociation curve shifts to the left (Fig. 5.5-7) see page 433.

2. Derangement of cellular metabolic system.

Carbonmonoxide causes toxic effects on cytochrome system of the cells causing derangement of the cellular metabolic system but the amount of CO required for producing cytochrome toxic effects is 1000 times (the lethal dose).

Sign and symptoms of co poisoning

depending upon its concentration in the inspired air are:

- *When the inspired air contains 1% CO*, saturation of haemoglobin with CO becomes 15 to 20%. Patients get headache and nausea within one hour of inhalation.
- *When the inspired air contains more than 1% CO*, the haemoglobin saturation becomes 30–40 %. This causes loss of consciousness.
- *When haemoglobin saturation with CO becomes 50%* death occurs.
- The symptoms of CO poisoning are of hypoxia, but there is no stimulation of respiration because arterial blood pO₂ remains normal.
- The cherry red color of COHb is visible on the skin, nail bed and mucous membrane.

Treatment of co poisoning.

When diagnosed timely, following measures should be taken promptly:

- Immediate termination of exposure to carbon monoxide,
- Immediate hyperbaric 100% O₂ therapy,
- Administration of air with few per cent of CO₂ to stimulate respiratory centres.

Pulmonary diseases: Physiological peculiarities

Physiological peculiarities of some of the common pulmonary diseases

are described to understand the pathophysiology of respiratory insufficiency occurring in these diseases.

From the physiological point of view the pulmonary diseases can be divided into two groups:

- Obstructive lung diseases and
- Restrictive lung diseases.

Obstructive lung diseases

The chronic obstructive lung diseases include asthma, chronic bronchitis and emphysema. The obstructive lung diseases are characterized by increased resistance to airflow.

The airway resistance mainly depends on the radius of the airway and on type of air flow. Resistance is low when air flow is laminar and high when air flow is turbulent. Upper airway resistance usually does not increase, except in conditions like nasal congestion, deviated nasal septum or enlarged adenoids. Mouth breathing is common in these conditions.

Lower airway resistance

chiefly lies in the medium sized bronchi (2-4 mm diameter). Smooth muscle contraction mainly increases airway resistance by reducing airway's radius. The diameter of these bronchi is altered by following factors:

- **Bronchomotor tone** is chiefly regulated by autonomic neural discharge (see page 393) and also by local chemical mediators like prostaglandins, leukotrienes, kinins etc.
- **Radial traction by lung parenchyma**- Bronchi and bronchioles are surrounded by lung parenchyma. The constant pull of lung parenchyma helps in maintaining patency of the airway. This supportive action is known as radial traction. During expiration small airways (bronchioles) collapse.
- **Transmural pressure**- In quiet breathing, during inspiration, pressure is negative (because of negative intra pleural pressure with respect to intra-pulmonary pressure). Therefore, the airways remain patent. Same situation prevails during tidal expiration, however in forced expiration transmural pressure becomes positive, which tends to

collapse the small airways. The condition worsened in emphysema due to loss of radial traction.

- **Mucous secretion.** Presence of mucous or any other material in airways also increases airway resistance.

Mechanisms of airway obstruction

in the obstructive lung diseases include:

- *The airway lumen*, may be partially obstructed by excessive secretions (chronic bronchitis), oedema fluid, or aspiration of food or fluids.
- *The airway wall smooth muscles* may be contracted (asthma) or thickened because of inflammation and oedema (asthma, bronchitis), or mucous glands may be hypertrophied (chronic bronchitis).
- *Outside the airway*, the destruction of lung parenchyma may decrease radial traction, causing the airways to be narrowed (emphysema).

1. Asthma

Asthma is considered an inflammatory disease of the bronchioles caused by the hypersensitivity of the bronchioles to foreign substances in the air. Asthma is a chronic life-long disease with periods of remissions and *exacerbation*.

Aetiopathogenesis.

Functional abnormality in asthma is airway narrowing produced by following effects of allergic reactions:

- *Spasm of bronchial smooth muscle*, which is triggered by exposure to provoking agents such as allergen or exercise,
- *Inflammation of bronchial wall* (predominantly eosinophilic/producing mucosal oedema) and
- *Secretion of thick mucus* into the lumen of bronchioles.

Symptoms.

The above changes increase the airway resistance; thus asthma is an obstructive lung disease. The asthmatic person can usually inspire adequately but has great difficulty during expiration. During attack of

asthma patient may have:

- Dyspnoea, or air hunger,
- Cough,
- With repeated acute attacks patient may get progressive fatigue and even eventual respiratory arrest.
- *Pulmonary function abnormalities* may occur in patients over the years. During asthmatic attack because of difficulty in expiring air there occurs:
 - Reduced maximum expiratory rate,
 - Increase in FRC and in RV.
 - There is a reduction in TV), VC and forced expiratory volume-one (FEV₁).

Gas exchange abnormalities.

There is no decrease in diffusion capacity in asthma. Alveolar ventilation is uneven and decreased causing *mild hypoxia*. However, with increasing severity of attack pO₂ decreases in direct proportion to the drop in FEV₁. Hyperventilation in response to hypoxia leads to decreased pCO₂. When the attack is prolonged patient may get acidosis, dyspnoea and cyanosis. A normal or increased pCO₂ in asthma along with increasing hypoxaemia is an ominous sign of impending respiratory arrest.

Treatment

Therapeutically the drugs used are:

- β adrenergic agonists are used to treat mild to moderate asthmatic attack.
- Steroids both as inhaler or systemically may be used to reduce inflammation.
- Agents that block synthesis of leukotrienes or their receptors are also useful in certain cases.

2. Chronic bronchitis and emphysema

Chronic bronchitis,

i.e. inflammation of the bronchial tree occurs due to cigarette smoking, exposure to oxidant gases, dust and irritants. Mucosal inflammation is exacerbated by superadded infection. It is characterized by an increase in volume of submucosal glands and increase in number of goblet cells in the surface epithelium.

- Chronic cough and hypersecretion of mucus are the hallmark of chronic bronchitis.
- Increased air flow resistance occurs due to chronic inflammation of the small airways and the condition is termed *small airway disease*.

Pulmonary emphysema

literally means excess air in the lung. Chronic pulmonary emphysema, however, signifies a complex obstructive and destructive process of the lungs and is usually a consequence of long-term smoking.

Development of emphysema

involves two main events:

- ***Airway obstruction*** is caused by changes of chronic bronchitis (as described above) which include chronic infection, excess mucus and inflammatory oedema of the bronchial epithelium. Furthermore, the smaller peripheral bronchi are thickened and distorted by the scar tissue and at the segmental level there may be loss of bronchial cartilage. All these changes are termed as *small airway disease*.
- ***Destruction of alveolar walls***. The obstruction of the airway makes it especially difficult to expire, causing entrapment of air in the alveoli and overstretching of the alveoli. This combined with lung infection causes marked destruction of alveolar cells. Usually there is loss of some elastic tissues because of the proteolytic enzyme called elastase.

3. Chronic obstructive pulmonary disease

Chronic obstructive pulmonary disease (COP) is the term used to denote the clinical entity having combined effects of chronic bronchitis and chronic pulmonary emphysema. Genetic factors also predispose to COPD by producing deficiency of anti trypsin activity. In the lungs

normally action of elastase and other proteolytic enzymes (produced by leucocytes) is antagonized by anti trypsin activity. It is characterized by following respiratory physiological changes:

Increased airway resistance

occurs due to chronic bronchial obstruction. So, the movement of air through the respiratory passages become difficult. Expiration is especially difficult because the force on the outside of the lung compresses the bronchioles, which further increases their resistance.

Decreased diffusing capacity

of the lungs results from destruction of alveolar membrane. So, ability of the lungs to oxygenate the blood and to remove the carbon dioxide is reduced.

Abnormal ventilation–perfusion ratio (VA/Q)

occurs as:

- *Very low VA/Q ratio* occurs in the areas of lungs with bronchiolar obstruction. In these areas alveolar ventilation (VA) is much less than the blood supply (perfusion), resulting in poor aeration of blood (*physiological shunt formation*).
- *Very high VA/Q ratio* occurs in the areas of lungs having marked loss of alveolar walls. In such areas, VA is much more as compared to perfusion, resulting in wasted ventilation (*physiological dead space formation*).

Increased pulmonary resistance

may occur due to decrease in number of capillaries owing to the destruction of lung parenchyma. The increased pulmonary vascular resistance may in turn cause pulmonary hypertension.

Pulmonary function tests

in patients with moderate to severe COPD may reveal following abnormalities:

- *Decreased forced expiratory flow* occurs due to: loss of lung elasticity, increase in airway resistance upstream from equal pressure point and an increase in compliance of the airway downstream from equal

pressure points.

- *Forced vital capacity (FVC)* may be normal or decreased (reflecting increased residual volume).
- Forced expiratory volume in first second (FEV_1) is reduced as is the ratio of FEV_1/FVC .
- RV and FRC are increased. TLC may also be increased in some cases.

Restrictive lung diseases

The restrictive lung diseases include pulmonary fibrosis, silicosis, asbestosis, tuberculosis, pneumothorax, pleural effusion and paresis of respiratory muscles (e.g. in poliomyelitis and myasthenia gravis).

Characteristic features.

Restrictive lung diseases are characterized by low lung volumes. Patients with restrictive lung disease find it easier to breath at low lung volumes because it is difficult to expand the lungs.

Mechanisms of restriction of lung expansion

include:

- *Abnormalities of lung parenchyma.* Diseases in which excessive pulmonary fibrosis decreases lung elasticity as occur in pulmonary fibrosis, pneumonia, silicosis, asbestosis and tuberculosis.
- *Abnormalities of pleura* as occur in pneumothorax and pleural effusion.
- *Paresis of respiratory muscles* as occurs in poliomyelitis and myasthenia gravis.

I. Lung parenchymal diseases

1. Pneumonia.

The term pneumonia includes an inflammatory condition of the lung in which alveoli are filled with fluid and inflammatory cells. It is characterized by clinical and radiological consolidation of the involved parts of lung parenchyma.

Causes.

The pneumonia is usually an infective process caused by bacterial (commonly pneumococcal or viruses) but can also result from noninfective causes such as chemical or radiation injury to the lungs.

Functional abnormalities

which occur in patients with pneumonia are:

- *Restrictive pulmonary function defect* as occurs due to total replacement of alveolar gases by the inflammatory exudates in the involved part of lung.
- *VA/Q* is decreased because in the involved areas of lung, perfusion is normal but alveolar ventilation is markedly decreased, resulting in *physiological shunt formation*.
- *Hypoxia* may develop depending upon the extent of involvement of lung parenchyma.

Clinically

patient may develop:

- *Fever which* occurs in response to infection
- *Compression of chest* and feeling of chest pain.
- *Respiratory efforts may be increased* due to stimulation by hypoxia and associated fever, leading to hypocapnia and respiratory alkalosis.
- *Heart rate* may be increased in response to hypoxia.
- *Retention of CO₂* occurs only in later stages in severe disease when patient gets exhausted and respiratory effort is failing.
- *Cerebral hypoxia* may develop in severe cases causing delirium which is characterized by confused mental state, illusion, hallucination, disorientation, hyperexcitability and loss of memory.

2. Pulmonary tuberculosis

- Pulmonary tuberculosis is a chronic infection of the lung parenchyma caused by the acid-fast bacteria called *Mycobacterium tuberculosis* or tubercle bacilli.

- The invasion of lung parenchyma by tubercle bacilli causes infiltration of the infected area by macrophages and walling off of the lesion by fibrous tissue to form the so-called tubercle.
- Tuberculosis in its late stages causes many areas of fibrosis and reduces the total amount of lung tissue.
- Initially the alveoli in the affected part become nonfunctioning due to thickness of respiratory membrane. When a large part of the lung is involved, the diffusing capacity is very much reduced.

3. Atelectasis.

Atelectasis refers to the collapse of alveoli with absence of air in the involved parts.

Causes.

Atelectasis may develop due to:

- ***Obstruction of bronchus or a bronchiole.*** Air trapped distal to the bronchial obstruction is absorbed causing collapse of the alveoli attached to the bronchus or bronchiole.
- ***Lack of surfactant*** increases the surface tension of alveolar fluid and causes collapse of the alveoli. Marked lack of surfactant is seen in a disease called hyaline membrane disease or the so-called respiratory distress syndrome.
- ***Pressure from the pleural cavity*** caused by presence of air (pneumothorax), fluid (hydrothorax) or blood (haemothorax) in the pleural cavity may cause collapse of the lung, depending upon their amount present.

Functional abnormality.

When a large portion of the lung is collapsed, the partial pressure of oxygen is reduced in blood leading to respiratory disturbances. Marked collapse is a common cause of dyspnoea.

4. Pulmonary oedema.

Pulmonary oedema refers to collection of serous fluid in the alveoli and the interstitial spaces of the lung tissue.

Causes

of pulmonary oedema are:

- *Increased pulmonary capillary pressure* as occurs in left ventricular failure or mitral valve disease.
- *Pneumonia*
- Effect of harmful chemicals like chlorine or sulphur dioxide.

Functional abnormalities

produced by pulmonary oedema are:

- *Diffusion capacity of the lung* is decreased due to increased thickness of respiratory membrane. So the ability of the lungs to oxygenate the blood and to remove the carbon dioxide is reduced.
- *Marked alveolar oedema* is fatal and causes sudden death due to suffocation.

II. Diseases of pleura

The disease of pleura includes:

1. Pleural effusion.

Pleural effusion refers to accumulation of large amount of fluid in the pleural cavity. Normally, there is very little pleural fluid because the fluid which is produced by a pressure gradient pushing fluid from parietal capillaries to pleural space is promptly absorbed by a net force driving pleural fluid from pleural space to visceral capillaries and lymphatics.

Causes

of pleural effusion include:

- *Excessive transudation* of fluid from the pulmonary capillaries due to:
- Increased hydrostatic pressure as occurs in left ventricular failure or
- Decreased oncotic pressure as occurs in

hypoproteinaemia.

- **Exudation in inflammatory conditions** of pleura (pleuritis or pleurisy) results due to damage of capillary membranes, allowing leakage of fluid and plasma proteins into the pleural cavity. The high-protein content of pleural fluid increases its osmotic pressure which pulls more fluid.
- **Obstruction to lymphatics** in inflammatory and neoplastic conditions also leads to collection of fluid in the pleural cavity.

Functional abnormalities

produced in pleural effusion depend on the size of effusion and the rate at which fluid accumulates.

- Pleural effusion essentially produces a *restrictive abnormality* with decrease in FVC, FRC, TLC and RV.
- When large pleural effusion develops quickly, it causes atelectasis which is associated with dyspnoea and *hypoxia* producing hyperventilation and hypocapnia.
- Moderate to massive effusion causes shift of the mediastinal structures to the opposite side. When this occurs rapidly, this may compromise cardiac output and hypotension.

2. Pneumothorax.

Pneumothorax refers to presence of air in the pleural cavity. Normally, there is a negative pressure in the pleural space (about -0.66 kPa), which becomes positive in pneumothorax.

Causes.

Pneumothorax occurs due to entry of air into the pleural cavity either due to a hole in the chest wall and parietal pleura or a hole in the lung parenchyma and visceral pleura as may occur in accidents, bullet injuries or stab injuries.

Types of pneumothorax and functional abnormalities

produced in them are:

- i. **Open pneumothorax** refers to the condition in which an open

communication is developed between the pleural cavity and the atmosphere. So the air is present in the pleural cavity at atmospheric pressure which reduces all lung volumes. Thus, there occurs a restrictive ventilatory impairment leading to reduction in FVC, FRC and TLC in proportion to the volume of pneumothorax. Depending upon the degree of lung collapse produced there occurs proportionate hypoxia, hypocapnia, dyspnoea and cyanosis.

ii. *Closed pneumothorax* develops when after the entry of air into the pleural cavity the hole in the pleura is sealed. As normally, the partial pressure of gases in the capillaries in the pleura are about 5.3 to 6 kPa less than atmospheric pressure, so there is a significant gradient for absorption of gases from pleural space to capillaries. Thus, the air entrapped in the pleural cavity is slowly absorbed; and so not much functional abnormalities are produced.

iii. *Tension pneumothorax* occurs when the hole produced in pleura is valvular which allows entry of air into the pleural cavity during inspiration but prevents the exit of air during expiration. As a result the intrapleural pressure keeps on rising progressively leading to collapse of ipsilateral lung and pushing the mediastinum and contralateral lung.

- Squeezing of both lungs leads to marked hypoxaemia.
- Displacement of mediastinal structures leads to progressive fall in cardiac output.
- Decreased cardiac output and hypoxia combined produce loss of consciousness and hypotension, and ultimately may prove fatal soon.

Tension pneumothorax requires treatment as a medical emergency.

III. Pulmonary vascular disorders

Pulmonary vascular disorders include: pulmonary hypertension and pulmonary embolism.

1. Pulmonary hypertension.

The mechanisms responsible for genesis of pulmonary hypertension are:

- *Increased pulmonary resistance.* The most common cause of pulmonary hypertension occurs due to:
- Pulmonary vasoconstriction because of alveolar hypoxia (see page 417)
- Obstruction of pulmonary vessels e.g thromboembolism
- Pulmonary capillaries obliteration e.g in emphysema

Increase in left atrial pressure-for details see page 467

Increased pulmonary blood flow due to congenital heart diseases like ASD, VSD or patent ductus arteriosus, the high blood flow is accommodated by recruitment and distension of pulmonary blood vessels. However, sustained high blood flow results in structural changes in smaller vessels leading to rise in pulmonary arterial pressure and ultimately shunt in the heart is reversed (i.e instead of left to right, become right to left).

2. Pulmonary embolism.

Occlusion of pulmonary vessels by an embolus results in following effects:

A. *When a large embolus gets lodged in a major branch of the pulmonary artery,* it results in reduction in cardiac output and cor-pulmonale. Whereas, when small segmental arteries get blocked by medium sized emboli, then pulmonary infarction, cyanosis, tachypnea and pleural pain occurs. In nut shell there is high VA/Q ratio due to increase in physiological dead space and hypoxia, and pulmonary hypertension occurs.

B. *The substances released from the thrombo-emboli* (e.g Histamine, serotonin and prostaglandins) cause constriction in pulmonary vasculature and bronchoconstriction.

C. *Surfactant synthesis* also get reduced due to compromised blood flow, and results in collapse of alveoli and exudation of fluid (pulmonary oedema).

The above-mentioned effects are responsible for dyspnoea and syncope may occur in massive embolism.

Artificial respiration and cardiopulmonary resuscitation

Artificial respiration

Artificial respiration (AR) alone is required as an emergency life saving procedure:

I. *When there is sudden stoppage of breathing* as seen in:

- Drowning,
- Electrocution,
- Anaesthetic accidents,
- Carbon monoxide poisoning,
- Strangulation and
- Accidents.

II. *AR may also be needed when breathing is expected to stop gradually* as in paralysis of muscles in:

- Poliomyelitis,
- Diphtheria and
- Ascending paralysis.

It is important to note that the tissues of brain, particularly cerebral cortex, develop irreversible damage if oxygen supply is stopped for 5

minutes. So, the resuscitation must be started quickly without any delay, before the development of cardiac failure.

Methods of artificial respiration

Presently, AR can be given by two types of methods:

- Manual methods, e.g. mouth-to-mouth breathing method.
- Mechanical methods.

Mouth-to-mouth breathing method

Various manual methods of AR have been described in past and discarded. Presently, the only manual method employed is mouth-to-mouth breathing (exhaled air ventilation) because:

- It can be applied quickly without waiting for the availability of any aid.
- It is simple and effective measure of resuscitation.
- It can be applied in all age groups.
- It is the only technique capable of producing adequate ventilation.
- It also works by expanding the lungs.

Procedure

- The procedure should be performed swiftly and alertly.
- The procedure is performed after placing the patient in supine position.
- It is essential to provide and maintain a clear airway for the procedure to be effective. Therefore, any foreign material present in the mouth cavity must be removed with fingers, e.g. grass, straw, etc. (in case of drowning patients), artificial denture if any: mucus, saliva and blood clot. The tongue must be drawn forward and it must be prevented from falling posteriorly causing airway obstruction. The clothes around the neck and chest region must be loosen. If the mouth is full of blood, mouth-to-nose respiration should be given.
- To begin with patient's neck is extended by placing one hand under the

neck and lifting it and pressing the forehead with the other hand (Fig. 5.7-6A). This prevents the flaccid tongue from falling back into the pharynx.

- Then the patient's nostrils are closed by the thumb and index finger of the hand (Fig. 5.7-6B).
- The resuscitator then takes a deep breath and exhales air into the patient's airway after tightly placing his mouth over patient's mouth and noting the expansion of the chest at the same time. The volume of the air exhaled must be twice the normal tidal volume. This expands the patient's lungs.
- Then, the resuscitator removes his mouth from that of the patient, allowing expiration to occur passively due to the elastic recoil of the lungs and chest (Fig. 5.7-6C).
- Some of the air is likely to enter the stomach through the oesophagus. It can be easily expelled by pressure on the epigastrium.
- The above procedure is repeated 12 to 16 times per minute till spontaneous breathing returns, or till the patient is shifted to a hospital.
- It is important to remember that:
- Mouth-to-mouth method is the most effective manual method, because the CO₂ present in the expired air by the resuscitator can also directly stimulate the respiratory centres and facilitate the onset of respiration.
- The expired air by the resuscitator contains 16% oxygen which is sufficient to revive the patient.

FIGURE 5.7-6 Mouth-to-mouth breathing: **(A)** the neck is extended by placing one hand under the neck and pressing the forehead with other hand; **(B)** nostrils are closed with thumb and index finger and resuscitator exhales into the patient's airway by tightly placing his mouth over the patients mouth; and **(C)** allows the patient to exhale passively by unsealing nose and mouth.

Mechanical methods of AR

The mechanical respirators are employed when AR has to be continued for long periods. The mechanical respirators are of two types:

- Tank respirators and
- Ventilators.

1. Tank Respirators or the so-called iron lung chambers as the name indicates consist of an airtight chamber made of iron or steel. There are various types of mechanical respirators. A commonly used respirator is the Drinker respirator. In this respirator, the patient is kept inside the tank by placing the head outside the chamber. In the Drinker method, alternate positive and negative pressure breathing machines produce periodic inflation and deflation of the lungs.

2. Ventilators are the AR machines by which air or oxygen is pumped into the lungs with pressure intermittently through a rubber tube introduced into the patient's trachea. Inflation occurs when air is pumped and expiration occurs by elastic recoil of chest and lungs, when it is stopped. Presently two types of ventilators are available:

- *Volume ventilator pumps* a constant volume of air into the patient's lungs intermittently with minimum pressure.

- *Pressure ventilator pumps* the air with a constant high pressure into the patient's lungs.

Cardiopulmonary resuscitation

Cardiopulmonary resuscitation (CPR) is required in some patients when heart and respiration both stop. Breathing usually stops before the heart stops, so AR should be started immediately. The CPR may be required in patients with:

- Ventricular fibrillation following a heart attack,
- Victim of electrocution,
- Drowning.

Emergency plan of CPR

The following plan called ABC of CPR has proved useful in reviving such patients:

A: Airway care

is required in unconscious patients. Immediately, tilt head back with a hand under the neck to maintain an open airway (Fig. 5.7-6A).

B: Breathing

by the AR method is required when the patient is not breathing. Mouth-to-mouth respiration should be immediately started (see page 480). Feel carotid pulse, if present continue AR only.

C: Cardiac massage

is required when carotid pulse cannot be felt. During external cardiac massage (procedure described below) sternum should be depressed by 4–5 cm at a rate of 80 to 90 times per minute. The cardiac compression should be alternated with mouth-to-mouth respiration at a rate of one ventilation to five chest compression (1:5).

Procedure of external cardiac massage.

Effective cardiac massage can be carried out without opening the chest. The person conducting external cardiac massage places the heel of one hand on the lower sternum above the xiphoid process and the heel of the other hand on top of the first (Fig. 5.7-7). Pressure is applied straight

down, depressing the sternum 4 or 5 cm toward the spine. This procedure is repeated 80–90 times per minute. Manually squeezing the ventricles is also effective, if the chest is already open, but emergency thoracotomies should not be performed.

FIGURE 5.7-7 Procedure showing external cardiac massage.

Precautions

to be taken during CPR are:

- CPR must be started at the earliest, because a delay of more than 4–5 minutes may cause irreversible damage to the brain.
- The patient should not be made to sit or stand. No pillow should be put under his head, because it will bend the head and occlude trachea.
- Nothing orally should be given to an unconscious person.
- The feet and legs should be raised with a pillow under the hip to improve cerebral blood flow.

- While giving cardiac massage, the pressure should not be applied over the ribs as they are likely to fracture.

Pulmonary function tests

Role of pulmonary function tests in clinical practice

The evaluation of pulmonary function begins with a careful history taking meticulous clinical examination and radiographs of chest. In addition, various pulmonary function tests are employed to help the clinician to make a physiological assessment of lung function rather than to make a pathological diagnosis. The roles of pulmonary function tests in clinical practice are:

1. In diagnosis of pulmonary diseases, pulmonary function tests may be employed:
 - For early diagnosis of a disease, e.g. decreased diffusing capacity is the earliest change seen in interstitial lung disease,
 - For confirmation of clinical diagnosis and
 - For exclusion of a diagnosis.
2. To follow the progress of disease and its response to treatment.
3. To objectively assess the severity of disease.
4. To assess respiratory status before anaesthesia and also to assess the capacity of the individual to tolerate the risk of surgery especially cardiothoracic surgery involving removal of a lung or its part.
5. To assess physical fitness for certain jobs such as those involving strenuous physical exercise, flying at high altitude, etc.
6. To obtain medicolegal information in certain situation.

Classification

Pulmonary function tests can be classified into following groups:

- A. Ventilatory function tests,
- B. Tests of diffusion,
- C. Tests of ultimate purpose of respiration and
- D. Tests during exercise.

Ventilatory function tests

Ventilatory function tests are meant for the assessment of the expansion of lungs and chest wall, and for the assessment of restrictive and obstructive ventilatory defects. The assessment of ventilatory functions can be accomplished by:

- I. Measurement of various lung volume and capacities,
- II. Measurement of dead space,
- III. Measurement of compliance and
- IV. Measurement of airway resistance.

I. Measurement of various lung volumes and capacities

Various lung volumes and capacities have been described on page 401. Most of the lung volumes and capacities except residual volume, functional residual capacity and total lung capacity can be measured by spirometry. Functional residual capacity is determined by nitrogen wash-out method or helium dilution method, and then residual volume and total lung capacity are calculated.

Spirometry

Spirometry refers to recording of volume changes during various clearly defined breathing manoeuvres. It can be performed using a simple spirometer, a modified spirometer called respirometer or computerized spirometer.

- **Simple spirometer**

(Fig. 5.7-8) is made of metal. It consists of following parts:

- *Outer chamber* or container which is filled with water.
- *Floating drum* or a gas bell with 6-litre capacity, floats in the water in an inverted manner. It is attached to a chain which passes over a pulley bearing a balancing weight and a writing needle (pen). The needle (pen) moves with the movement of the floating drum. The floating drum is thus counterpoised and has very little inertia and friction.
- *Inner chamber* is open at the top end which lies above the water level in outer chamber and is connected to a tube at the bottom end. At the end of tube, a mouthpiece is attached through which the subject is made to respire.
- *Kymograph* is a recording drum on which the movements of the needle are recorded.

FIGURE 5.7-8 Simple spirometer.

• **Procedure.**

The whole procedure is explained to the subject thoroughly and then he is made to breathe through the mouthpiece of the spirometer. As explained above and shown in [Figure 5.7-8](#), the arrangement in spirometer is such that when the subject expires the floating drum (gas bell) moves up and the counterweight along with writing needle (pen) moves down, and thus the expiration is recorded as downward deflection on the kymograph. Conversely, when the subject inspires, the floating drum moves down and the counterweight with writing pen moves up; and thus the inspiration is recorded as an upward deflection on the kymograph. The record of various lung volume and capacities so obtained on the kymograph is called spirogram.

To measure the various lung volumes and capacities the subject is instructed to expire or inspire as described:

- First, he is asked to breath normally (tidal respiration) for a few times,
- Then he is asked to inspire as deeply and fully as possible and
- Thus, while keeping the nostrils closed with his thumb and index finger, he is asked to expire with a maximum effort. It is preferable to take three recordings, at intervals of 5 minutes, for each determination. The maximum volume of the three readings should be considered the reporting value. The various lung volumes and capacities are then calculated from the record (spirogram so obtained) (see page 401 [Fig. 5.2-6](#)) which in general give information about the ventilatory functions.

Of the various static and dynamic lung volumes and capacities which serve as more useful pulmonary function tests are:

1. Vital capacity

Measurement of vital capacity under different conditions is the most commonly performed pulmonary function test.

Slow vital capacity

Slow vital capacity is the volume of air expired (after maximum inspiration) during a slowly performed maximum expiratory effort. It is used to evaluate the size of the lungs (see [Fig. 5.2-6](#)). The vital capacity can be decreased by either decrease in TLC as seen in restrictive lung disease or by increase in reserve volume ie seen in obstructive lung disease.

Forced vital capacity

FVC or TVC is the volume of air that can be expired rapidly with a maximal expiratory effort after a maximal inspiration.

FVC is reduced in:

- *Conditions producing restrictive defect*, such as kyphoscoliosis, pleural effusion, pneumonia, etc. and
- *Condition producing trapping of air* due to collapse of distal air during a forced expiratory manoeuvre.

Components of FVC

The volume of air expired can be timed by recording the forced vital

capacity on a spirograph moving at the known speed. From the graph so obtained (Fig. 5.2-7), the FVC can be divided into following components:

i. Forced expiratory volume during first second (FEV₁)

- FEV₁ is the volume of air expired during the first second of FVC.
- It is the most commonly used screening test for airway diseases.
- The FEV₁ is actually a flow rate, its unit are L/sec.
- FEV₁% is the percentage of VC expired in one second, i.e. $FEV_1\% = FEV_1/FVC \times 100$ normally FEV₁% or about 80% of the FVC (Fig. 5.2-8A).

Clinical application. Useful in distinguishing between restrictive and obstructive lung disease:

- Patients with *restrictive lung disease* (e.g. kyphoscoliosis and ankylosing spondylitis) have a reduced FVC but are able to achieve relatively high flow rates; therefore, their FEV₁% exceeds 80% (Fig. 5.2-8B).
- Patients with *obstructive lung disease* (e.g. bronchial asthma) have low flow rates as a result of high airway resistance therefore their FEV₁% is abnormally low (Fig. 5.2-8C).

ii. Forced expiratory volume in 2 sec (FEV₂).

It represents the volume of air expired in first 2 second of an FVC, FEV₂% is about 90% of FVC under normal condition.

iii. Forced expiratory volume in 3 sec (FEV₃).

It represents the volume of air expired in first 3 second. Normally FEV₃% is 98–100% of FVC.

Flow–volume curve

The rate of air flow noted during maximum expiration can be plotted versus volume change to give a flow–volume curve (Fig. 5.7-9). This curve may be altered dramatically in obstructive and restrictive diseases. However, due to technical problems, flow-volume curve is not routinely plotted in clinical respiratory laboratories.

FIGURE 5.7-9 Flow–volume curve during maximum expiration.

Flow volume loop

Flow Volume loop is a relationship between volume and flow during maximum inspiratory and expiratory effort, which can be recorded with recent computerized recorders for ventilatory function. The normal pattern of pressure volume loop is a 'triangle sitting on a semi circle'. (Fig

5.7-10).

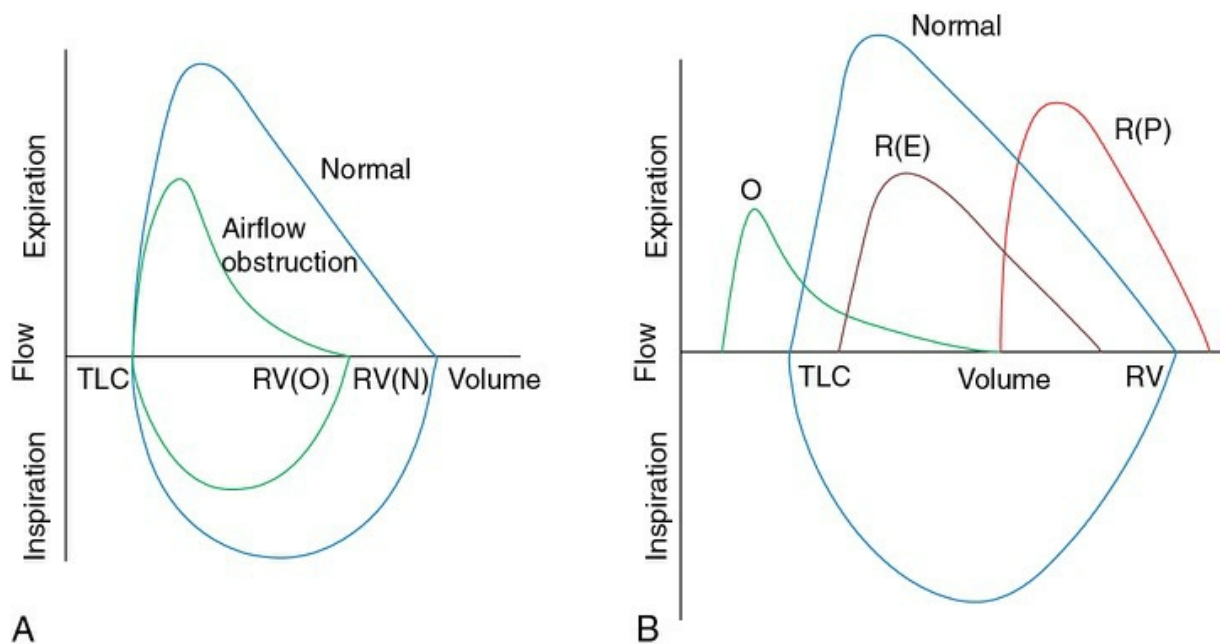

FIGURE 5.7-10 Flow–volume loops in a normal individual and a patient with airflow obstruction - **A**; and in different conditions - **B**; R(E) - extraparenchymal restrictive disease; O = obstructive disease. R(P) Parenchymal restrictive disease

Clinical significance of Flow Volume loop is as under:

During expiration depending on the mechanical properties of the lung and resistance to airflow; the flow is effort dependent in early part but, in later part it is effort independent. Therefore,

- In case of air flow obstruction, the flow rate at any given volume is decreased, particularly in later part of expiration and scooped out appearance to the expiratory curve (Fig 5.7-10B). Therefore, in obstructive lung disease an abnormal flow-volume loop may appear before any abnormality is appreciated in FEV_1/FEV or $FFF_{25-75\%}$

2. Forced expiratory flow rate during 25–75% of expiration (FEF_{25-75%})

- It is the mean expiratory flow rate during middle 50% of FVC (Fig. 5.2-9A), and so is also called the mid-expiratory flow rate.
- This measurement can be done from the same record as FEV₁. The total expired volume is divided into four equal parts. The flow rate is calculated for the middle two parts (25 to 75%), i.e. the middle half.
- Mid expiratory time (MET) refers to the time taken for FEF 25-75%. Its normal value is 0.5 sec which is increased in obstructive lung disorders. It may be the only abnormality indicating early disease in smokers with COPD.

3. Peak expiratory flow rate

Peak expiratory flow rate (PEFR) refers to the maximum rate of air flow observed during a sudden forced expiration, from the position of full inspiration. It can be measured by a simple device known as peak flow meter (Fig. 5.7.11) which can be used by the patients even at home. The best of three efforts should be noted as the value of PEFR. It is a good and reproducible measure of degree of airflow obstruction.

FIGURE 5.7-11 Peak flow meter.

Maximum breathing capacity (MBC) or maximum voluntary ventilation (MVV)

For details see page 403.

5. Spirometric response to inhaled bronchodilators

In this test forced expirogram is recorded before and 10–20 mins after inhalation of two puffs of Salbutamol inhaler (separated by 30–60 seconds interval). Each puff delivers 100 µg of bronchodilator. Test is used for finding out:

- Whether the air flow obstruction is reversible or not, specially in suspected asthma patients and also

- To know the degree of reversibility in severe cases of asthma.

6. Functional residual capacity

FRC is the volume of the air remaining in the lungs after normal tidal expiration. For details see page 401.

Functional residual capacity can be measured by nitrogen wash-out method or helium dilution method.

For details see page 401

Common abnormal patterns of TLC, FRC and RV

- *Normal TLC with increased FRC, RV and RV/TLC ratio* is seen in patients with severe airway obstruction with air trapping. Since FVC is reduced in such patients so FRC and RV are increased.
- *Reduced TLC, RV and FRC* is seen in patients with restrictive lung disorders like interstitial lung disease. On spirometry, FVC is also reduced in such patients.
- *Reduced TLC with increased RV and FRC* may be seen in patients with mixed obstructive and restrictive lung disorders.

II. Measurement of dead space

Dead space air is the portion of minute ventilation that does not take part in exchange of gases. Normally, it is constituted by the air present in the conducting zone of respiratory passages (*anatomical dead space*), but in some diseases may additionally include also poorly perfused alveoli (*physiological dead space*). For details see page 421.

III. Measurement of compliance

Compliance (C) expresses the distensibility (expansibility) of the lungs and chest wall. Reduced compliance produces a condition called RLD. In clinical testing, the restrictive lung diseases are evaluated indirectly by measurement of various lung volumes and capacities as described above. Thus, direct measurement of compliance in the respiratory system is rarely done for clinical use; however it may be required for research purposes. For details see page 408.

IV. Measurement of airway resistance

Airway resistance is the resistance caused by friction of gas molecules

between themselves and the walls of the airways. Airway resistance is increased in many obstructive lung diseases. Like compliance, airway resistance is also seldom measured directly for clinical use. However, it may be required for research purposes (for details see page 409).

Tests of diffusion

Pulmonary diffusion refers to transfer of gases from alveoli to capillary blood across the respiratory membrane. The exchange of gases in the lungs was earlier believed to be dependent merely on the ability of the gases to diffuse across the respiratory membrane. This term led to the use of term *diffusion capacity*. However, later it was realised that many other factors like ventilation–perfusion balance, pulmonary capillary blood volume, Hb concentration of the blood and rate of reaction of gases with Hb are also involved in the exchange of gases. Therefore, nowadays, the term *transfer factor*, rather than diffusion capacity is used.

For estimation of transfer factor (diffusion capacity) of O₂ see page 428.

Tests of ultimate purpose of respiration

Since the ultimate purpose of respiration is to supply O₂ from atmosphere to tissues and removal of CO₂ from the tissues into the atmosphere; so, the estimation of arterial blood pO₂, pCO₂ and pH (blood gas analysis) are most fundamental of all the pulmonary function tests.

Estimation of arterial pO₂, pCO₂ and pH

For blood gas analysis, arterial blood sample is usually taken from the radial artery or femoral artery. The estimation of pO₂, pCO₂ and pH can be done within a minute or so using a very small sample of blood with the help of miniaturised glass electrodes.

Arterial pO₂ levels in young healthy adult vary from 85 to 105 mmHg with a mean of 95 mmHg. The value may drop by upto 15% in healthy elderly subjects due to an increase in ventilation-perfusion inequality.

Causes of decreased arterial pO₂ are:

- Alveolar hypoventilation, i.e. inadequate intake of air.
- Diffusion defect, i.e. inadequate transport of O₂ across the respiratory membrane.

- Arteriovenous admixture, i.e. right to left vascular shunt and
- Decreased ventilation-perfusion ratio, i.e. physiological shunt as seen in patients with emphysema.

Arterial pCO₂ and pH level in normal adult are about 40 mmHg and 7.4, respectively and are basically determined by the volume of alveolar ventilation:

- *Hypoventilation* causes increased pCO₂ and reduction in arterial pH (respiratory acidosis),
- *Hyperventilation* produces decreased pCO₂ and increase in arterial pH (respiratory alkalosis).

Tests during exercise

Because of enormous physiological reserves, both the cardiac and pulmonary functions may be normal at rest in early stages of the disease. Exercise testing provides information about the total cardiopulmonary performance of the individual and unmasks the abnormality not detected by the function tests performed at rest. The exercise may be performed on a treadmill or a cycle ergometer. Measurement of pulse rate, minute ventilation, O₂ uptake and arterial blood gas tension during graded exercise are extremely useful specially when the cause of dyspnoea is obscure.

SECTION 6

Excretory System

OUTLINE

Introduction

- 6.1. Kidneys: Functional anatomy and blood flow
- 6.2. Mechanism of urine formation: Glomerular filtration and tubular transport
- 6.3. Concentration, dilution and acidification of urine
- 6.4. Regulation of body fluid osmolality, composition and volume
- 6.5. Applied renal physiology including renal function tests
- 6.6. Physiology of micturition

Introduction

Concept of excretory system: *Excretion*. Literally, the word excretion means elimination of any matter from the body of an organism. The organs that are involved in the process of excretion include:

- *Kidneys*, which excrete water and water-soluble waste products,
- *Lungs*, which excrete carbon dioxide, water vapour and other volatile substances such as acetone,

- *Skin*, which excretes water and salts mainly in the form of sweat and
- *Gastrointestinal tract*, which excretes faeces (excreta).

However, *sensu stricto*, the term excretion refers to elimination of principal products of metabolism except carbon dioxide. The principal products of metabolism, other than carbon dioxide, are ammonia, urea, uric acid, creatinine, various pigments and inorganic salts. Of these, carbon dioxide is a universal metabolic waste which is discharged by the respiratory organs. The remaining excretory substances, in bulk, are excreted by the kidneys. Small quantities of some of the excretory substances are also eliminated by the skin.

Excretory organs. Thus, in the strictest sense, kidneys are the excretory organs. Together with a pair of ureters and a urinary bladder, kidneys constitute the excretory system. Most excretory substances are in solution in water. Water itself is not considered a waste product, but any excess of it is eliminated along with the excretory substances dissolved in it. The final product is called urine. That is why, the kidneys may also be called as urinary organs and the excretory system as urinary system.

Functions of excretory organs

Excretory organs, i.e. the kidneys, serve several major functions:

1. *Excretory function.* As mentioned above, the kidneys excrete a number of end products of metabolism in urine. Thus, formation of urine is the major function of the kidneys. The kidneys eliminate these substances from the body at a rate that matches their production. Thus, they regulate their concentration within the body fluids. In addition to the metabolic wastes, they also excrete foreign substances from the body, such as drugs, pesticides and other chemical ingested in food.
2. *Regulation of water and inorganic ion balance.* Control of volume of body fluids and their inorganic ion balance is an important homeostatic role of kidneys. The kidneys accomplish this task by working in concert with components of cardiovascular system, endocrine and central nervous system. Therefore, it has been discussed in chapter on 'Regulation of Body Fluid, Osmolality, Composition and Volume' on page 529.
3. *Regulation of acid–base balance.* Kidneys, in co-ordination with lungs, liver and buffers in the body play a role in regulation of the acid–base

balance. This co-ordinated function has been discussed in a separate chapter on 'Physiology of Acid–Base Balance', in Section 12 on 'Specialized Integrative Physiology' (page 1227).

4. *Hormonal function.* As an endocrine gland, the kidneys produce and secrete renin, calcitriol and erythropoietin.

- *Renin* activates the renin–angiotensin–aldosterone system that influences the blood pressure and sodium and potassium balance (page 534).
- *Calcitriol* (1,25-dihydroxy vitamin D₃) influences calcium balance (page 727).
- *Erythropoietin* stimulates the erythrocyte production by the bone marrow. Decreased erythrocyte production is a cause of anaemia seen in chronic renal failure (page 545).

Overview of excretory system

This section on excretory system is devoted to the major function of excretory system—the formation of urine and physiology of micturition. In addition, important applied aspects have also been included. This section begins with a chapter on 'Functional Anatomy of Kidneys and Renal Blood Flow', which is mandatory to understand renal physiology.

CHAPTER

6.1

Kidneys: Functional anatomy and blood flow

FUNCTIONAL ANATOMY

- Gross anatomy
 - External features
 - Gross internal structure
- Microscopic structure
 - Structure of nephron
 - Glomerulus
 - Renal tubule
 - Collecting duct
 - Types of nephrons
 - Juxtaglomerular apparatus

RENAL BLOOD FLOW

- Renal blood vessels
 - Arrangement of arterial vessels
 - Arrangement of venous vessels
 - Renal blood flow: characteristic features

- Regulation of renal blood flow
- Measurement of renal blood flow

Functional anatomy of kidneys

Gross anatomy

External features

Gross anatomical features of a human kidney, illustrated in Fig. 6.1-1A, are:

FIGURE 6.1-1 Gross anatomical features **(A)** and coronal section through human kidney **(B)**.

Location.

The kidneys are bean-shaped organs that lie retroperitoneally on the posterior abdominal wall, one on each side of the vertebral column at the level of T₁₂ to L₁ vertebrae. The right kidney lies slightly inferior to the left kidney.

Size and shape.

During life, the kidneys are reddish-brown in colour. Each kidney in an adult human weighs about 150 g and measures approximately 10 cm in length, 5 cm in width and 2.5 cm in thickness.

Surface, borders and poles.

Each kidney has anterior and posterior surfaces, medial and lateral margins, and superior and inferior poles. The lateral margin is convex and the medial margin is concave, where the renal sinus and renal pelvis are located.

Renal hilum and sinus.

The renal hilum is a vertical cleft present on the concave medial margin. It is the entrance to space within the kidney—the renal sinus. Through the renal hilum the renal artery enters, and the renal vein and renal pelvis leave the renal sinus. The *renal sinus* is thus occupied by the renal pelvis, calyces, vessels, nerves and a variable amount of fat.

Renal pelvis and calyces.

The renal pelvis is the flattened, funnel-shaped expansion of the superior end of ureter. Within the renal sinus, the pelvis divides into two (or three) parts called *major calyces*. Each major calyx divides into a number of *minor calyces*. The end of each minor calyx is shaped like a cup into which fits a projection of kidney tissue called renal papilla (the apex of renal pyramid).

Gross internal structure

Gross internal structure of the kidney, as seen in coronal section through the organ, exhibits that kidney tissue consists of an outer region called the cortex and an inner region called the medulla (Fig. 6.1-1B).

Medulla.

It is made up of triangular areas of renal tissue that are called the renal pyramids. Pyramids are 4–14 in number and separated from each other by cortical columns of Bertin. Each pyramid has a base directed towards the cortex, and an apex (or renal papilla) which is directed towards the renal pelvis and fits into the minor calyx. Pyramids show striations that pass radially towards the apex. These striations are due to straight portion of the nephron and extend some distance upwards into the cortex where they are called medullary rays. The medulla can be subdivided into two parts:

- *Outer medulla* that is further subdivided into the outer stripe, and the inner stripe.

- *Inner medulla* is also called papillary zone.

Cortex.

The renal cortex can be divided into two parts which are continuous with each other:

- *Cortical arches* or cortical lobules refer to the tissue lying between the bases of pyramids and surface of the kidney.
- *Renal columns* refer to the cortical tissue that lies in between the pyramids.
- *Lobe of kidney*. Each pyramid, surrounded by a shell of cortex, constitutes a lobe of the kidney. This lobulation is obvious in the fetal kidney.

Microscopic structure of kidney

Microscopically, the cortex and medulla of the kidney are composed of nephrons, blood vessels, lymphatics and nerves.

Nephron is a structural and functional unit of the kidney. Each kidney contains approximately 1.2 million nephrons. Each nephron is capable of forming urine.

Structure of the nephron

A nephron consists of two major parts (Fig. 6.1-2):

- Renal corpuscle, and
- Renal tubule.

FIGURE 6.1-2 Part of a typical nephron. Organization of cortical and juxtamedullary nephrons showing different parts. Note differences between two types of nephrons.

Renal corpuscle.

Renal corpuscle or Malpighian corpuscle is a rounded structure comprising glomerulus surrounded by glomerular capsule (Fig. 6.1-3A).

FIGURE 6.1-3 Structure of a glomerulus (A) and glomerular membrane (B).

Glomerulus.

Glomerulus refers to a rounded tuft of anastomosing capillaries about 200 μm in diameter. Blood enters the glomerulus through an *afferent arteriole* and leaves it through an *efferent arteriole* (note that the efferent vessel is an arteriole and not a venule). The afferent and efferent arterioles lie close together at a point that is referred to as the *vascular pole* of the renal corpuscle.

Glomerular capsule.

Glomerular capsule, also known as Bowman's capsule, encloses the glomerulus and is formed of two layers: the inner layer covering the glomerular capillaries is called *visceral layer*, and the outer layer is called *parietal layer*. In fact, the Bowman's capsule represents the cup-shaped blind beginning of the renal tubule. The space between the visceral and parietal layer of the capsule (called Bowman's space or urinary space) is continuous with the lumen of the renal tubule.

Ultrastructure of glomerular membrane.

Glomerular membrane refers to the membrane that separates blood of glomerular capillaries from the fluid present in the Bowman's space. It is also called *filtration barrier* and consists of three major layers (Fig. 6.1.3B):

1. **Capillary endothelium.** It is fenestrated (i.e. it contains pores with diameter 70–90 nm) and is freely permeable to water, small solutes and even to small proteins.

2. **Basement membrane.** It consists of a matrix of glycoproteins and mucopolysaccharides. Compared with typical membranes, the glomerular basement membrane is very thick. It comprises three layers:

- Lamina rara externa or outer cement layer,
- Lamina densa and
- Lamina rara interna.

No pores have been demonstrated in the basement membrane; however, its permeability corresponds to pore size (of about 8 nm).

3. **Bowman's visceral epithelium** or the inner layer of Bowman's capsule, which forms the third layer of glomerular membrane, is formed by special cells called *podocytes*. Podocytes have finger-like processes that encircle the outer surface of capillaries. The processes of podocytes interdigitate to cover the basement membrane and are separated by gaps called the *filtration slits* (~25 nm diameter). Each filtration slit is covered by a layer of fine filaments that constitute the diaphragm.

Mesangium is an important component of renal corpuscle; it consists of mesangium cells that are present between the capillary endothelial cells and the basement membrane, especially where the basement membrane encloses more than one capillary. These cells provide structural support for the glomerular capillaries, secrete the extracellular matrix and exhibit phagocytic activity.

Renal tubule.

Renal tubule is a long complicated tubule, which is divisible into the following main parts (Fig. 6.1-2), is about 15 mm long and 55 μm in diameter:

1. **Proximal tubule.** The proximal tubule initially forms several coils, *proximal convoluted tubule (PCT)*, followed by a straight segment, *proximal straight tubule (PST)* or *pars recta* that descends towards the medulla.

2. **Intermediate tubule or loop of Henle** that consists of:

- Descending thin segment (DTS),
- Ascending thin segment (ATS) and
- Thick ascending limb (TAL).

In *juxtamedullary nephrons*, the DTS joins ATS to form the hair pin band (loop). The ATS reaches up to the junction of outer and inner medulla. In *cortical nephrons*, there is no ATS; the DTS is continuous at the bend of loop with the thick ascending limb (TAL). Near the end of thick ascending limb (TAL), the nephron passes between its

afferent and efferent arteriole. This short segment of the thick ascending limb is called the *macula densa*.

3. *Distal convoluted tubule (DCT)* is about 5 mm long. It begins a short distance beyond the macula densa and extends to a point in the cortex where the connecting tubules (CNT) of two or more nephrons join to form the cortical collecting ducts.

4. *Collecting duct* is about 20 mm long which passes through the renal cortex and medulla. The collecting duct, strictly speaking, is not a part of the nephron, since embryologically it is derived from the ureteric buds. It is divisible into three parts:

- *Cortical collecting duct (CCD)*, i.e. the portion present in the cortex,
- *Outer medullary collecting duct (OMCD)*, i.e. the portion present in the outer medulla and
- *Inner medullary collecting duct (IMCD)*, i.e. the portion present in the inner medulla. Several IMCDs coalesce together before finally opening at the tip of the renal papilla.

Characteristics of epithelium lining the renal tubule.

The epithelium lining the different segments of renal tubule has some special characteristic features which are suited to perform specific transport functions (Figs 6.1-2, 6.1-4).

FIGURE 6.1-4 Ultrastructure of an epithelial cell lining the proximal convoluted tubule.

Type of cells. The cells lining the renal tubule are mostly cuboidal, except in the thin segment where these are flat or squamous type.

Apical surface of cuboidal cells bear a few microvilli in general, which are numerous, dense and amplified in proximal tubule cells to form the so-called brush border.

Basolateral membrane of the proximal convoluted tubule cells, thick ascending segment cells and distal convoluted tubule cells is highly invaginated and contains many mitochondria. These infoldings create basal spaces. In contrast, the cells of descending thin limb and ascending thin limb of loop of Henle have poorly developed basolateral surfaces and contain a few mitochondria.

Lateral surfaces of the cells of renal tubules bear the lateral cell process which interdigitate with lateral processes of the adjacent cells. *Lateral intercellular* spaces are present in between the interdigitations. Lateral intercellular spaces do not communicate with the basal spaces. The lateral surfaces of cells form two types of tight junctions:

- *Leaky tight junctions* that permit water and solutes to diffuse across them. These are present in the *proximal tubule*.
- *Tight tight junctions* that do not permit water and solutes to diffuse across them easily. They are present in the *distal tubule*.

Cortical collecting duct is composed of two cell types:

- *Principal cells (P cells)* have a moderately invaginated basolateral membrane and contain few mitochondria. They are involved in Na⁺ absorption and also antidiuretic (vasopressin) stimulated water reabsorption.
- *Intercalated cells (Ic cells)* have a high density of mitochondria. They are concerned with acid secretion and HCO₃⁻ absorption.

Inner medullary collecting duct is composed of a single layer of cells that have poorly developed apical and basolateral surfaces and a few mitochondria.

In the interstitial tissue of medulla, type I medullary interstitial cells are present, which contain lipid droplets and also secrete prostaglandins (predominantly PGE₂).

Types of nephrons

There are two types of nephrons: cortical (superficial) and juxtamedullary. Differences between the cortical and juxtamedullary nephrons are depicted in [Fig. 6.1-2](#) and [Table 6.1-1](#).

TABLE 6.1-1

Differences between Cortical and Juxtamedullary Nephron

Feature	Cortical nephron	Juxtamedullary nephron
Location of glomerulus	Upper region of cortex	Near junction of cortex and medulla
Percentage of total nephron	85%	15%
Size of glomeruli	Small	Larger
Size of loop of Henle	Small, extends up to outer layer of medulla	Large, extends deep into the medulla
Descending limb of loop of Henle comprises	Thin segment	Thin segment
Ascending limb of loop of Henle comprises	Thick segment	Thin segment
Efferent arterioles	Have large diameter and break up into peritubular capillaries	Have small diameter and continue as vasa recta
Rate of filtration	Slow	High
Major function	Excretion of waste products in urine	Concentration of urine by countercurrent system

Juxtaglomerular apparatus

Juxtaglomerular apparatus as the name indicates (juxta—near) refers to collection of specialized cells located very near to the glomerulus. It

forms the major component of renin–angiotensin–aldosterone system
The juxtaglomerular apparatus comprises three types of cells (Fig. 6.1-5):

- Juxtaglomerular cells,
- Macula densa cells and
- Mesangial cells.

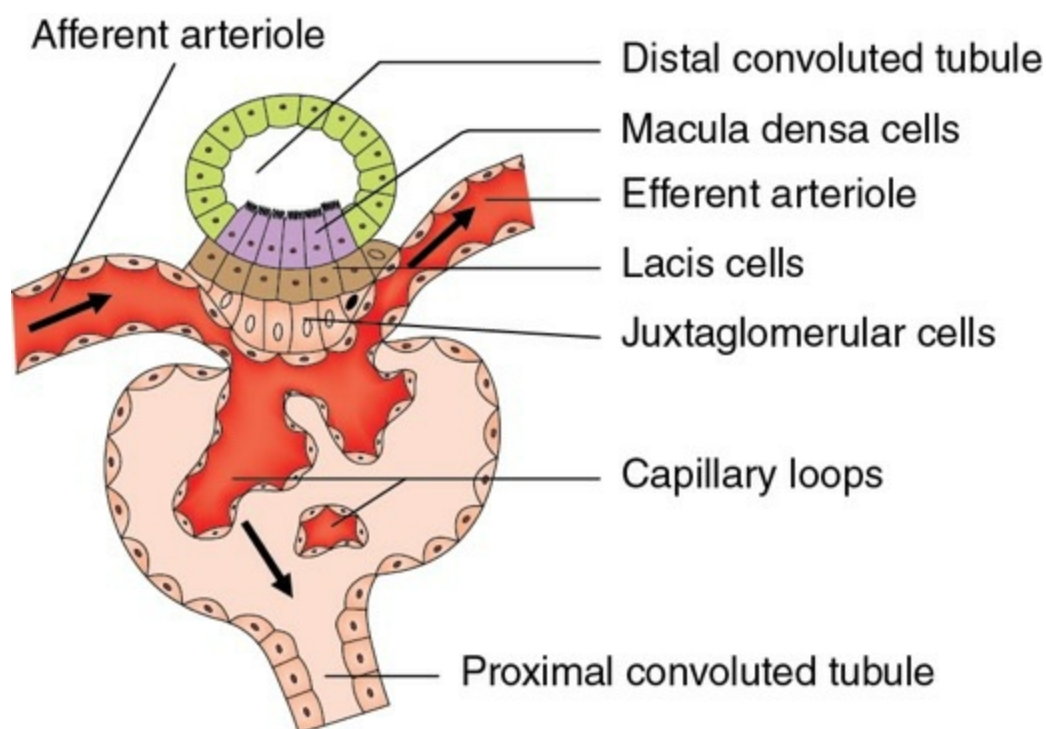

FIGURE 6.1-5 Juxtaglomerular apparatus.

1. Juxtaglomerular cells.

Juxtaglomerular (JG) cells are specialized *myoepithelial* (modified vascular smooth muscle) cells located in the media of the *afferent arteriole* in the region of juxtaglomerular apparatus.

Characteristic features of juxtaglomerular cells are:

- They have well-developed Golgi apparatus and endoplasmic reticulum, abundant mitochondria and ribosomes.
- They synthesize, store and release an enzyme called *renin*. Renin is stored in the secretory granules of JG cells and, therefore, these are also called *granular cells*.

- They act as *baroreceptors* (tension receptors) and respond to changes in the transmural pressure gradient between the afferent arterioles and the interstitium.
- They are densely innervated by *sympathetic nerve* fibres and release their renin content in response to sympathetic discharge.
- As these cells act as vascular volume receptors, they monitor renal perfusion pressure and are stimulated by hypovolaemia or decreased renal perfusion pressure. The granulation of these cells increases when there is sustained hypotension in afferent arteriole, in sodium deficiency.

2. Macula densa cells.

Macula densa cells refer to the specialized renal tubular epithelial cells of a short segment of the thick ascending limb of loop of Henle which passes between the afferent and efferent arterioles supplying its glomerulus of origin.

Characteristic features of macula densa cells are:

- They are not well adapted for reabsorption.
- They are not innervated.
- They have prominent nuclei, and their Golgi complex is usually located between the nucleus and the cell base (i.e. towards the afferent arteriole), while in other tubular cells the Golgi complex is located near the apical membrane. These characteristics suggest that these cells may be secreting a substance towards the arteriole.
- These cells are in direct contact with the mesangial cells and in close contact with the juxtaglomerular cells.
- They act as chemoreceptors and are stimulated by decreased NaCl concentration and causing increased renin release.

3. Mesangial cells.

Mesangial cells or *lakis* cells are the interstitial cells of the juxtaglomerular apparatus.

Characteristic features of these cells are:

- They are in contact with both the macula densa cells (on one side) and juxtaglomerular cells (on the other side).
- Structurally, these cells act as supporting cells and plugging device at the glomerular entrance.
- Functionally, these cells possibly relay the signals from macula densa to granular cells after modulating the signals. In this way, a decreased intraluminal Na^+ load, Cl^- load or both in the region of macula densa stimulates the juxtaglomerular cells to secrete renin.
- They also show granulation to secrete renin in conditions of extreme hyperactivity.
- They also secrete various substances and take up immune complexes.

Innervation of kidney

Renal vessels are innervated by sympathetic and parasympathetic fibres.

Parasympathetic innervation

is by vagus nerve, but its function is uncertain.

Sympathetic innervation.

Preganglionic sympathetic fibres arise from the neurons of lower thoracic and upper lumbar (T_{10} – L_2) intermediolateral segments of spinal cord. The cell bodies of the postganglionic neurons are located in the ganglia of sympathetic chain and superior mesenteric ganglion. The fibres from these neurons are carried by the renal nerves, which travel along the renal blood vessels as they enter the kidney. The efferent fibres are mainly distributed to afferent and efferent arterioles, cells of renal tubule and also to JG cells.

Afferents from the kidney

(afferents of renorenal reflex and pain fibres) run along with the efferent fibres and enter in the spinal cord through the thoracic and upper lumbar dorsal roots.

Note.

Renorenal reflex. An increase in uteteral pressure of one kidney reflexly reduces efferent nerve activity of contralateral kidney and causes

increased excretion of sodium and water, known as renorenal reflex.

Renal blood flow

Renal blood vessels

Arrangement of arterial vessels (renal artery and its branches) in the kidney (fig. 6.1-6)

- *Renal artery* (one for each kidney), a major branch from the aorta, divides into a number of lobular arteries at the hilum of kidney.
- *Lobular artery* (one for each pyramid) divides into two or more interlobar arteries.
- *Interlobar arteries* enter the tissue of the renal columns and run towards the surface of kidney. Reaching the level of the bases of the pyramids, the interlobar arteries divide into arcuate arteries.
- *Arcuate arteries* run at right angles to the parent interlobar arteries. They lie parallel to the renal surface at the junction of pyramid and cortex. They give a series of interlobular arteries.
- *Interlobular arteries* run through the cortex at right angles to the renal surface to end in a subcapsular plexus. It has been held that interlobular arteries divide the renal cortex into small lobules. Each interlobular artery gives off a series of afferent arterioles.
- *Afferent arterioles*. Each afferent arteriole enters the Bowman's capsule and divides into a rounded tuft of anastomosing capillaries called *glomerulus*. As mentioned earlier, this capillary network has special features owing to which it works as a sieve allowing plasma filtration with retention of plasma proteins and blood cells. The glomerular capillaries join to form the efferent arteriole.
- *Efferent arterioles* leaving the glomeruli of two types of nephrons exhibit different behaviour:
- *Efferent arterioles* arising from the cortical nephrons

divide into *peritubular capillaries* that surround the proximal and distal convoluted tubule forming a rich meshwork of microvessels. This meshwork functions to remove water and solutes that have diffused from the renal tubules. These capillaries drain into interlobular veins.

- *Efferent arterioles arising from the juxtamedullary nephrons* give rise to vasa recta. The vasa recta descend with the long loops of Henle into renal medulla and return to the area of the glomerulus, and drain into interlobular or arcuate vein.

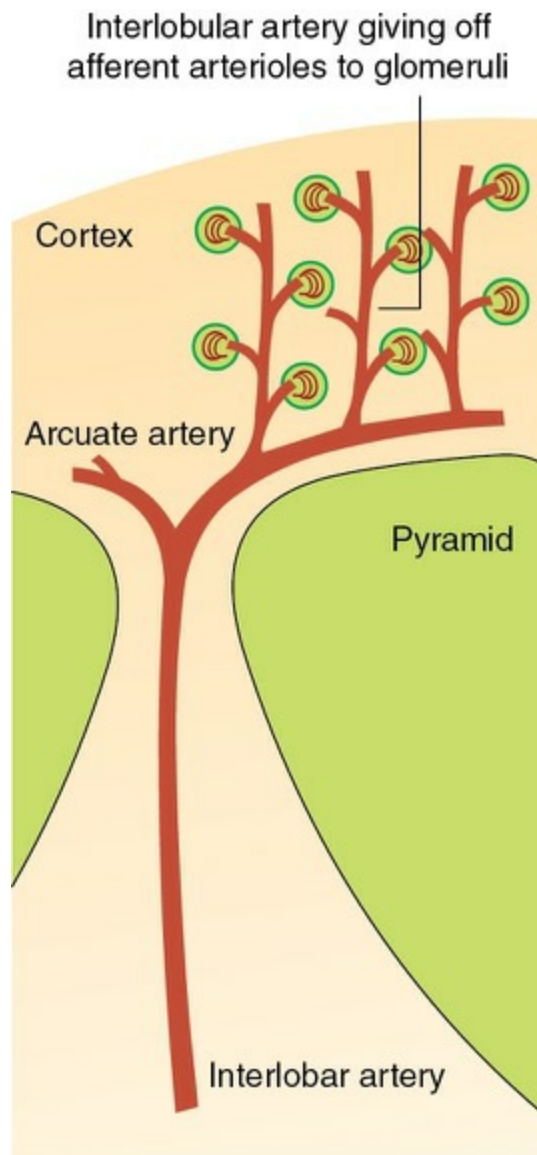

FIGURE 6.1-6 Scheme to show arrangement of arteries within the kidney.

Side branches arising from the vasa recti form capillary network at different levels along the loop of Henle (Fig. 6.1.7).

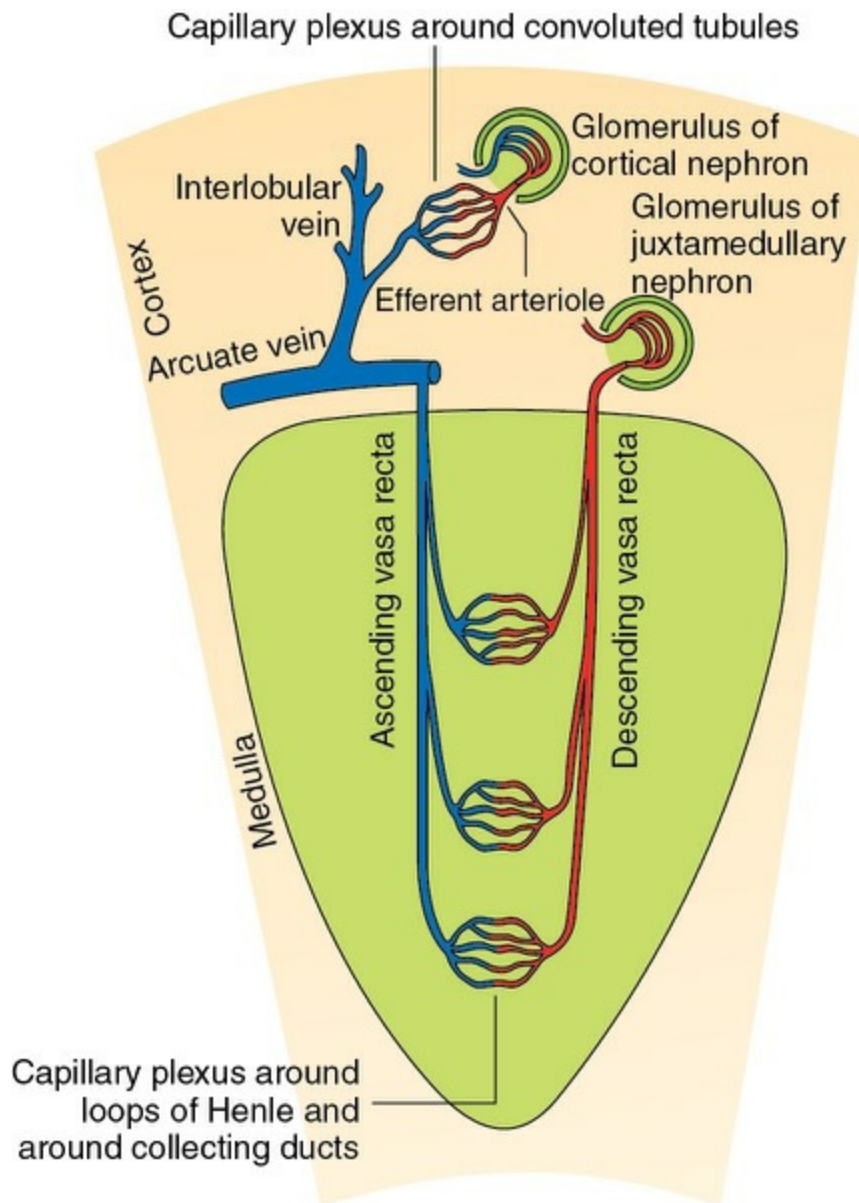

FIGURE 6.1-7 Scheme to show behaviour of efferent arterioles arising from the glomeruli of cortical and juxtamedullary nephrons.

Arrangement of venous vessels (renal veins)

The pattern of renal venous system is similar to that found in the end arterial system, except for the presence of multiple anastomoses between veins at all levels of the venous circulation. The corresponding veins which run parallel to the arterial vessels are the interlobular veins, the arcuate veins, the interlobar veins and the renal veins which exit the kidney at the hilus.

Characteristics of renal blood flow

Amount and rate of blood flow

- *Rate of renal blood flow* under basal conditions, approximately 1200 ml/min (400 ml/100 g tissue/min), is very high compared to other tissues, e.g.
- Coronary blood flow: 80 ml/100 g/min,
- Brain blood flow: 55 ml/100 g/min and
- Skeletal muscle blood flow: 4 ml/100 g/min.
- *Total renal blood flow* is approximately 20% of resting cardiac output, while the two kidneys make <0.5% of total body weight.
- *Range of blood flow* to kidney is rather narrow. It allows only a 25% increase (300 ml) over the basal renal blood flow of 1200 ml/min. This reserve is much higher in other organs.
- *Higher blood flow* to kidneys is related to its excretory function rather than its metabolic requirement.
- Blood flow to the kidneys is directly proportional to the pressure difference between the renal artery and renal vein, and is inversely proportional to the resistance of the renal vasculature. Because the afferent arteriole, the efferent arteriole and the intralobular artery are the major resistance vessels in the kidneys, they determine renal vascular resistance.
- *In face of blood pressure changes*, the renal blood flow shows remarkable constancy due to autoregulation.
- *During exercise*, sympathetic tone to renal vessels increases and shunts renal blood flow to the skeletal muscles.

Renal blood flow and oxygen consumption

- *Renal O₂ consumption* (approximately 6 ml/100 g tissue/min) is very high being only second to the heart (i.e. 8 ml/100 g tissue/min) in the body.

- *Arteriovenous O₂ difference* (approximately 1.5 ml/dL) of blood is smallest of the major organ system ([Table 6.1-2](#)).
- *Oxygen consumption (VO₂)* in kidneys is directly proportional to the renal blood flow, and arteriovenous O₂ difference does not change in spite of massive alteration in blood flow. This is a unique feature of kidneys, because in most body organs, the (A-V) O₂ difference is inversely proportional to their blood flow. Thus, unlike other organs, where the blood flow is related to O₂ requirements of the organ, in the kidneys, the O₂ consumption is a function of blood flow.
- *Renal oxygen consumption correlates* best with the active reabsorption of Na⁺, but a significant fraction is also required for H⁺ secretion via the H⁺-ATPase pumps.
- Some basic differences in the determinants of blood flow in the kidney vis-à-vis other organs, notably the muscular vascular bed, are summarized in [Table 6.1-3](#).

TABLE 6.1-2

Arteriovenous O₂ Difference in Major Organ Systems of the Body

Organ	Arterial O ₂ content (ml%)	Venous O ₂ content (ml%)	A-V O ₂ difference (ml%)
Kidneys	19	17.5	1.5
Heart	19	8	11
Brain	19	12	07
Whole body	19	14	05

TABLE 6.1-3

Basic Differences in the Determinants of Renal Blood Flow vis-à-vis Muscular Blood Flow

Muscle blood flow (MBF)	Renal blood flow (RBF)
MBF increases or decreases to maintain a constant O ₂ . MBF changes according to O ₂ demands	RBF is regulated to maintain a constant GFR. O ₂ consumption changes with GFR, which in turn changes with RBF
When O ₂ consumption increases, the blood flow increases in excess of the requirement. Hence, the	O ₂ consumption parallels the change in RBF;

(A-V) O₂ difference falls

hence, (A-V) O₂ difference remains constant despite marked changes in RBF

Intrarenal distribution of renal blood flow

Of the total renal blood flow, approximately 90% perfuses the cortex, while only 10% perfuses the medulla (9% outer medulla and 1% inner medulla). As the main function of the renal cortex is filtration, therefore renal cortical blood flow is relatively greater. Low blood flow to the medulla is due to relatively high vascular resistance in vasa recta because of the following three reasons:

- *Long length* (40 mm) of vasa recta (vascular resistance is proportional to the length of the vessel),
- *Increased viscosity of blood* near the hair pin bend of loop of Henle (resistance is proportional to the viscosity of blood). Sudden increase in the viscosity of blood in the region of inner medulla occurs due to loss of large amounts of water, as the osmotic pressure of interstitium in this region is very high (2000 mOsm/L) and
- *Low hydrostatic pressure head*, because the diameter of efferent arterioles arising from the juxtamedullary nephrons is small.

Physiological significance of low perfusion of medulla. Low medullary blood flow plays an important role in the urinary concentration mechanism (page 518).

Hydrostatic pressure in renal vessels and their physiological significance

- ***Glomerular capillaries*** have relatively high hydrostatic pressure (45 mmHg), which is an important factor in the formation of glomerular filtrate.
- ***Peritubular capillaries*** have very low hydrostatic pressure (8 mmHg only) due to drop in the pressure in efferent arterioles. This low hydrostatic pressure in peritubular capillaries facilitates the reabsorptive function of the proximal and distal *convoluted* tubules.
- Renal veins have hydrostatic pressure of only 4 mmHg.

Renal portal circulation.

It has been mentioned above that the afferent arterioles arise from the interlobular arteries and each breaks up into a bunch of capillaries, called the glomerulus. The glomerular capillaries drain into efferent arterioles which again break up into peritubular capillary network which ultimately drains into an interlobular vein.

Vein. In this way, two sets of capillaries are formed and thus renal circulation becomes a sort of portal circulation.

Regulation of renal blood flow

The regulatory mechanisms affect the renal blood flow (RBF) and glomerular filtration rate (GFR) by changing the arteriolar resistance. Therefore, before discussing the various regulatory mechanisms, it will be worthwhile to understand the *relationship between selective changes in the resistance of afferent and/or efferent arterioles and RBF and GFR* (Fig. 6.1-8):

- Constriction of afferent arteriole decreases both RBF and GFR, without change in filtration fraction (FF) (Fig. 6.1-8A).
- Dilatation of the afferent arteriole increases both RBF and GFR, without change in FF (Fig. 6.1-8B).
- *Constriction of the efferent arteriole* decreases the RBF and increases GFR, and FF (Fig. 6.1-8C).
- *Dilatation of the efferent arteriole* increases the RBF and decreases the GFR, and FF (Fig. 6.1-8D).

Regulatory mechanisms of renal blood flow include:

- Autoregulation,
- Hormonal regulation and
- Nervous regulation.

FIGURE 6.1-8 Relationship between selective changes in arteriolar resistance and of either afferent or efferent arteriole and renal blood flow (RBF) and glomerular filtration rate (GFR). P_{GC} : hydrostatic pressure in glomerular capillaries.

Autoregulation of renal blood flow

Renal blood flow (RBF) and thus the glomerular filtration rate (GFR) remain constant over a wide range of renal arterial pressures (80–200 mmHg) (Fig. 6.1-9). This occurs due to an intrarenal mechanism known as autoregulation (also see page 315). Autoregulation of RBF is accomplished by changing renal vascular resistance. When arterial pressure changes (between 80–200 mmHg), a proportionate change occurs in the renal vascular resistance which maintains a constant RBF.

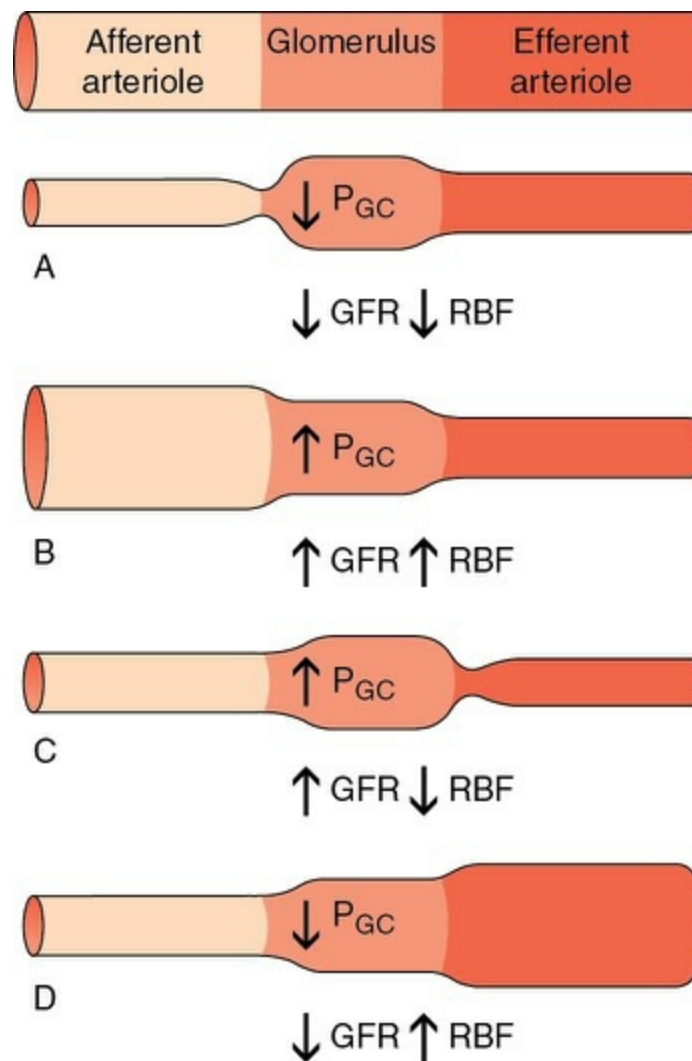

FIGURE 6.1-9 Autoregulation maintains renal blood flow (RBF) and glomerular filtration rate (GFR) constant over a wide range of arterial pressure (80–200 mmHg).

Mechanisms of autoregulation.

Autoregulation has been observed to persist after renal denervation, in the isolated perfused kidney, in the transplanted kidney, after adrenal demedullation, and even the absence of erythrocytes; thus ruling out the role of all these factors.

Two mechanisms are considered responsible for autoregulation of RBF and GFR: one mechanism that responds to changes in arterial pressure, and another that responds to changes in NaCl concentration of tubular fluid.

1. **Myogenic mechanism.** It is related to an intrinsic property of vascular smooth muscle: the tendency to contract when it is stretched. Thus, when renal arterial pressure is raised, the afferent arterioles are stretched,

which contract and increase the vascular resistance. The increased vascular resistance offsets the effect of increased arterial pressure and thereby maintains a constant RBF and GFR (Fig. 6.1-9).

2. *Tubuloglomerular feedback mechanism.* Tubuloglomerular feedback (TGF) mechanism is based on the NaCl concentration of tubular fluid. It involves a feedback loop which operates as (Fig. 6.1-10):

- Changes in the GFR cause changes in NaCl concentration of fluid in the loop of Henle.
- Changes in the NaCl concentration are sensed by the macula densa cells and converted into a signal.
- The signal from the macula densa cells changes the vascular resistance in afferent arterioles.
- Signals obtained due to increased concentration of NaCl produce vasoconstriction; conversely signals obtained due to decreased NaCl cause vasodilatation of afferent arterioles.
- The effector mechanism responsible for vasoconstriction and vasodilatation is not exactly known. Perhaps, adenosine triphosphate (ATP), which selectively constricts the afferent arterioles and metabolites of arachidonic acid, may contribute to TGF mechanism.

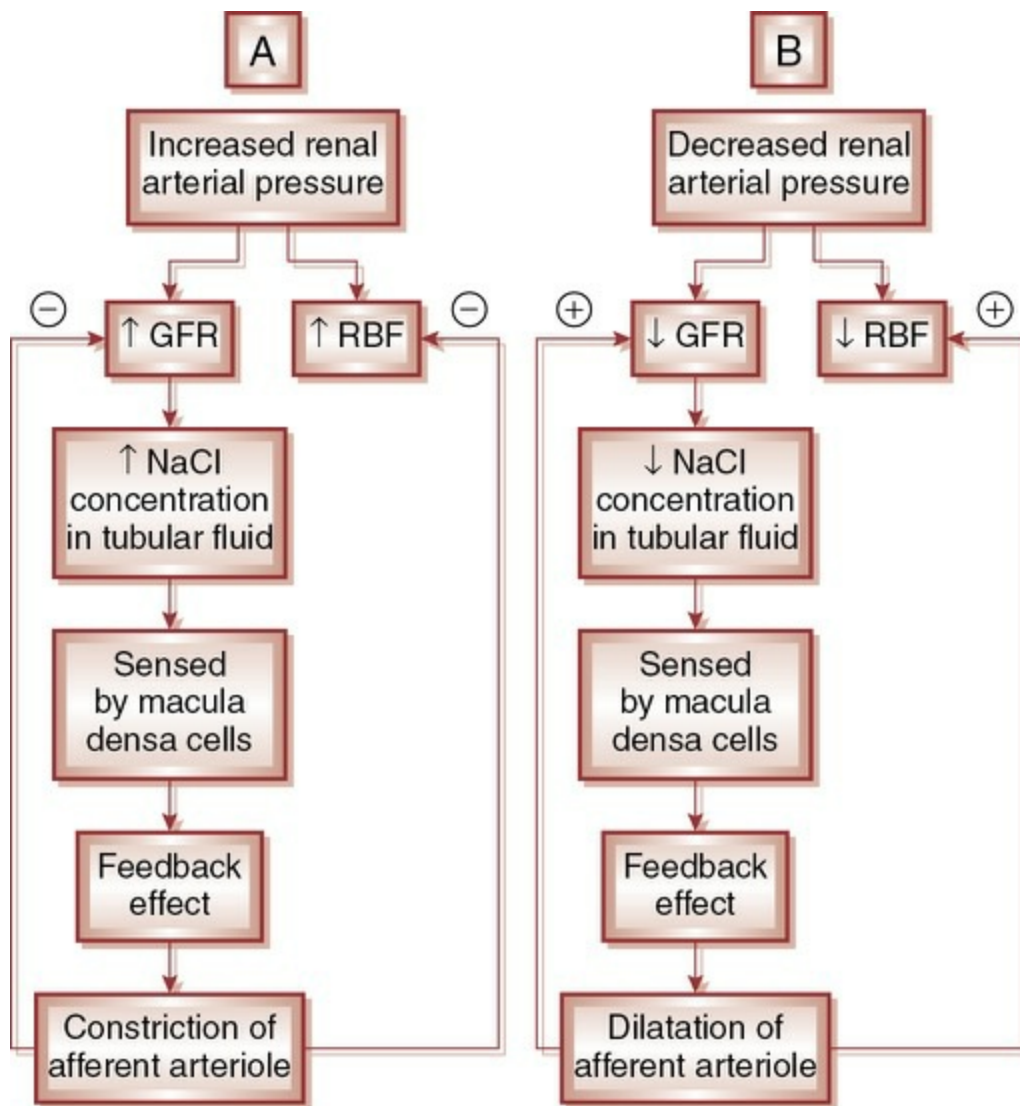

FIGURE 6.1-10 Tubuloglomerular feedback mechanism which maintains a constant RBF and GFR when renal arterial pressure increases (A) or decreases (B).

Physiological significance and certain important facts about autoregulation

Physiological significance. A small change in GFR has great effect on urinary output and therefore on loss of solutes and water. If RBF and GFR were to change suddenly in proportion to change in blood pressure, urinary excretion of fluid and solute would also change suddenly. Such changes in water and solute excretion, without comparable alterations in intake, would prove disastrous due to alterations in fluid and electrolyte balance. Thus, autoregulation of RBF and GFR is an effective mechanism for uncoupling renal function from fluctuations in arterial pressure and maintain fluid and electrolyte balance.

Certain important facts about autoregulations to be noted are:

- Autoregulation of RBF and GFR is virtually absent at the mean arterial blood pressure below 80 mmHg,
- Autoregulation is not a perfect mechanism, i.e. RBF and GFR do change slightly with variation in arterial blood pressure and
- Several hormones and other factors can change RBF and GFR, despite autoregulation mechanisms.

Hormonal regulation

As mentioned above, despite autoregulation, several hormones and other factors have a major effect on RBF and GFR by affecting afferent and/or efferent arteriolar resistance (Table 6.1-4).

TABLE 6.1-4
Hormones Influencing the RBF and GFRs

Hormone	Stimulus	Effect on GFR	Effect on RBF
Vasoconstrictors			
•Norepinephrine	ECV		
•Angiotensin II	ECV		
•Endothelin	Stretch, ↓ ECV, Angiotension II, bradykinin, epinephrine		
Vasodilators			
•Prostaglandins (PGI ₂ and PGE ₂)	ECV, Stretch, Angiotensin II	NC	
•Nitric oxide (NO)	Stretch, ACh, Histamine, bradykinin, ATP		
•Bradykinin	Prostaglandin, ↓ ACE		
•ANP	ECV		
•Glucocorticoids	Administration in therapeutic dose		
•Dopamine	–	NC	
•Histamine	Inflammation, injury	NC	

ECV: effective circulatory volume; NC: no change; ACE: angiotensin-converting enzyme.

1. Hormones that cause vasoconstriction,
and thereby decrease RBF and GFR include:

- *Norepinephrine* causes an intense vasoconstriction of both afferent and efferent arterioles.
- *Angiotensin II*, in low concentrations, causes a predominant constriction of the efferent arterioles. However, at higher concentrations, it causes constriction of both afferent as well as efferent arterioles.
- *Endothelin* causes profound vasoconstriction of the afferent and efferent arterioles. It is secreted by endothelial cells of renal vessels, mesangial cells and distal tubular cells. Its production is elevated in a number of glomerular diseases.

2. Hormones that cause vasodilatation,

and thereby increase RBF and GFR include:

- *Prostaglandins* (PGE₂ and PGI₂) are produced locally within the kidneys in conditions such as haemorrhage and increase RBF by dampening the vasoconstrictor effects of sympathetic nerves and angiotensin II.
- *Nitric oxide (NO)* causes vasodilatation of both afferent and efferent arterioles. In addition, it also decreases total peripheral resistance.
- *Bradykinin* is a vasodilator that acts by stimulating the release of NO and prostaglandins.
- *Atrial natriuretic peptide (ANP)*. Its secretion by the heart rises with hypertension and expansion of extracellular fluid volume. It causes vasodilatation of the afferent arterioles and vasoconstriction of efferent arterioles. The net effect of ANP is therefore to produce a modest increase in GFR with little change in RBF.
- *Glucocorticoids*, when administered in therapeutic doses, increase RBF and GFR.
- *Dopamine*. The proximal tubule produces the vasodilator hormone dopamine which increases RBF and inhibits renin secretion.
- Histamine increases RBF without elevating GFR, by decreasing the resistance of afferent and efferent arterioles.

Nervous regulation

The afferent and efferent arterioles are innervated by sympathetic nerve fibres from T₁₀ to L₂ intermediolateral grey segments of spinal cord through the splanchnic nerves. The sympathetic cell bodies are located in the superior mesenteric ganglion.

- *Under normal circulatory conditions*, sympathetic tone is minimum.
- *Mild to moderate stimulation* of sympathetic nerves usually has mild effects on RBF because of autoregulation mechanism.
- *Strong acute stimulation* of sympathetic nerves may produce marked fall in RBF (even to 10–30% of normal) temporarily due to constriction of both afferent and efferent arterioles. This effect is mediated mainly by α_1 -adrenergic receptors and to a lesser extent by postsynaptic α_2 -adrenergic receptors.

Note. This system works to preserve arterial pressure at the expense of maintaining normal RBF in conditions of acute hypotension due to severe haemorrhage. Further, an increase in sympathetic activity also increases the release of epinephrine and angiotensin-II, enhancing vasoconstriction (vide infra).

Measurement of renal blood flow/renal plasma flow

Renal blood flow can be measured by the following methods:

1. With the help of electromagnetic flow meter.
2. *PAH clearance method.* Renal blood flow (RBF) as well as renal plasma flow (RPF) can be measured by this method, see page 553.
3. Renal blood flow can also be measured indirectly from the filtration fractions:

$$FF = \frac{GFR}{RPF}$$

Transposing gives:

$$\text{RPF} = \frac{\text{GFR}}{\text{FF}}$$

Renal blood flow can be calculated by dividing the renal plasma flow by 1 – haematocrit (see page 133).

- Transport across distal tubules and collecting duct
- Renal handling of common solutes and water
- Renal handling of sodium
- Renal handling of potassium and potassium homeostasis
- Renal handling of organic substances
- Renal handling of glucose
- Renal handling of urea
- Renal handling of uric acid
- Summary of effects of renal handling of common solutes and water

Introduction

The main function of the kidneys is to clear waste products from blood and excrete them in the urine. In addition to the metabolic wastes, the kidneys also excrete foreign substances from the body such as drugs, pesticides and other chemicals ingested in food. The kidneys accomplish their excretory function by formation of urine.

Processes concerned with urine formation.

Three processes are involved in urine formation ([Fig. 6.2-1](#)):

- *Glomerular filtration*, i.e. filtration of plasma from the glomerular capillaries into the renal tubules is the first step in the formation of urine.

- *Tubular reabsorption*, i.e. the return of needed solutes and water from the tubules into the blood, is the second step in the process of urine formation. It changes the composition of glomerular filtrate and reduces its volume markedly.
- *Tubular secretion* involves net movement of water and unwanted solutes (that could not be filtered) from the blood into the tubules.

FIGURE 6.2-1 Steps involved in the formation of urine: 1, filtration; 2, reabsorption; 3, secretion; and 4, excretion.

Thus, the excretion of each substance in the urine involves a specific combination of filtration, reabsorption and secretion as expressed by the following relationship: $\text{Urinary excretion} = \text{Filtration} - \text{Reabsorption} + \text{Secretion}$ (Fig. 6.2-1).

Glomerular filtration

Glomerular filtration refers to the process of ultrafiltration of plasma from the glomerular capillaries into the Bowman's capsule. The understanding of the process of glomerular filtration involves a review

of:

- Characteristics of filtration membrane,
- Composition of glomerular filtrate,
- Dynamics of glomerular filtration,
- Glomerular filtration rate,
- Filtration fraction,
- Factors affecting glomerular filtration,
- Regulation of glomerular filtration and
- Measurement of glomerular filtration.

Characteristics of filtration membrane

As described on page 481 (Fig. 6.1-3B), the filtration membrane consists of three layers: capillary endothelium, glomerular basement membrane (GBM) and Bowman's visceral epithelium (podocytes). Glomerular filtration occurs across this membrane.

Characteristic features of the filtration membrane are:

High permeability.

The glomerular membrane is highly permeable to water and 100% dissolved substances because of its porous nature.

Permeability selectivity.

The filtration membrane exhibits a high degree of permeability selectivity based on two factors:

- *Pore size.* The capillary endothelial cells have pores that are 70–90 nm in diameter, the glomerular basement membrane (GBM) has no pores but its permeability corresponds to pore size of 8 nm, and the podocytes form filtration slits which are approximately 25 nm wide. From this it is clear that the glomerular filtration barrier for solutes resides at the level of GBM. The permeability of the membrane to various neutral solutes depending on their effective molecular diameter is (Fig. 6.2-2):

- Molecules less than 4 nm in size are freely filtered.
- Molecules with diameter more than 8 nm are not filtered at all (i.e. zero permeability).
- Filtration of molecules having diameter between 4–8 nm is inversely proportional to their diameter.
- *Electrical charge.* It may however, be realized that permeability of the filtration membrane is not simply related to molecular size but also to its shape and electrical charge. The pores in the filtration membrane are negatively charged due to presence of glycoproteins rich in sialic acid. Thus, with the same molecular size, compared to anionic particles, there is, in order, increasing permeability for neutral and cationic particles (Fig. 6.2-2). This explains why albumin (with a molecular diameter of 7 nm but a negative charge) is not filtered.

FIGURE 6.2-2 Effect of electrical charge and effective molecular diameter on filterability of dextran molecule through glomerular filtration membrane. A value of one indicates that it is filtered freely, whereas a value of zero

indicates that it is not filtered.

Composition of glomerular filtrate

The unique characteristic features of the glomerular filtration membrane determine the composition of glomerular filtrate, in that it is like that of plasma except for the absence of proteins (colloids) and cells. Capillary permeability alterations in disease do not alter rate of filtration of diffusible molecules. Thus, transfer of such substances into glomerular filtrate depends only on GFR. Filtration membrane permeability alteration in diseases, however, may alter diffusibility of colloids and cells. For example, in a number of glomerular diseases, the negative charge on the filtration membrane is reduced because of immunological damage and inflammation. As a result filtration of proteins is increased, and albumin appears in the urine in significant amounts (albuminuria or proteinuria). It is important to note that normally the amount of proteins in the urine is less than 100 mg/dL, and most of this is not filtered but comes from the shed tubular cells.

Dynamics of glomerular filtration

The forces which determine the bulk flow or ultrafiltration of protein free plasma across the glomerular membrane are the same which determine formation of tissue fluid, i.e. fluid exchange across capillaries in the rest of the body. Thus, the driving force for glomerular filtration is the net ultrafiltration pressure across the glomerular capillaries. Filtration is always favoured in the glomerular capillaries because the net ultrafiltration pressure always favours the movement of fluid out of the capillaries.

The glomerular filtration rate (GFR) will depend upon the balance of Starling forces (Fig. 6.2-3). For detailed information about Starling forces see page 318. According to Starling hypothesis, the GFR can be expressed as:

$$\text{GFR} = K_f \left[(P_{GC} - P_{BS}) - (\pi_{GC} - \pi_{BS}) \right]$$

FIGURE 6.2-3 Depiction of Starling forces across the glomerular filtration membrane: P_{GC} : glomerular capillary hydrostatic pressure, P_{BS} : Bowman's space hydrostatic pressure, π_{GC} : glomerular capillary oncotic pressure, π_{BS} : Bowman space oncotic pressure.

where:

GFR is the filtration across the glomerular membrane.

K_f or the filtration coefficient of the glomerular membrane.

- It is the product of glomerular membrane hydraulic permeability and the effective filtration surface area.

- The filtration coefficient (Kf) normally equals 12.5 m²/min/mmHg.

P_{GC} is glomerular capillary hydrostatic pressure

- It tends to force the fluid out through the glomerular membrane.
- It depends upon the arterial blood pressure, and pre- and postglomerular capillary resistance.
- Its normal value is about 45 mmHg.

P_{BS} or Bowman's space hydrostatic pressure

- It is analogous to P_i (hydrostatic interstitial pressure) in systemic circulation.
- It tends to force fluid inwards through the glomerular membrane.
- Its normal value is about 10 mmHg.

π_{GC} or glomerular capillary oncotic pressure

- It results from the osmotic pressure of plasma proteins.
- It tends to pull fluid inward through the glomerular membrane.
- Its normal value is 25 mmHg.

π_{BS} or Bowman's space oncotic pressure

- It is the oncotic pressure of the fluid in Bowman's space.
- Its normal value is zero, because glomerular filtrate contains no proteins.

Effective filtration pressure (EFP) is the net outward force and is calculated as the difference between the outwardly (i.e. P_{GC} and π_{BS}) and inwardly (P_{BS} and π_{GC}) directed forces (Fig. 6.2-3).

Thus, under normal circumstances,

$$\text{GFR} = 125(45 - 10) - (25 - 0) = 125 \text{ ml/min}$$

Normal glomerular filtration rate

As calculated above, the normal glomerular filtration rate (GFR) in an average-sized man is about 125 ml/min (range 90–140 ml/min). Its magnitude correlates fairly well with surface area, but values in women are 10% lower than those in men even after correction for surface area. Thus, in a 24 h period, as much as 180 L/day of plasma is filtered at the glomerulus. In other words, in one day kidneys filter an amount of fluid equal to 4 times the total body water, 15 times the ECF and 60 times the plasma volume. Of the 180 L/day of glomerular filtrate which passes through the remaining part of the nephron, 99% or more is reabsorbed and only 1% or less is excreted as urine.

After age of 30 years, GFR declines with age. However, this decline in GFR usually does not adversely affect the kidney's excretory function, or their ability to maintain fluid, electrolyte and acid–base balance.

Filtration fraction

The filtration fraction (FF) is the ratio of GFR to the renal plasma flow (RPF).

At normal values of GFR 125 ml/min and RPF 650 ml/min; the filtration fraction is approximately 0.2% (125/650). In other words, normally only about 20% of the renal plasma flow is actually filtered per minute.

Glomerular versus systemic filtration

Total filtration

Approximately 180 L of fluid is filtered from the glomerular capillaries; in contrast, only 20 L of fluid is filtered out per day in the rest of the systemic capillaries of the body. These figures demonstrate the massive scale at which glomerular filtration occurs.

Filtration coefficient (Kf).

The considerable greater rate of filtration in glomerular capillaries than systemic capillaries is mainly because the Kf is approximately 100 times higher in glomerular capillaries.

Hydrostatic pressure

within the glomerular capillaries is approximately twice as high in systemic capillaries. It also contributes to greater glomerular filtration.

Total capillary exchange area.

The total glomerular capillary exchange area is estimated to be 1.6 m², of which 2–3% is available for filtration. Thus, the glomerular filtration surface area measures between 500–810 cm². In contrast, the total exchange area of the systemic capillary bed is estimated to be 1000 m², of which only 25% is open at any time at rest. Thus, the systemic filtration area at rest measures about 250 m².

Balance of starling forces.

In the systemic capillary, the oncotic pressure does not vary over the length of capillary, as the filtration of fluid is small. The hydrostatic pressure at the arteriolar end exceeds the oncotic pressure of plasma proteins and favours filtration. However, over the length of the capillary, the hydrostatic pressure gradually declines and the net filtration pressure (NFP) becomes zero near the middle of the capillary. From here, the inward forces become dominant and the reabsorption process starts to reach its maximum at the venular end (Fig. 6.2-4A).

FIGURE 6.2-4 Balance of Starling forces: systemic capillary (A) versus glomerular capillary (B).

In the glomerular capillary,

the hydrostatic pressure does not decline over the length, because of the efferent arteriolar resistance. But, because of massive filtration of fluid, the oncotic pressure in the glomerular capillary increases over the length and becomes equal to hydrostatic pressure at the efferent end. Thus, there is no filtration of fluid in distal 25% of glomerular capillary (Fig. 6.2-4B).

However, if the rate of renal blood flow is increased, the equilibrium between the hydrostatic pressure (P_{GC}) and oncotic pressure (π_{GC}) would be reached more slowly, i.e. filtration would continue over a larger length of the glomerular capillary. From this it can be concluded, that besides Starling forces, the rate of renal blood flow is also an important factor determining the GFR.

Factors affecting glomerular filtration rate

1. Filtration coefficient (Kf).

Increased Kf raises GFR and decreased Kf reduces GFR. As mentioned earlier, Kf is the product of permeability and filtration area of the glomerular capillary membrane.

i. *Permeability of the glomerular capillaries is increased* in abnormal conditions like hypoxia and presence of toxic agents. In such conditions GFR is increased, because plasma proteins are also filtered to a variable degree. This causes increase in colloid osmotic pressure of Bowman's space fluid (normally this is zero because proteins are not filtered), which in turn increases GFR.

- *Decreased capillary permeability* occurs due to thickening of capillary membrane in some diseases leading to decreased GFR.

ii. *Alteration in GFR filtration area of glomerular capillaries* can alter the Kf. *Mesangial cells* contraction or relaxation is associated with alteration in coefficient of filtration.

- *Contraction of mesangial cells* leading to decreased Kf is

caused by vasoconstrictors like angiotensin II, endothelin, norepinephrine, thromboxane A_2 , leukotrienes C_4 and D_4 and histamine.

Relaxation of mesangial cells leading to increased Kf is caused by vasodilators like dopamine, cAMP, ANP, nitric oxide (NO) and prostaglandins (PGE).

2. Hydrostatic pressure in bowman's space fluid (P_{BS})

opposes filtration, and therefore GFR is inversely related to it. It is increased in acute obstruction of urinary tract (e.g. a ureteric obstruction by stone).

3. Glomerular capillary hydrostatic pressure (P_{GC}).

GFR is directly related to P_{GC} . Changes in P_{GC} serve as a primary means for physiological regulation of GFR. P_{GC} is mainly dependent on arterial pressure, renal blood flow, afferent arteriolar resistance and efferent arteriolar resistance.

i. *Arterial pressure.* GFR is autoregulated between arterial pressure of 80–200 mmHg. Increased arterial pressure above 200 mmHg may raise GFR and decreased arterial pressure below 70 mmHg may lower GFR.

ii. *Renal blood flow.* GFR is directly proportional to the renal blood flow (as described above page 484). However, renal blood flow is controlled by autoregulatory mechanisms.

iii. *Afferent and efferent arteriolar resistance.* Relation of afferent and efferent arteriolar resistance with GFR is described on page 486).

Note. In *acute renal failure*, GFR declines because of fall in P_{GC} .

4. Glomerular capillary oncotic pressure (π_{GC}).

GFR is inversely proportional to π_{GC} . In hyperproteinaemia and in haemoconcentration ratio, the π_{GC} is raised leading to decrease in GFR. Conversely, in hypoproteinaemia and haemodilution the π_{GC} is reduced leading to increased GFR.

5. Sympathetic stimulation.

See page 488.

Regulation of GFR

Regulation of GFR, like that of renal blood flow includes:

- Autoregulation,
- Nervous regulation and
- Hormonal regulation.

For details see page 486.

Measurement of glomerular filtration

Glomerular filtration rate can be measured by renal clearance of inulin, urea and creatinine. For details see page 551.

Tubular reabsorption and secretion

Of the 180 L glomerular filtrate formed per day, about 1.5 L (i.e. <1%) per day is excreted as urine. The different segments of the renal tubule viz. proximal tubule, loop of Henle, distal tubule and collecting duct determine the composition and volume of the urine by process of *selective reabsorption* of solutes and water and *selective secretion* of solutes. Consequently, the tubules precisely control the volume, osmolality, composition and pH of intracellular and extracellular fluid compartments. For conceptual understanding, this section on renal tubular reabsorption and secretion can be considered in the following subsections:

- *General Principles of Renal Tubular Transport*
- Transport mechanisms across cell membranes,
- Transepithelial transport pathways,
- Tubular mechanisms and patterns of renal handling of a substance and concept of renal clearance and

- Parameters of renal active transport.
- *Transport across different segments of renal tubule*
- Transport across proximal tubule,
- Transport across Henle's loop,
- Transport across distal tubule and
- Transport across collecting duct.
- *Tubular transport of common solutes and water*
- Tubular transport of Na^+ ,
- Tubular transport of Cl^- ,
- Tubular transport of K^+ ,
- Tubular transport of glucose and
- Tubular transport of water.

General principles of renal tubular transport

Transport mechanisms across cell membrane

The water moves across the cell membrane of renal tubular cells passively, while the solute movement occurs by both passive and active mechanisms.

- *Passive transport* does not need energy and occurs spontaneously, down an electrochemical gradient by the following mechanisms:
- Diffusion,

- Facilitated diffusion (channels, uniport, coupled transport, uniport or symport) and
- Solvent drag.
- *Active transport* requires direct input of energy and is abolished if cell metabolism is inhibited. Active transport can occur against an electrochemical gradient, but it does not mean that it only occurs against such gradients in the body. Most of the active transports are carrier mediated. Endocytosis is also a type of active transport and it will prove prudent to revise the various transport mechanisms described in [Chapter 1.3](#) page 26, before proceeding further.

Transepithelial transport pathways

In the renal tubule, a substance can be reabsorbed or secreted by two pathways:

- *Paracellular pathway* refers to transport between the cells ([Fig. 6.2-5A](#)). Examples of paracellular pathway include:
 - Reabsorption of Ca^{2+} and K^{+} across the proximal tubule,
 - Some of the water reabsorbed across the proximal tubule crosses the paracellular pathway and
 - Some solutes dissolved in this water (in particular Ca^{2+} , and K^{+}) are carried along with the reabsorbed fluid across the paracellular pathway by the process of solvent drag.
- *Transcellular pathway* refers to transport through the cells. Its example includes transcellular Na^{+} reabsorption by the proximal tubule, which is a two-step process ([Fig. 6.2-5B](#)):
 - *Movement of Na^{+} into the cell* across the apical membrane occurs down an electrochemical gradient established by $\text{Na}^{+}\text{-K}^{+}\text{-ATPase}$.

- *Movement of Na^+ into the ECF across the basolateral membrane occurs against an electrochemical gradient via $\text{Na}^+\text{-K}^+\text{-ATPase}$.*

FIGURE 6.2-5 Pathways of transepithelial transport: **A**, paracellular pathway; and **B**, transcellular pathway.

Tubular mechanisms, patterns of renal handling of substances and concept of renal clearance

Tubular mechanisms.

As mentioned earlier, the two main tubular mechanisms involved in renal handling of a substance are tubular reabsorption and tubular

secretion.

- **Tubular reabsorption** denotes the active transport of solutes and passive movement of water from the tubular lumen into peritubular capillaries. In other words, reabsorption is the removal of substances of nutritive value such as glucose, amino acids, electrolytes (Na^+ , K^+ , Cl^- , HCO_3^-) and vitamins from the glomerular filtrate. Small proteins and peptide hormones are reabsorbed in the proximal tubules by endocytosis.
- **Tubular secretion** refers to the transport of solutes from the peritubular capillaries into the tubular lumen, i.e. it is the addition of a substance to the glomerular filtrate.

Active secretion of substances occurs into the tubular fluid with the help of certain nonselective carriers. The carrier which secretes para-aminohippuric (PAH) acid can also secrete uric acid, bile acids, oxalic acid, penicillin, probenecid, cephalothin and furosemide. It is because of the common carrier that probenecid can block secretion of penicillin and maintain its plasma concentration for a longer time. For bases there is another carrier, which is also nonselectively involved in secretion of substances like acetylcholine, creatinine, dopamine, histamine, 5HT, thiamine, quinine, procaine, morphine and other bases.

Important Notes

The ensuing discussion includes the list and mechanism of the substances reabsorbed and/or secreted in different segments of renal tubule (page 496).

- Only two natural constituents of plasma (K^+ and H^+) are secreted by the distal tubules.
- Proximal tubular cells may secrete uric acid, and many drugs.
- Uric acid is the only organic substance that can be both reabsorbed and secreted.
- K^+ is the only inorganic substance which can be both reabsorbed and secreted.

Patterns of renal handling of a substance and concept of renal clearance.

Different patterns of renal handling of a substance include:

1. **Glomerular filtration only**, i.e. the substances are freely filtered, but neither reabsorbed nor secreted (e.g. inulin) (Fig. 6.2-6A). Such substances are called glomerular markers and are said to have renal clearance equal to GFR.
2. **Glomerular filtration followed by partial reabsorption** (Fig. 6.2-6B). Such substances have renal clearance less than GFR.
3. **Glomerular filtration followed by complete tubular reabsorption** (Fig. 6.2-6C). Such substances have lowest renal clearance, e.g. Na^+ , glucose, amino acids, HCO_3^- and Cl^- . The substances that are not filtered at all (e.g. protein), also have the lowest renal clearance.
4. **Glomerular filtration followed by tubular secretion** (Fig. 6.2-6D). Such substances that are both filtered across the glomerular capillaries and secreted from the peritubular capillaries into urine have the highest renal clearances (e.g. PAH).
5. **Glomerular filtration followed by partial reabsorption and secretion** (Fig. 6.2-6E). In such circumstances, depending upon which of the two process is dominant, there may be net reabsorption or net secretion of the substance. Net absorption is said to occur if the amount of substance excreted in urine is less than GFR in the same time. Similarly, net secretion is said to occur when the amount excreted is more than GFR in the same time.
6. **No glomerular filtration, no absorption, only secretion** (Fig. 6.2-6F). Many organic compounds are bound to plasma proteins and are therefore unavailable for ultrafiltration. Secretion is thus their major route of excretion in urine.

FIGURE 6.2-6 Different patterns of tubular handling of substances (for details see text).

Renal clearance.

From the above, the renal clearance can be defined as the volume of plasma that is cleared of a substance in 1 min by excretion of the substance in the urine. Further, from the above description and examples, the relative clearances of the common substances are:

$$\text{PAH} > \text{K}^+ (\text{high K}^+ \text{ diet}) > \text{inulin} > \text{urea} > \text{Na}^+ > \text{glucose, amino acids and HCO}_3^-.$$

Quantification of renal tubular transport

The parameters used for quantitative analysis of renal tubular transport are denoted by the capital letters with dots above them and include:

- Filtered load (F°),
- Excretion rate (E°),
- Reabsorption rate (R°),
- Secretion rate (S°),
- Renal tubular transport maximum (T_m) and
- Tubular fluid (TF) concentration and plasma concentration (P) ratio.

Filtered load.

It is the amount of a substance entering the renal tubule by glomerular filtration per unit time.

- Filtered load (F^o) is calculated by multiplying the glomerular filtration rate (GFR) with plasma concentration of the substance (P_x), i.e. $F^o = \text{GFR} \times P_x$ mg/min. As described on page 551, the GFR is equal to the clearance of inulin (C_{in}), therefore, $F^o = C_{in} \times P_x$.

Excretion rate.

It is the amount of substance that appears in the urine per unit time. The excretion rate (E^o) can be calculated by multiplying urine flow rate (V) and the urinary concentration of the substance (U_x).

$$\text{That is, } E^o = V \times U_x \text{ mg/min.}$$

Reabsorption rate (R^o).

Reabsorption of a substance is said to occur when the filtered load exceeds the excretion rate. The reabsorption rate of a substance is calculated by subtracting excretion rate from the filtered load, that is:

$$R^o = F^o - E^o$$

Secretion rate (S^o).

The net secretion of a substance is said to occur when the excretion rate is more than the filtered load. Under such circumstances, the secretion rate is calculated by subtracting filtered load from the excretion rate, that is:

$$S^o = E^o - F^o$$

Renal tubular transport maximum (T_m).

Renal tubular transport maximum T_m refers to the maximal amount of a solute that can be actively transported (reabsorbed or secreted) per minute by the renal tubules. In other words, the point at which carriers are saturated is the T_m . Therefore, it is important to note that T_m pertains

to solutes that are actively transported only and the substances that are passively transported (e.g. urea) do not exhibit T_m .

Maximum tubular secretory capacity (T_s) is the highest attainable rate of secretion. All substances secreted by the kidney do not have T_m .

- Secreted substances that have T_m include para-aminohippuric acid (PAH), penicillin, certain diuretics, salicylate and thiamine (vitamin B₁).
- Secreted substances that do not have T_m are secretion of K⁺ by the distal tubules.

Maximal tubular reabsorptive capacity (T_r) is the highest attainable rate of reabsorption. All substances reabsorbed by an active carrier-mediated mechanism do not have T_m .

- Substances that have T_m are phosphate ion, sulphate, glucose, many amino acids, uric acid and albumin, acetoacetate, β -hydroxybutyrate and α -ketoglutarate.
- Substances that do not have T_m include reabsorption of Na⁺ along the nephron and HCO₃⁻.

Threshold concentration is defined as the plasma concentration at which a substance first appears in the urine.

Tubular fluid concentration (TF)/plasma concentration (P_x) ratio

The TF/ P_x ratio compares the concentration of a substance in tubular fluid at any point along the nephron with its concentration in plasma. The tubular fluid, for such studies, is collected by micropuncture technique. A micropipette is inserted into the Bowman's space and different portions of the tubules of the living kidney in experimental animals and the composition of aspirated tubular fluid is determined by the use of microchemical techniques.

Significance of TF/ P_x ratio.

The TF/ P_x ratio may be 1, <1 or >1.

- **TF/ P_x ratio of 1.0** signifies that either there has been no reabsorption,

or reabsorption of the substance has been exactly proportional to the reabsorption of water.

For example, a TF/P_x of 1.0, indicates that concentration of Na^+ in tubular fluid and plasma is identical. For any freely filterable substance, TF/P_x ratio is 1.0 in Bowman's space (before any reabsorption or secretion has taken place to modify the tubular fluid).

- **TF/P_x ratio of <1.0** signifies that reabsorption of a substance has been greater than the reabsorption of water and its concentration in tubular fluid is less than that of plasma.

For example, a TF/P_{Na^+} of 0.8 indicates that the concentration of Na^+ in tubular fluid is 80% of Na^+ concentration in plasma.

- **TF/P_x ratio of >1.0** signifies that either the reabsorption of a substance has been less than the reabsorption of water or there has been secretion of the substance.

Tubular fluid concentration (TF)/plasma concentration of inulin (p_{inulin})

The substance inulin is freely filtered by glomerular capillaries but is neither reabsorbed nor secreted into the tubules. Thus, its concentration in tubular fluid is determined solely by how much water remains in the tubular fluid. So, TF/P inulin is used as a marker for water reabsorption along the nephron. Its value increases as water is reabsorbed. From the value of TF/P inulin, the *fraction of the filtered water that has been reabsorbed* can be calculated by following equation:

- Fraction of filtered H_2O reabsorbed = $1/TF/P_{inulin}$
- When TF/P_{inulin} is 2, then FF of H_2O reabsorbed is $1 - 1/2 = 0.5 = 50\%$
- Similarly, when TF/P_{inulin} is 3, then FF of H_2O reabsorbed is $1 - 1/3 = 0.67 = 67\%$.

$[TF/P_x]/[TF/P_{inulin}]$ ratio

The double ratio corrects the TF/P_x ratio for water reabsorption and gives the fraction of the filtered load remaining at any point along the nephron.

For example, a $[TF/P_K]/[TF/P_{\text{inulin}}]$ ratio of 0.3 at the end of proximal tubule indicates that 30% of filtered K^+ remains in the tubular fluid and 70% has been reabsorbed into the blood.

Transport across different segments of renal tubule

The substances transported across the different segments of renal tubules are described below and enlisted in [Table 6.2-1](#).

TABLE 6.2-1

Transport of Substances across Different Segments of Renal Tubule

Reabsorption		Nonreabsorption	Secretion
<i>Active</i>		<i>Passive</i>	
Proximal tubule			
Na^+	Cl^-	Inulin	H^+
K^+	HCO_3^-	Creatinine	Water
Ca^{2+}	HPO_4^-	Sucrose	Penicillin
Mg^{2+}	Water	Mannitol	Sulphonamide
HPO_4^{2-}	Urea		Creatinine
SO_4^{2-}			
NO_3^-			
Glucose			
Amino acids			
Protein			
Urate			
Vitamins			
Acetoacetate			
β -hydroxybutyrate			
Henle's loop			
Na^+	Cl^-		
K^+	HCO_3^-		
Ca^{2+}	Water		
Distal tubule and collecting duct			
Na^+	Cl^-		K^+
Ca^{2+}	HCO_3^-		H^+
Mg^{2+}	Water		
Water			

Transport across proximal tubule

The proximal tubule reabsorbs:

- Approximately 67% of the filtered water, Na^+ , Cl^- , K^+ and other solutes and
- Almost all the glucose and amino acids filtered by the glomerulus.

The proximal tubule does not reabsorb inulin, creatinine sucrose and mannitol.

The proximal tubule secretes H^+ , PAH, urate, penicillin, sulphonamides and creatinine.

Reabsorption

Characteristics of proximal tubule cells.

As shown in [Fig. 6.1-3](#), the proximal tubular cells are characterized by the presence of brush border on their luminal surfaces. The brush is composed of thousands of villi which increase the absorptive surface area of each cell 20-fold. The substances absorbed are transferred to the peritubular capillaries from the basolateral membrane of the cells.

Key element in the proximal tubular reabsorption is $\text{Na}^+-\text{K}^+-\text{ATPase}$ in the basolateral membrane. The reabsorption of every substance including water is linked in some way to the operation of $\text{Na}^+-\text{K}^+-\text{ATPase}$.

Sodium reabsorption

The process of sodium reabsorption in proximal tubule is isosmotic, i.e. the reabsorption of sodium and water are exactly proportional.

Therefore, both $\text{TF}/P_{\text{Na}^+}$ and TF/P_{osm} are 1.0.

Mechanisms of Na^+ reabsorption.

Mechanism of Na^+ reabsorption in the early proximal tubule and late proximal tubule is different.

In early proximal tubule, Na^+ is reabsorbed by *cotransport with H^+ or organic solutes (glucose, amino acids, phosphate and lactate)*. The Na^+ absorption is a two-step process ([Fig. 6.2-7](#)):

- *Across the basolateral membrane*, Na^+ moves against an electrochemical gradient via $\text{Na}^+-\text{K}^+-\text{ATPase}$ pump, which pumps Na^+ into the paracellular spaces and lowers the intracellular Na^+ concentration.

- *Across the apical membrane*, the sodium moves down an electrochemical gradient as above. The entry of Na^+ is mediated by specific antiporter and symporter proteins, and not by diffusion through channels:
- $\text{Na}^+ - \text{H}^+$ -*antiporter* is the main determinant of Na^+ and H_2O reabsorption in the proximal tubule. $\text{Na}^+ - \text{H}^+$ exchange is linked directly to the reabsorption of HCO_3^- .

Note: Carbonic anhydrase inhibitors (e.g. acetazolamide) are diuretics that act in the early proximal tubule by inhibiting the reabsorption of filtered HCO_3^- .

- Na^+ -*glucose (and other organic solutes) symporter* mechanisms are also involved in the entry of Na^+ in the proximal cells. The glucose, amino acids, phosphate and lactate are almost completely absorbed along with Na^+ (Fig. 6.2-8) by the symporter (carrier) proteins which are different for different molecules. The carrier for glucose in proximal tubule is called sodium-dependent-glucose transporter-I (SGLT-1). The glucose and other organic solutes that enter the cell with Na^+ leave the cell across the basolateral membrane by passive transport mechanism.

Note. The reabsorption of $\text{Na}^+ - \text{HCO}_3^-$ and Na^+ - organic solutes across the proximal tubule establishes a transtubular osmotic gradient that provides the driving force for the passive absorption of water by osmosis. Because more water than Cl^- is reabsorbed in the early segment of proximal tubule, the Cl^- concentration in tubular fluid rises along the length of the early proximal tubule (Fig. 6.2-8).

FIGURE 6.2-7 Mechanism of reabsorption of sodium and other solutes across early proximal tubule.

FIGURE 6.2-8 Concentration of solutes in tubular fluid as a function of length along the proximal tubule. TF is the concentration of substance in the tubular fluid, and P_x is the concentration of substance in the plasma. Values above 100 indicate that relatively less of substance than water was absorbed; and values below 100 indicate that relatively more of substance than water was reabsorbed.

In the late proximal tubule the Na^+ is reabsorbed primarily by *chloride-driven sodium transport mechanism* across both the transcellular and paracellular pathways.

- *Reabsorption via paracellular pathway.* The filtered glucose, amino acids and HCO_3^- have already been almost completely removed from the tubular fluid by reabsorption in the early proximal tubule. So the fluid entering the late proximal tubule contains very little of these substances but contains a high concentration of Cl^- (140 mEq/L) compared with that in the early proximal tubule (105 mEq/L). This high Cl^- (140 mEq/L) concentration in the lumen of late proximal

tubule and comparatively low concentration (105 mEq/L) in the interstitium creates a concentration gradient which favours the diffusion of Cl^- from the tubular lumen across the tight junctions into lateral intercellular space. Movement of negatively charged Cl^- causes the tubular fluid to become positively charged relative to the blood. This causes the diffusion of Na^+ across the tight junctions into the blood.

- *Transcellular Na^+ reabsorption* across the luminal membrane of late proximal tubule cells occurs due to parallel operation of Na^+-H^+ and one or more Cl^- anion (formate) antiporters (Fig. 6.2-9).
- *Across the basolateral membrane*, the Na^+ leaves the cell by the action of $\text{Na}^+-\text{K}^+-\text{ATPase}$ pump, and Cl^- leaves by K^+-Cl^- cotransporter (Fig. 6.2-9).

FIGURE 6.2-9 Mechanism of reabsorption of sodium and other solutes across late proximal tubule (for understanding see text).

Water reabsorption

Approximately 67% of the filtered water is absorbed in the proximal tubule by osmosis in response to a transtubular osmotic gradient established by the solute reabsorption (i.e. $\text{Na}^+\text{-Cl}^-$, $\text{Na}^+\text{-glucose}$ and so forth).

- Two-thirds of H_2O reabsorption occurs through the transcellular pathway and one-third through the tight junction's paracellular pathway (Fig. 6.2-10).
- The osmotic water flowing across the proximal tubule also causes some reabsorption of K^+ and Ca^{2+} by the process of *solvent drag*.
- The osmotic water absorption is termed as *obligatory water absorption* as it cannot be changed according to the needs of the body.

FIGURE 6.2-10 Routes of water and solute reabsorption across the proximal tubule (for understanding see text).

Protein reabsorption

Normally, only a small amount of proteins is filtered by the glomerulus (40 mg/L). However, because of high GFR (180 L/day) the total amount of protein filtered per day is significant (180 L/day × 40 mg/L = 7.2 g/day). Normally, the proteins are completely taken into the cells of proximal tubules by the process of endocytosis. Once inside the cells, enzymes digest the proteins and peptides into their constituent amino acids which exit across the basolateral membrane and return to the blood in the peritubular capillaries.

When the amount of filtered proteins increases (due to disruption of glomerular filtration barrier in kidney diseases), the reabsorbing mechanisms saturate and the proteins may appear in the urine (*proteinuria*).

Secretion in proximal tubule.

The cells of proximal tubule, in addition to reabsorbing solutes and water, also secrete organic anions and organic cations, which include some end products of metabolism circulating in plasma, exogenous organic compounds and certain drugs (Table 6.2-2).

TABLE 6.2-2

Some Organic Anions, Cations, Organic Compounds and Drugs Secreted by Proximal Tubule Cells

Anions Secreted by Proximal Tubule	
Endogenous anion	Drugs
PAH	Acetazolamide
cAMP	Furosemide
Bile salts	Penicillin
Oxalate	Probenecid
Prostaglandins	Salicylate (aspirin)
Water	NSAIDs
Cations Secreted by Proximal Tubule	
Endogenous cation	Drugs
Creatinine	Atropine
Dopamine	Cimetidine
Epinephrine	Morphine
Norepinephrine	Quinine
	Procainamide
	Verapamil

Mechanism of secretion of organic anions

can be considered by the example of para-aminohippuric acid (PAH)

secretion. PAH is a foreign substance (a weak organic acid) that is neither stored nor metabolized and is excreted virtually unchanged in the urine. Because 10% of PAH is bound to plasma proteins, so it is cleared from the plasma, both by glomerular filtration and tubular secretion through the kidney. As with glucose, the filtered load of PAH increases in direct proportion to the plasma PAH concentration.

Secretion of PAH occurs from the peritubular capillary blood into tubular fluid via carriers in the proximal tubule by a transport maximum T_m limited process.

- The carrier which secretes PAH is nonselective, i.e. it can transport most of the organic anions listed in [Table 6.2-2](#).
- At low plasma concentration of PAH, the secretion rate increases as the plasma concentration increases. But, once the carriers are saturated, further increase in plasma PAH concentration does not cause further increase in secretion rate T_m ([Fig. 6.2-11](#)).
- The PAH is taken into the cell across the basolateral membrane against its chemical gradient, in exchange for α -ketoglutarate (α KG) via a PAH- α KG *antiport mechanism*. The resultant high intracellular concentration of PAH provides the driving force for PAH exit across the luminal membrane into the tubular fluid via a PAH-anion (A^-) antiporter and possibly a voltage-driven PAH transporter ([Fig. 6.2-11](#)).

FIGURE 6.2-11 Mechanism of secretion of organic anion (e.g. PAH) across the proximal tubule.

Note. PAH clearance can be used to measure renal plasma flow (see page 553).

Mechanism of secretion of organic cations

- *Across the basolateral membrane*, the organic cations enter the cell by facilitated diffusion. This mechanism is driven by the magnitude of the voltage difference (negative potential) across the basolateral membrane.
- *Across the luminal membrane*, the organic cations enter into the tubular fluid by an $OC^+ - H^+$ antiport (Fig. 6.2-12).
- The carrier which secretes organic cation into the tubular fluid is nonselective, i.e. it can transport most of the organic cations listed in Table 6.2-2.

FIGURE 6.2-12 Mechanism of secretion of organic cations (OC^+) across the proximal tubule (for understanding see text).

Transport across loop of henle

About 20% of filtered Na^+ and Cl^- , 15% of filtered water and cations such as K^+ , Ca^{2+} and Mg^{2+} are reabsorbed in the loop of Henle. Reabsorption occurring in different parts of the loop of Henle is:

Thin descending limb of loop of henle.

Water absorption occurs passively (because of hypertonic interstitial fluid) exclusively in this part of loop of Henle. It is accompanied by diffusion of sodium ions from interstitial fluid into tubular lumen.

Thin ascending limb of loop of henle.

Limited passive reabsorption of Na^+ and Cl^- occurs in this water-impermeable limb. Because of impermeability to water, the fluid leaving this limb is hypotonic relative to plasma.

Thick ascending limb of loop of henle.

This limb is impermeable to water but is involved in the reabsorption of 20% of the filtered Na^+ , Cl^- and other cations. About half of the Na^+ is reabsorbed actively and transcellularly, while the other half of the Na^+ is reabsorbed passively by paracellular pathway along with other cations, as described:

- Na^+ , K^+ - 2Cl^- symporter-mediated active transport of sodium. Salient points are (Fig. 6.2-13):
- The key element involved is Na^+ - K^+ -ATPase located in the basolateral membrane which extrudes Na^+ , leading to low intracellular Na^+ concentration.
- Due to low intracellular Na^+ , a chemical gradient is created which favours movement of Na^+ from the lumen into the cell.
- The movement of Na^+ across the apical membrane is mediated by Na^+ - K^+ - 2Cl^- symporter.
- This symporter, with downhill movement of Na^+ and Cl^- , drives the uphill movement of K^+ influx.
- Cl^- delivery is rate-limiting, as NaCl transport increases directly with the tubular fluid Cl^- concentration.
- Na^+ leaves the cell across the basolateral membrane by the action of Na^+ - K^+ -ATPase.
- Cl^- exits into interstitium via Clc-kbcl^- channels. Bartin, (an integral membrane protein) present in the cell membrane that is necessary for normal functioning of Clc-kbcl^- channel.

- Due to the presence of 'tight' tight junctions, Na^+ is unable to leak back into the tubule to produce a luminal potential, however, some of the K^+ which enters the cell leaks back across the apical membrane into the tubular lumen, and into the interstitium by ROMK and other K^+ channels, generating a lumen-positive transepithelial potential difference of +6–+10 mV.

FIGURE 6.2-13 The active (transcellular) and passive (paracellular) transport mechanism operating across the

tubular cells in thick ascending limb (TAL) of loop of Henle.

Note. Thick ascending limb is the site of action of the loop diuretics (e.g. furosemide, ethacrynic acid), which inhibit $\text{Na}^+-\text{K}^+-2\text{Cl}^-$ transporter.

- **Dent disease.** Some of Cl^- absorption in thick ascending loop of Henle occurs with Na^+ , K^+ and Ca^{2+} . In kidneys, a type of Cl^- channel has been identified which is linked with Ca^{2+} . Gene mutation of this channel is associated with Ca^{2+} containing renal stones and hypercalciuria, is known as Dent disease.
- **Na^+-H^+ antiporter-mediated active reabsorption** of sodium also occurs transcellularly leading to H^+ secretion (HCO_3^- reabsorption) (Fig. 6.2-13).
- **Paracellular passive reabsorption of Na^+ , K^+ , Ca^{2+} and Mg^{2+}** is the function of voltage across the thick ascending limb. Because of the unique location of transport proteins in the apical and basolateral membranes, the tubular fluid is positively charged relative to the blood. The increased salt reabsorption by the thick ascending limb increases the magnitude of positive charge in the lumen which plays a major role in driving the passive paracellular reabsorption of cations (Fig. 6.2-13)

Note. Thick ascending limb is *impermeable* to water. Thus, NaCl and other solutes are reabsorbed without water. As a result, tubular fluid Na^+ and tubular fluid osmolarity decreases to less than their concentration in plasma (i.e. $\text{TF}/P_{\text{osm}} < 1.0$). This segment is therefore called the *diluting segment*. Further, Na^+ reabsorbed from this segment is the main driving force behind the countercurrent multiplier system which concentrates Na^+ and urea in medullary interstitium.

Applied Aspects

Bartter's syndrome: Bartter's syndrome is a rare disease that most often presents in neonatal period or early childhood with polyuria, polydipsia, salt craving and growth retardation. Blood pressure remains normal or low. It may result due to mutation affecting any of the ion transport proteins in TAL: $\text{Na}^+-\text{K}^+-2\text{Cl}^-$ symporter, the ROMK K^+ channel, $\text{Clc-}kbcl$ channel or bartin. The TAL transporters function in an integrated manner to maintain electrical potential difference and Na^+ gradient between the tubular lumen and cell.

- Loss of lumen positive electric transport potential, (that normally derives paracellular absorption of Na^+ , Ca^{2+} and Mg^{2+}) causes NaCl wasting, hypercalciuria and hypomagnesium.
- Bartter's syndrome due to mutation of bartin is also associated with deafness, because striavascularis in the inner ear is responsible for maintaining high K^+ concentration in scala media.

Transport across distal tubules and collecting duct

Approximately 7% of the filtered NaCl and about 8–17% of water is reabsorbed and K^+ and H^+ are secreted in these segments.

Early distal tubule (initial segment of distal tubule) reabsorbs Na^+ , Cl^- and Ca^{2+} , and is impermeable to water.

- Na^+-Cl^- symporter mechanism is involved in the transport of Na^+-Cl^- across the apical membrane. Across the basolateral membrane, Na^+ leaves the cell via the action of $\text{Na}^+-\text{K}^+-\text{ATPase}$, and Cl^- leaves the cell by diffusion via channels (Fig. 6.2-14).
- Because of *impermeability to water*, the reabsorption of NaCl in this segment occurs without water leading to dilution of tubular fluid. This is why it is also called cortical diluting segment.
- *Thiazide diuretics* reduce NaCl reabsorption by inhibiting Na^+-Cl^- cotransport.

FIGURE 6.2-14 Mechanism of reabsorption of Na^+ and Cl^- in the early distal tubule. This segment is impermeable to water (see text for details).

Late distal tubule and collecting duct have two cell types (principal cells and intercalated cells) which perform both reabsorption and secretory functions:

Principal cells reabsorb Na^+ , Cl^- and H_2O and secrete K^+ (Fig. 6.2-15):

- *Na^+ reabsorption.* Na^+ is actively transported using $\text{Na}^+-\text{K}^+-\text{ATPase}$ across the basolateral membrane. Across the apical membrane, Na^+ diffuses passively due to chemical gradient.
- *Cl^- reabsorption* occurs passively through paracellular pathway. Cl^- is driven by the lumen negative charge generated by the diffusional influx of sodium.
- *H_2O absorption* occurs in response to the effect of antidiuretic hormone (ADH) on the principal cells. ADH increases H_2O permeability by directing the insertion of H_2O channels in the luminal membrane. In the absence of ADH, the principal cells are virtually impermeable to

water.

- K^+ secretion. K^+ uptake across the basolateral membrane occurs via the action of $Na^+-K^+-ATPase$ followed by diffusion down its electrochemical gradient across the apical cell membrane into the tubular fluid.

FIGURE 6.2-15 Mechanism of transport in principal cells and intercalated cells of the late distal tubule and collecting duct (see text for details). CA = carbonic anhydrase.

Role of aldosterone on principal cell functions. Aldosterone increases Na^+ reabsorption and increases K^+ secretion. Like other steroid hormones, the action of aldosterone takes several hours to develop because new protein synthesis is required. About 2% of overall Na^+ absorption is affected by aldosterone.

Effect of amiloride. Amiloride is a diuretic that inhibits Na^+ reabsorption by distal tubule and collecting duct by directly inhibiting Na^+ channels in the luminal cell membrane. Thus, indirectly, by reducing the negative charge in lumen, the amiloride also inhibits Cl^- reabsorption and K^+ secretion. As the K^+ excretion in urine is decreased, it is called *potassium sparing diuretic*. Other potassium sparing diuretics are spironolactone and triamterene.

Intercalated cells reabsorb K^+ and secrete H^+

- *K^+ reabsorption*, occurs probably by a H^+-K^+ -ATPase located in the apical cell membrane.
- *H^+ secretion* (HCO_3^- reabsorption) or HCO_3^- secretion (H^+ reabsorption) can occur by H^+ -ATPase. This function is important for acid–base balance (see page 523).
- *Aldosterone* increases H^+ secretion by intercalated cells by stimulating the H^+ -ATPase (in addition to its actions on the principal cells).

Renal handling of common solutes and water

After discussing the transport across different segments of renal tubule, it will be worthwhile to discuss briefly the renal handling of common solutes and water, which include:

- Renal handling of sodium and water,
- Renal handling of potassium,
- Renal handling of glucose,
- Renal handling of urea,
- Renal handling of uric acid and
- Renal handling of acid–base balance (see page 523).

Renal handling of sodium and water

Site and mechanisms of reabsorption of sodium.

Percentage reabsorption of the filtered sodium in different segments of the renal tubule is:

- Proximal tubule : 60%
- Loop of Henle (mainly thick ascending limb) : 30%
- Distal tubule : 7%
- Cortical collecting duct : 3%

Mechanisms of reabsorption, as described in detail above in the subsection on transport across different segments of renal tubule are summarized in [Table 6.2-3](#).

TABLE 6.2-3

Summary of Mechanism of Na⁺ Absorption across Different Segments of Renal Tubule

Segment of the tubule	Absorption active/passive/impermeable	Mediated by
Proximal tubule		
• Early proximal tubule	Active	<ul style="list-style-type: none"> • Na⁺-K⁺ antiporter and • Na⁺-H⁺ antiporter • Na⁺-glucose (and other organic solutes) symport
• Late proximal tubule	Active	<ul style="list-style-type: none"> • Cl⁻-driven Na⁺ transport
Loop of Henle		
• Descending thin segment (DTS)	Passively secreted in interstitium	
• Ascending thin segment (ATS)	Passive	
• Thick ascending limb (TAL)	Active (transcellular)	<ul style="list-style-type: none"> • Na⁺-K⁺-2Cl⁻ symporter • Na⁺-H⁺ antiporter
Distal tubule and collecting duct		
• Early distal tubule	Active	<ul style="list-style-type: none"> • Na⁺Cl⁻ symporter
• Late distal tubule and collecting duct (principal cell)	Active	<ul style="list-style-type: none"> • Na⁺ channels (ENa) • Regulated by aldosterone

Sodium recycling. The sodium which is actively pumped out from the thick ascending limb (TAL) into the outer medullary interstitium mostly enters the outer medullary descending thin segment (DTS). This results in recycling of Na⁺ in the long loops of the juxtamedullary nephrons. The recycling causes accumulation of Na⁺ in the interstitium of the renal medulla.

Reabsorption of water

Site and mechanism of reabsorption.

Water is absorbed passively by osmosis in response to a transtubular osmotic gradient. Rapid diffusion of water across the cell membrane occurs through water channels made up of proteins called *Aquaporins*.

Different types of aquaporins are aquaporin-1, 2, 5 and 9. Mostly, these aquaporins are present in the kidney. The other sites include are: leucocytes, liver, lung and lacrimal gland. In the collecting ducts, reabsorption of water is controlled by antidiuretic hormone (ADH). Renal handling of water by different segments of renal tubule is as:

Proximal tubule: Passively reabsorbed (67%).

Loop of Henle

• Descending thin segment (DTS)	: Passively reabsorbed (15%)
• Ascending thin segment (ATS)	: Impermeable
• Thick ascending limb (TAL)	: Impermeable

Distal tubule and collecting duct (8–17%)

• Distal convoluted tubule (DCT)	: Impermeable
• Connecting tubule (CNT)	: Impermeable
• Cortical collecting duct (CCD)	: Reabsorbed (ADH)
• Outer medullary duct collecting (OMCD)	: Reabsorbed (ADH)
• Inner medullary duct collecting (IMCD)	: Reabsorbed (ADH)

Obligatory and facultative reabsorption of water

Obligatory reabsorption.

About 85% of the filtered water is always reabsorbed, irrespective of the body water balance. This reabsorption occurs by osmosis in response to a transtubular osmotic gradient and is called obligatory (must occur) reabsorption.

- About 67% of obligatory reabsorption occurs in the proximal tubules and
- About 15–18% of obligatory reabsorption occurs in the descending thin segment of loop of Henle.

Facultative reabsorption.

The remaining 15–18% of the water may or may not be absorbed depending upon the body water balance. It is called facultative (optional) reabsorption.

Facultative reabsorption of water occurs from the collecting tubule and is under the control of ADH.

Regulation of nacl and water absorption

1. **Hormonal regulation.** Various hormones including angiotensin II, aldosterone, ADH, ANP, urodilatin epinephrine and norepinephrine (released from sympathetic nerves) and dopamine regulate NaCl reabsorption. ADH is the only major hormone that directly regulates the amount of water excreted by kidney. [Table 6.2-4](#) summarizes for each hormone, the major stimulus for secretion, the nephron site of action and the effect on transport.

2. **Role of Starling forces.** Although Na^+ reabsorption is an active process, it is affected by the passive Starling forces operating between the intercellular spaces and the peritubular capillaries in the proximal tubule.

- *Starling forces that favour* the movement of reabsorbed substances into the capillaries are capillary oncotic pressure (π_c) and the hydrostatic pressure in the intercellular spaces (P_i).
- *Opposing Starling forces* are the interstitial oncotic pressure (π_i) and the capillary hydrostatic pressure (P_c).
- Starling forces do not affect transport by the loop of Henle, distal tubule and collecting duct because these segments are less permeable to water than the proximal tubule.
- Starling forces across the peritubular capillaries around the proximal tubule are changed by:
 - Dilatation of efferent arteriole (\uparrow es P_c)
 - Constriction of efferent arteriole (\downarrow es P_c).

3. **Role of glomerulotubular balance in the proximal tubule.**

Glomerulotubular balance (GTB) in the proximal tubule maintains

reabsorption at a constant fraction (2/3 or 67% of the filtered Na⁺ and H₂O). For example, if GFR spontaneously increases, the filtered load of Na⁺ also increases. Without a change in reabsorption, this situation would lead to increased Na⁺ excretion. However, GTB functions such as Na⁺ reabsorption will also increase, ensuring that a constant fraction is reabsorbed.

Mechanism of GTB is based on Starling forces in the peritubular capillaries, which alter the reabsorption of Na⁺ and H₂O in the proximal tubule (Fig. 6.2-16):

- *Route of isosmotic fluid reabsorption* is from the lumen, to the proximal tubule cell, to the lateral intercellular space and then to the peritubular capillary blood.
- *Starling forces in the peritubular capillary blood* govern how much of this isosmotic fluid will be reabsorbed.
- *Fluid reabsorption* is increased by increase in oncotic pressure of the peritubular capillaries blood (π_C) and decreased by decrease in π_C .
- *Increase in GFR and filtration fraction* causes the protein concentration and π_C of peritubular capillary blood to increase. This increase, in turn, produces an increase in fluid reabsorption. Thus, there is matching of filtration and reabsorption, i.e. GTB.

4. *Effects of ECF volume on proximal tubular reabsorption*

- *ECF volume contraction increases reabsorption.* ECF volume contraction increases peritubular capillary protein concentration and oncotic pressure (π_C) and decreases peritubular capillary hydrostatic pressure (P_C).

Together, these changes in Starling forces in peritubular capillary blood cause an increase in proximal tubular reabsorption.

- *ECF volume expansion decreases reabsorption.* ECF volume expansion decreases peritubular capillary protein concentration and oncotic pressure (π_c) and increases peritubular capillary hydrostatic pressure (P_c). Together, these changes in Starling forces in peritubular capillary blood cause a decrease in proximal tubular reabsorption.

FIGURE 6.2-16 Mechanism of glomerulotubular balance (isosmotic reabsorption).

Hormonal Regulation of NaCl and Water Reabsorption

Hormone	Major stimulus for secretion	Nephron (site of action)	Effect on transport
Angiotensin II	Renin	PT	Na ⁺ , Cl ⁻ and H ₂ O reabsorption
Aldosterone	Angiotensin and ↑ [K ⁺] _p	TAL, DT/CD	NaCl and H ₂ O reabsorption
Atrial natriuretic peptide	ECV	CD	NaCl and H ₂ O reabsorption
Urodilatin	ECV	CD	NaCl and H ₂ O reabsorption
Sympathetic nerves	ECV	PT, TAL, DT/CD	NaCl and H ₂ O reabsorption
Dopamine	ECV	PT	NaCl and H ₂ O reabsorption
ADH	Posm	DT/CD	H ₂ O reabsorption

PT, proximal tubule; TAL, thick ascending limb; DT/CD, distal tubule and collecting duct; ECV, effective circulatory volume; [K⁺]_p, plasma K⁺ concentration; and P_{osm}, plasma osmolarity.

Renal handling of potassium and potassium homeostasis

General considerations

Functions of K⁺

Potassium (K⁺) is one of the most abundant cations in the body. It is the *principal intracellular cation*, and is equally important in the extracellular fluid for specific functions. Potassium is required for following biochemical functions:

- Maintenance of intracellular osmotic pressure,
- Optimal activity of enzyme pyruvate kinase (of glycolysis),
- Proper synthesis of DNA and proteins by ribosomes,
- Optimal cell growth,
- Transmission of nerve impulse,
- Generation of cell membrane potential and muscle contraction,
- Extracellular K⁺ influences cardiac muscle activity and

- Regulation of acid–base balance and water balance in the cells.

Daily requirement and sources

- *Daily requirement* of K^+ is about 3–4 g/day.
- *Sources* of K^+ are bananas, oranges, pineapples, potatoes, beans, chicken, liver and tender coconut water.

Potassium homeostasis

Distribution of K^+

- *Total body K^+* constitutes about 50 mEq/kg of body weight, or 3500 mEq for a 70 kg individual.
- *Intracellular K^+* . K^+ is predominantly an intracellular cation. Ninety-eight per cent of the K^+ in the body is located within cells, where its average concentration is 150 mEq/L.
- *Extracellular fluid (ECF)* contains only 2% of the total body K^+ , where its normal concentration is approximately 4 mEq/L.

Shifts of K^+ between ICF and ECF

Hyperkalaemia, i.e. ECF K^+ concentration > 5.0 mEq/L, occurs when K^+ is shifted out of cells in following conditions:

- Insulin deficiency,
- β -adrenergic antagonists,
- Acidosis (exchange of extracellular H^+ for intracellular K^+),
- Hyperosmolarity (H_2O flows out of the cells, K^+ diffuses out with H_2O),
- Inhibition of Na^+-K^+ pump (e.g. digitalis), as when pump is blocked, K^+ is not taken up into cells,
- Exercise and
- Cell lysis (therefore, care should be taken to avoid haemolysis of RBCs for the estimation of serum K^+).

Hypokalaemia, i.e. ECF K^+ concentration < 3.5 mEq/L, occurs when K^+ is shifted into the cells, as is caused by:

- Insulin,
- β -adrenergic agonists,
- Alkalosis (exchange of intracellular H^+ for extracellular K^+) and
- Hypoosmolarity (H_2O flows into the cell, K^+ diffuses in with H_2O).

External versus internal K^+ balance

Despite wide fluctuations in dietary K^+ intake, its concentration in ICF and ECF remains constant. Two sets of regulatory mechanisms safeguard K^+ homeostasis: one type of mechanism maintains external K^+ balance and the second set of mechanism maintains the internal K^+ balance.

External K^+ balance refers to maintenance of constant amount of K^+ in the body. It is accomplished by adjusting renal K^+ excretion to match the dietary K^+ intake. Normally, all the K^+ absorbed by GIT is excreted by the kidneys. However, it is a slow process and at least takes 6 h. This arrangement ensures a long-term, chronic constancy of K^+ content. However, rapid losses of large amount of K^+ can cause serious hypokalaemia. Conversely, hyperkalaemia can occur when K^+ is absorbed from GIT or infused intravenously much faster than the kidney can excrete it.

Internal K^+ balance refers to the constancy of K^+ distribution in ICF and ECF. Rapid changes in ECF are not uncommon. After a meal, the K^+ absorbed by the GIT enters the ECF within minutes and as mentioned above, the kidney takes at least 6 h to excrete it. Therefore, certain mechanisms are required to keep a balance between ECF and ICF, otherwise even after normal meals the plasma K^+ levels will rise to fatal levels. The internal K^+ balance is maintained by various hormones which allow a rapid to and fro shift between ECF and ICF (Fig. 6.2-17).

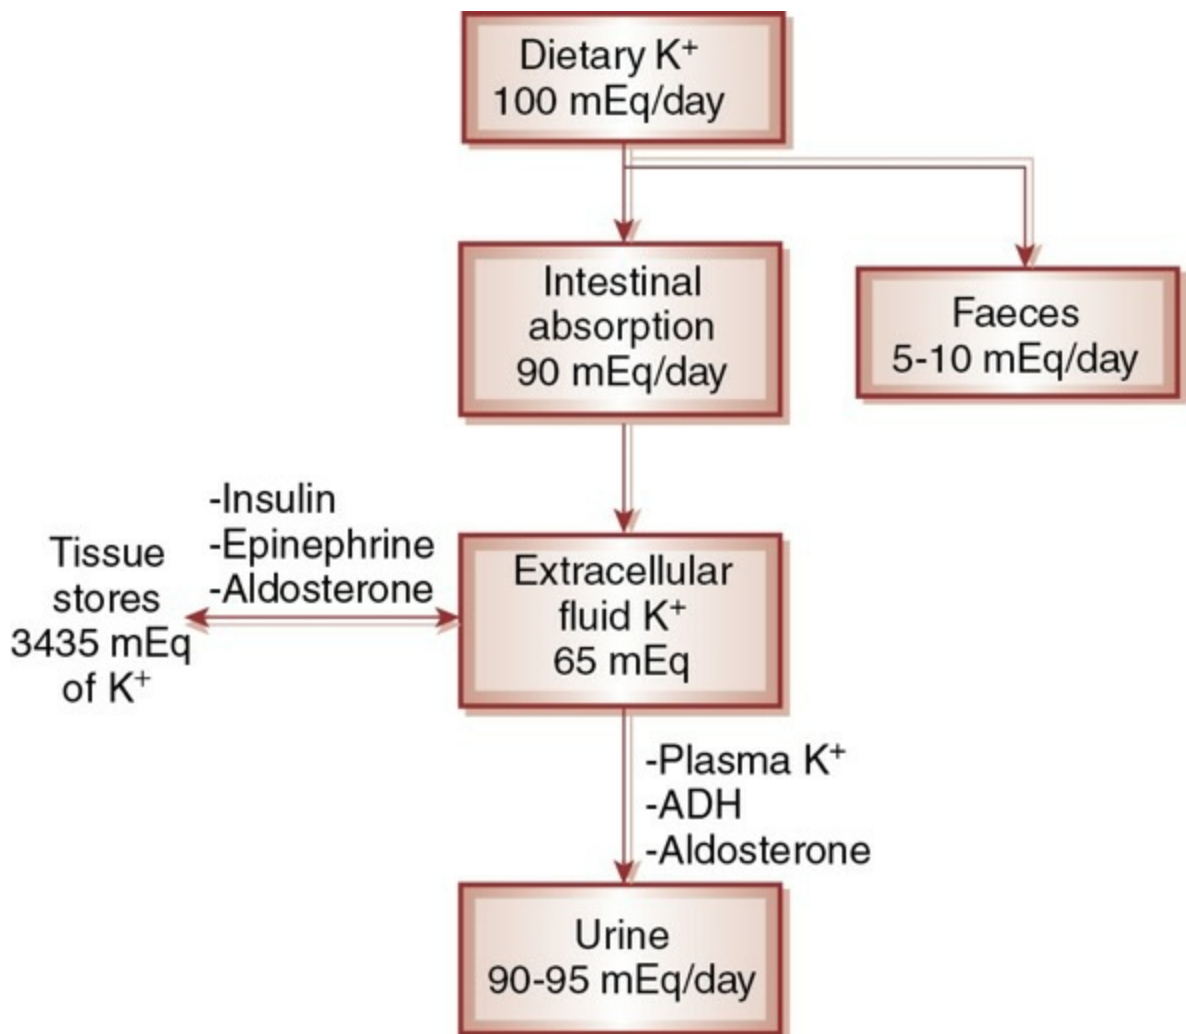

FIGURE 6.2-17 An overview of potassium homeostasis (for explanation see text).

Maintenance of internal K⁺ balance

The internal K⁺ balance is maintained by rapid redistribution of K⁺ between ICF and ECF. Factors involved in it are summarized in Fig. 6.2-17. Before discussing the role played by each factor, it will be worthwhile to understand the mechanism involved in the regulatory process.

Mechanism of control of K⁺ entry into the cells.

The primary mechanisms which affect the movement of K⁺ into and out of the cells are:

1. **Na⁺-K⁺-ATPase activity** is the main factor controlling entry of K⁺ into the cells. All the major hormones involved in maintaining internal K⁺ balance (i.e. epinephrine, insulin and aldosterone), increase K⁺ uptake of cells (particularly of skeletal muscle, liver, bone and red blood cells) by stimulating activity of the Na⁺-K⁺-ATPase pump. The activity of Na⁺-K⁺-

ATPase is increased.

- *Rapidly* (within minutes) by increased turnover rate of existing $\text{Na}^+\text{-K-ATPase}$ to handle the acute changes in plasma K^+ levels.
- *Slowly* (within hour to day) by an increase in the number of $\text{Na}^+\text{-K}^+\text{-ATPase}$ units in the membrane. The slow increase in $\text{Na}^+\text{-K}^+\text{-ATPase}$ activity is required to produce a chronic increase in K^+ uptake by the cells.

For example, an increase in plasma K^+ levels that follows K^+ absorption by GIT, stimulates insulin secretion from the pancreas, aldosterone release from the adrenal cortex and epinephrine secretion from the adrenal medulla to stimulate $\text{Na}^+\text{-K}^+\text{-ATPase}$ activity for handling the raised K^+ plasma levels. In contrast, a decrease in plasma K^+ levels inhibits the release of these hormones. It is important to note that insulin and epinephrine act within a few minutes, while aldosterone requires about 1 h to stimulate K^+ uptake into the cells.

2. **Potassium permeability.** Increase in K^+ permeability will result in loss of intracellular K^+ to ECF and vice versa. K^+ permeability increases in a condition called hypokalaemic periodic paralysis.

3. **Intracellular anions**, e.g. organic phosphates, DNA and RNA serve to counterbalance the positive charge of K^+ . Loss of these anions is associated with loss of K^+ from the cells.

Shift of K^+ between ECF and ICF

Common causes of shift of K^+ from ECF to ICF and from ICF to ECF are depicted in [Fig. 6.2-18](#).

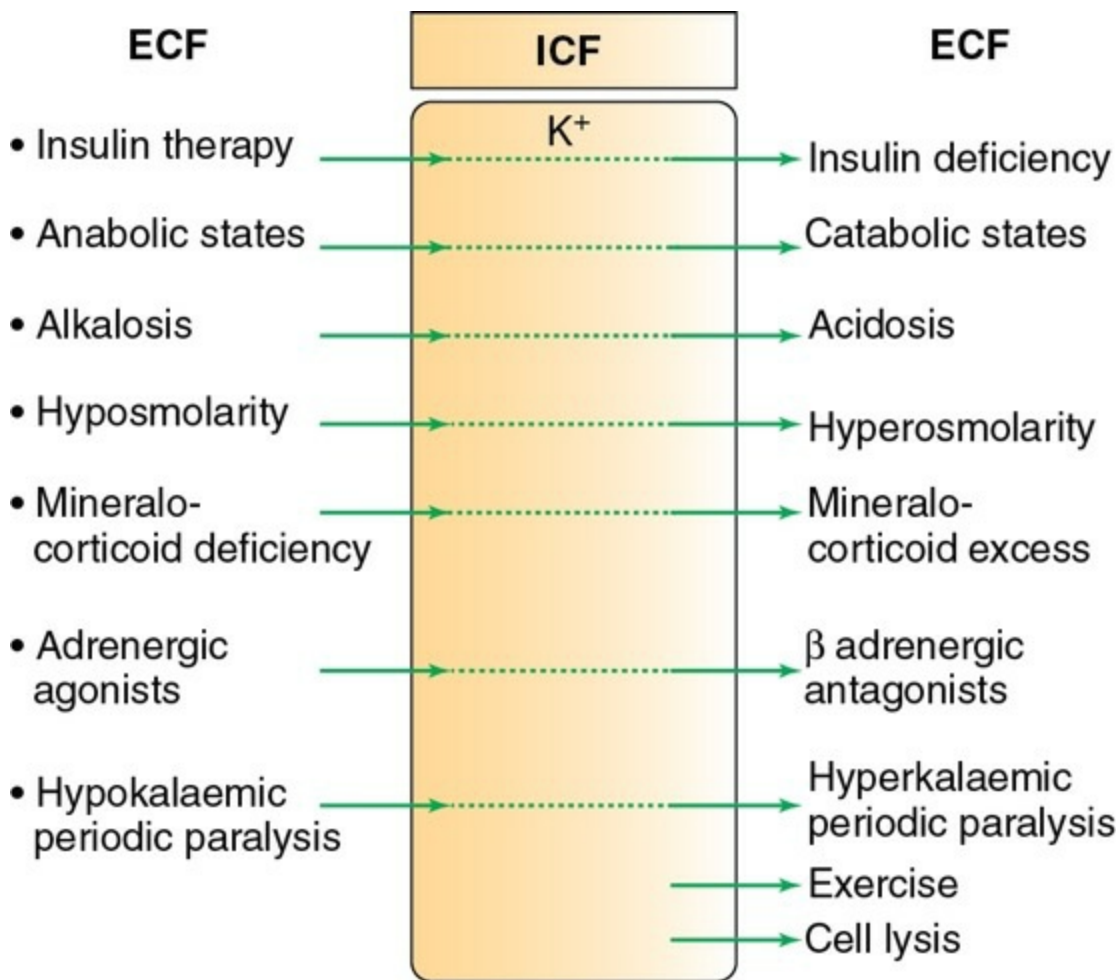

FIGURE 6.2-18 Causes of shift of K⁺ between ECF and ICF.

Role of hormones in maintaining internal K⁺ balance

1. *Epinephrine*. It influences the K⁺ distribution across the cell by activating α and β_2 receptors.

- Stimulation of α -receptors releases K⁺ from cells, especially in the liver. This mechanism is important in producing local hyperkalaemia in the muscle, which subserves two beneficial functions: vasodilatation and activation of glycogenolysis. Both activities support vigorous exercise.
- Stimulation of β_2 receptors causes K⁺ uptake by cells. This mechanism lowers plasma K⁺ during acute stress,

e.g. myocardial ischaemia.

2. **Insulin.** It is the most important hormone that shifts K^+ into cells after ingestion of K^+ in a meal by stimulating $Na^+-K^+-ATPase$. The role of insulin explains:

- Greater rise in plasma K^+ after a K^+ rich meal in an individual with diabetes mellitus (insulin deficiency) as compared to a normal person.
- Role of insulin infusion (with glucose to prevent insulin-induced hypoglycaemia) in correcting hyperkalaemia.

3. **Aldosterone.** It promotes K^+ uptake into the cells by activating $Na^+-K^+-ATPase$; therefore:

- *Hypokalaemia* occurs when aldosterone levels are increased (e.g. in primary aldosteronism) and
- *Hyperkalaemia* occurs when aldosterone level falls (e.g. in Addison's disease).

The aldosterone also stimulates urinary K^+ excretion (discussed later in this chapter).

Effect of other factors on internal K^+ balance.

Certain factors which do not contribute to K^+ homeostasis, but do affect the internal K^+ balance are described below. The extent to which these factors are able to alter plasma K^+ depends upon the integrity of homeostatic mechanisms that regulate plasma K^+ (e.g. secretion of epinephrine, insulin and aldosterone).

1. **Acid–base balance** influences the internal K^+ balance in following ways:

- *Metabolic acidosis produced by inorganic acids* (e.g. HCl and H_2SO_4) is associated with entry of H^+ into the cells and

movement of K^+ into the ECF, producing hyperkalaemia.

- *Metabolic acidosis produced by organic acids* (e.g. lactic acid, acetic acid and keto acids) usually does not produce hyperkalaemia. It is because in such circumstances, the anions enter the cell along with H^+ , and thereby eliminate the need for K^+/H^+ exchange across the cell membrane. Further, organic anions may stimulate insulin secretion which moves K^+ into the cells. This movement may counteract the direct effect of acidosis, which moves K^+ out of the cell.
- *Respiratory acidosis* has very little effect on plasma K^+ levels, because the resting membrane potential does not change when CO_2 enters the cells, or when it reacts with water to form H^+ and HCO_3^- .
- *Metabolic alkalosis* decreases plasma K^+ because K^+ enters the cells in exchange of H^+ .

2. *Plasma osmolarity* influences the internal K^+ balance as:

- *Hyperosmolarity*. In this condition, water moves out of the cells because of the osmotic gradient across the cell membrane until the intracellular osmolarity equals that of ECF. The loss of water shrinks cells and causes K^+ to rise. The rise in intracellular K^+ leads to diffusion of K^+ into the ECF, producing hyperkalaemia.
- *Hypoosmolarity*, results in hypokalaemia because of movement of K^+ into the cells by the effect just opposite to that seen in hyperosmolarity.

3. *Exercise*. During exercise, more K^+ is released from the skeletal muscle cells than during rest. This is because during the depolarization that accompanies muscle contraction, K^+ exits from the muscle cells. However, most of the K^+ released enter the T tubules, from which K^+ is rapidly taken back into the cell on repolarization, but a little K^+ does enter the interstitial fluid and plasma. Therefore, the ensuing hyperkalaemia depends on the degree of exercise. After slow walking, plasma K^+ level increases by 0.3 mEq/L, but with more vigorous exercise the K^+ levels may increase upto 2.0 mEq/L above normal. However, exercise-induced hyperkalaemia usually does not produce symptoms and is reversed after several minutes of rest. Exercise-induced hyperkalaemia is unusual under the following circumstances:

- *Patients with disturbed T tubule architecture of muscles*. Such patients may develop hyperkalaemia with minimal exercise. For example, even fist clenching may be associated with significant hyperkalaemia.
- *Patients with certain endocrine disorders* that effect release of insulin, epinephrine or aldosterone may develop potentially life-threatening hyperkalaemia.
- *Patients with impaired K^+ excretion* (e.g. renal failure) may also develop significant hyperkalaemia after exercise.
- *Individuals taking β -blockers*, e.g. propranolol for treatment of hypertension may get significant hyperkalaemia after exercise.

4. *Drug-induced hyperkalaemia* for one-third of total cases of clinically significant hyperkalaemia. Drugs that induce hyperkalaemia include:

- Potassium supplements,
- Angiotensin-converting enzyme (ACE) inhibitors,

- K^+ -sparing diuretics,
- Heparin and
- Prostaglandin-suppressing drugs.

Risk for drug-induced hyperkalaemia is increased in:

- Elderly individuals,
- Patients with diabetes mellitus and
- Patients with renal insufficiency.

Maintenance of external potassium balance

As mentioned earlier, external potassium balance refers to maintenance of constant body potassium, i.e. renal excretion matches dietary intake.

Intestinal absorption versus renal excretion

Absorption. The average diet contains approximately 100 mEq/day (~ 5 g/day) of potassium. Normally, 90% of the dietary K^+ is absorbed and about 10% is lost through faeces and sweats (Fig. 6.2-17). This amount (90%) of absorption is essentially constant, and not physiologically regulated and therefore, play little role in maintenance of the external potassium balance.

Excretion. Normally, kidneys excrete 90–95% of K^+ ingested in the diet (Fig. 6.2-17) and thus play a major role in maintaining external potassium balance. Excretion equals intake, even when intake increases by as much as 10-fold. Therefore, the K^+ excretion can vary widely from 1 to 110% of the filtered load, depending upon the dietary intake, aldosterone levels and acid–base balance. The transport pattern of K^+ by the major nephron, i.e. renal handling of the K^+ is described. It will be noted that the *main event that regulates external potassium balance is K^+ secretion* from the blood into the tubular fluid by the cells of the distal tubule and collecting duct system, and not the reabsorption in the proximal tubule which is load dependent.

Transport of potassium across major nephron

Glomerular filtration.

Filtration occurs freely across the glomerular capillaries and potassium is not bound to plasma proteins. Therefore, TF/P_{K^+} in Bowman's space is 1.00.

Tubular reabsorption and secretion.

As shown in Fig. 6.2-19, 67% of the filtered K^+ is reabsorbed in the proximal tubule, 20% in loop of Henle and approximately 10% is delivered to the early distal tubule. In contrast to proximal tubule and loop of Henle, which are capable of only reabsorbing K^+ , the distal tubule (DT) and collecting duct (CD) are able to either reabsorb or secrete K^+ . The role of reabsorption or secretion by DT and CD depends on a variety of hormones and factors.

FIGURE 6.2-19 Potassium transport along the nephron: **A**, during dietary potassium depletion; and **B**, during normal and increased dietary intake.

Reabsorption of K^+ by proximal tubule.

In proximal tubule, potassium reabsorption is load dependent like that of Na^+ . Two mechanisms involved in K^+ reabsorption are:

1. **Beek flow** or solvent drag. By this mechanism, approximately 7% of the filtered K^+ is reabsorbed passively in proportion to the H_2O reabsorption.
2. **Paracellular transport**. About 60% of the filtered K^+ is reabsorbed actively by a unique paracellular transport, which has the following steps (Fig. 6.2-20):
 - **Concentration gradient** is created between the paracellular

space and tubules fluid by active K^+ uptake via Na^+-K^+ -ATPase located in the lateral cell membrane facing the lateral intercellular spaces.

- *Diffusion of K^+ along the concentration gradient* occurs from the tubular lumen into the lateral intercellular spaces. In this way, luminal fluid equilibrates with low K^+ concentration in the intercellular space.
- *Exit from basolateral membrane* of most of the K^+ that enters the cell actively from lateral surface (as described above), occurs by three pathways ([Fig. 6.2-20](#)):
 - The conductive K^+ channel,
 - The K^+-Cl^- cotransporter and
 - The Na^+-K^+ -ATPase pump.

FIGURE 6.2-20 Mechanism of K^+ reabsorption in proximal tubule cells.

The K^+ that exits from the basolateral membrane is immediately absorbed in the peritubular capillaries.

Reabsorption of K^+ by loop of henle.

Twenty per cent of the filtered K^+ is reabsorbed in the thick ascending limb (TAL) of loop of Henle, along with Na^+ reabsorption by two mechanisms:

1. $Na^+-K^+-2Cl^-$ active transport mechanism. Salient points of this mechanism are described on page 500 and depicted in Fig. 6.2-13.
2. Paracellular passive reabsorption occurs as a function of voltage gradient across the thick ascending limb. For details see page 493 and Fig. 6.2-13.

Reabsorption and secretion of K^+ by distal tubule and collecting duct

Early distal tubule. Normally, in the distal convoluted tubule, K^+ is secreted. However, when there is need to conserve body K^+ (e.g. during K^+ depletion), K^+ is reabsorbed. Both, secretion as well as reabsorption occurs in the same cell, i.e. distal tubular cell, depending upon the status of K^+ balance in the body.

Late distal tubule and collecting duct either reabsorb or secrete K^+ , depending upon the dietary intake.

- **Reabsorption of K^+** occurs only when the dietary intake is very low (i.e. during K^+ depletion). Under these circumstances, K^+ excretion can be as low as 1% of the filtered load (Fig. 6.2-19A), because the kidneys conserve as much K^+ as possible.
- **Intercalated cells** are involved in the reabsorption of K^+ . Exact mechanism and cellular pathway of reabsorption is still not known. Probably, $H^+-K-ATPase$ located in the apical cell membrane plays a role.
- **Secretion of K^+** is variable and accounts for the wide range of urinary K^+ excretion, depending upon the dietary K^+ intake, aldosterone levels, acid–base status and urine rate of flow.

Principal cells are involved in the K^+ secretion.

Mechanism of K^+ secretion is as follows (Fig. 6.2-15):

- At the basolateral membrane, K^+ is actively transported into the cell by $Na^+-K^+-ATPase$. As in all cells, this mechanism maintains a high intracellular K^+ concentration.
- At the apical membrane, K^+ is passively secreted into the lumen through K^+ channels, down its electrical and chemical gradient.
- **Regulation of K^+ secretions.** See regulation of urinary K^+ excretion.

Hormones and factors that regulate urinary K^+ excretion

As mentioned earlier, regulation of urinary K^+ excretion is achieved mainly by alterations in K^+ secretion by principal cells of the distal tubule and collecting ducts. In a nutshell, K^+ secretion by the principal cells is increased when the electrochemical driving force for K^+ across the apical membrane is increased and vice versa. Hormones and other factors involved in regulation of K^+ tubular secretion and thus of urinary K^+ excretion, include:

- Plasma K^+ level,
- Aldosterone,
- Glucocorticoids,
- Antidiuretic hormone,
- Acid–base balance,
- Flow of tubular fluid and
- Luminal anions.

1. *Plasma K^+ level*, which mainly depends on

- *Dietary intake* of K^+ , is an important determinant of K^+ secretion by principal cells (Fig. 6.2-21). Hyperkalaemia, resulting from a high K^+ diet or any other factor (e.g. rhabdomyolysis), stimulates K^+ secretion within minutes.
- *Mechanisms* involved in high secretion of K^+ in hyperkalaemia are:
 - *Stimulation of $Na^+-K^+-ATPase$* , caused by hyperkalaemia, increases K^+ uptake across the basolateral membrane. Increased levels of intracellular K^+ increase the electrochemical gradient across the apical membrane.

- *Permeability of apical membrane* to K^+ is increased by hyperkalaemia.
- *Aldosterone secretion* is increased by hyperkalaemia, which (as discussed below), acts synergistically with plasma K^+ levels to stimulate K^+ secretion.
- *Flow rate of tubular fluid* is increased by hyperkalaemia, which (as discussed below) stimulates K^+ secretion by principal cells.
- *Hypokalaemia*, resulting from a low K^+ diet or other factors (e.g. diarrhoea) decreases K^+ secretion by mechanisms opposite to those described for hyperkalaemia. In addition, hypokalaemia also stimulates α -intercalated cells to reabsorb K^+ by the H^+-K^+ -ATPase.

2. *Aldosterone*. Salient points on the role of aldosterone in regulating K^+ secretion by principal cells are:

- *Aldosterone secretion is increased* by hyperkalaemia and angiotensin II (after activation of renin–angiotensin system).
- *Aldosterone secretion is decreased* by hypokalaemia and atrial natriuretic peptide (ANP).

Acute increase in aldosterone does not increase K^+ secretion. This is because of the fact that due to acute increase in Na^+ and water reabsorption caused by aldosterone the tubular flow is decreased, which in turn decreases K^+ secretion (as discussed below in detail).

- *Chronic rise in aldosterone level increases K⁺ secretion by the principal cells via following mechanisms:*
 - By increasing Na⁺-K⁺-ATPase activity.* Aldosterone increases the amount of Na⁺-K⁺-ATPase in principal cells. This leads to increased pumping of Na⁺ out of the cell in the basolateral membrane and increased Na⁺ entry into the cells across the luminal membrane. Stimulation of Na⁺-K⁺-ATPase simultaneously increases K⁺ uptake into the principal cells, increasing the intracellular K⁺ concentration and the driving force for K⁺ secretion.

It is important to note that chronic stimulation of Na⁺ reabsorption results in volume expansion and thereby returns tubular flow to normal and thus does not affect the K⁺ secreting action of aldosterone. Further, like other steroid hormones, the action of aldosterone takes hours to develop because new protein synthesis is required.

- By making the transepithelial potential difference (TEPD) more lumen negative.* By increasing the Na⁺ reabsorption from lumen, the aldosterone makes the TEPD more lumen negative which in turn favours K⁺ secretion;
- By increasing the permeability of apical membrane to K⁺,* aldosterone increases K⁺ secretion.

3. *Glucocorticoids* indirectly increase K⁺ excretion by increasing GFR, which increases tubular flow. Increased tubular flow increases K⁺ secretion (as discussed below).

4. *Antidiuretic hormone*. ADH increases Na^+ and water reabsorption and decreases the tubular flow, which in turn decreases K^+ secretion (as discussed below). However, the ADH-induced increased Na^+ uptake across the luminal membrane of the principal cells creates an electrochemical gradient which increases K^+ secretion into the lumen. In this way, the inhibitory effect (through decreasing tubular flow) and stimulatory effect (through increasing electrochemical driving force for K^+) of ADH on K^+ secretion enable urinary K^+ excretion to be maintained constant, despite wide fluctuations in water excretion.

5. *Flow of tubular fluid*. Salient points of effect of flow of tubular fluid on K^+ secretion are:

- *Tubular flow rate* is increased by ECF volume expansion and with diuretic therapy; while it is decreased in volume contraction caused by severe haemorrhage, or vomiting or diarrhoea.

Increase in tubular fluid flow increases K^+ secretion rapidly, while decrease in tubular fluid flow decreases the secretion of K^+ by distal tubule and collecting ducts by following two mechanisms:

- *Change in the electrochemical driving force for K^+ across the apical membrane*. K^+ secretion in the tubular fluid leads to increased K^+ levels in the fluid and thus reduces the electrochemical driving force for K^+ exit across the apical membrane. The increased tubular fluid flow rate prevents the rise in K^+ concentration as the secreted K^+ is immediately washed down the stream.
- *Stimulation of K^+ uptake across basolateral membrane*. Increased tubular flow rate increases the amount of Na^+ reabsorbed across the apical membrane of principal cells. The increased Na^+ reabsorption in turn

increases the K^+ uptake across the basolateral membrane by increasing the $Na^+-K^+-ATPase$ activity.

Note 1. The increase in K^+ secretion with the increase in tubular fluid flow rate is directly proportional to the dietary intake of K^+ (Fig. 6.2-22).

Note 2. Thiazide and loop diuretic increase the K^+ secretion by increasing the tubular fluid flow through the distal tubule and collecting ducts.

6. **Acid–base balance** effects the K^+ secretion by distal tubule and collecting ducts in the following manner:

- *Acute acidosis* reduces K^+ secretion by two mechanisms:
 - *By decreasing $Na^+-K^+-ATPase$ activity* across the basolateral membrane, it reduces the intracellular K^+ concentration and thus reduces the electrochemical driving force for K^+ exit across the apical membrane.
 - *By reducing the permeability of apical membrane K^+* , it decreases K^+ secretion and also tends to increase intracellular K^+ concentration.

So, as a net result of the above two mechanisms, K^+ secretion by the principal cells decreased while their K^+ content remained unchanged.

- *Acute alkalosis* has exactly the opposite effect to acute acidosis and thus as a net result increases K^+ secretion by the principal cells.
- *Chronic acidosis*, i.e. when metabolic acidosis lasts for several days, there occurs an increase in K^+ secretion by the mechanisms: depicted in Fig. 6.2-23.

Renal handling of organic substances

Renal handling of glucose

Glomerular filtration

Glucose is freely filtered into the glomerular filtrate. Filtration load of glucose increases in direct proportion to the plasma glucose concentration (P glucose). Filtered load of glucose = $GFR \times P$ glucose P_G .

Mechanism of tubular reabsorption.

All the filtered glucose is completely reabsorbed into the proximal tubule by an active transport mechanism (Fig. 6.2-24):

- *Carrier-mediated Na⁺-glucose cotransport.* Carrier protein located at the apical membrane in the proximal tubule reabsorbs glucose from tubular fluid into the blood.
- The carrier protein for glucose in early and late proximal tubule is called SGLT-2 and SGLT-1, respectively (SGLT = sodium-dependent glucose transporter).
- The carrier is driven by the Na⁺ concentration gradient which exists between the high tubular (Na⁺) concentration and the low intracellular (Na⁺) gradient produced by the pumping out of Na⁺ through the basolateral surface.
- Phlorhizin, (a plant glucoside) inhibits glucose transport in kidney by binding with carrier protein SGLT₂.
- *Facilitated diffusion* moves the glucose out of the cell through the basolateral membrane. The carrier for facilitated diffusion across the basolateral membrane in early and late proximal tubule is called GLUT-2 and GLUT-1, respectively (GLUT = glucose transporter).

FIGURE 6.2-24 Mechanism of glucose reabsorption in: **A**, early proximal tubule; and **B**, late proximal tubule.

Characteristics of glucose transport and glucose excretion.

Glucose is reabsorbed by a transport maximum process, i.e. there is a limited number of Na^+ -glucose carriers. The characteristics of glucose transport and glucose excretion can be elicited from the glucose titration curve which is constructed by plotting the following pairs of variables:

- The filtered load against plasma glucose concentration,

- The excretion rate against plasma glucose concentration and
- The difference between the filtered load and excretion rate (i.e. maximum tubular reabsorption capacity, T_r) against plasma concentration.

Glucose titration curve (Fig. 6.2-25) depicts that:

FIGURE 6.2-25 Glucose titration curve (for details see text).

Filtered load increases with the plasma glucose concentration (P_G).

Renal threshold, i.e. the plasma glucose concentration at which glucose first appears in the urine (glycosuria) is about 180–200 mg%. At plasma levels below the renal threshold, the reabsorption of glucose is complete (100%), i.e. all of the filtered glucose can be reabsorbed because plenty of carriers are available and hence no glucose is excreted in urine. In this region, the line of reabsorption is the same as that of filtration.

Transport maximum (T_m) refers to the plasma concentration at which carriers are fully saturated. As shown in Fig. 6.2-25, beyond plasma

glucose concentration of 350 mg% (T_{mG}), the reabsorption rate does not increase, i.e. becomes constant and is independent of P_G . Thus, beyond T_{mG} levels, all the additional filtered glucose is excreted in the urine. Therefore, as the T_{mG} is reached, the urinary excretion rate increases linearly with increase in plasma glucose concentration (Fig. 6.2-25).

Splay refers to the region of the glucose curve between threshold and T_{mG} , i.e. between P_G 180 and 350 mg%. It represents the excretion of glucose in urine before the T_{mG} is fully achieved. Note in the region of splay, the reabsorption curve is rounded, indicating that though the reabsorption rate is increasing with increase in P_G , the reabsorption is less than filtration. Similarly, the excretion curve is also rounded in the region of splay, indicating that though the urinary excretion is increasing with increase in P_G , there is no linear relation.

Causes of splay are:

- *Heterogeneity in glomerular size, proximal tubular length and number of carrier proteins for glucose reabsorption.* For example, a nephron with a large glomerulus (i.e. a high filtered load), or a short proximal tubule (i.e. low reabsorptive capacity) will spill glucose into the urine at a lower P_G than predicted from the T_{mG} for the whole kidney.
- *Variability in T_{mG} of the nephron.* For example, there is variability in the number of glucose carriers, the transport rate of the carriers and the binding affinity of the Na^+ -glucose carriers.

Renal handling of proteins, peptides and amino acids

Normally, a small amount of protein is filtered by the glomerulus and almost all is absorbed in the proximal tubule (see page 497). Normally, upto 150 mg of proteins are excreted daily in urine and of this only 15 mg is albumin and the rest are low molecular weight proteins (LMWP). About 25 mg of LMWP are the *Tamm-Horsfall* proteins derived from the cells of thick ascending limb (TAL). The rest are derived from plasma proteins and include microproteins, lysozymes and light chains of immunoglobulins.

Proteinuria

Proteinuria is labelled when excretion of proteins in urine is more than 150 mg/day. It may be of the following types:

1. **Glomerular proteinuria** occurs when the glomerular permeability increases and allows albumin and other large proteins to be filtered.
2. **Tubular proteinuria**. Normally, low molecular weight proteins enter the glomerular filtrate in fairly large amounts. When tubular reabsorption for these proteins is impaired, e.g. in *tubulointerstitial disorders and Fanconi's syndrome*, then large amounts of low molecular weight proteins are excreted in urine.
3. **Overflow proteinuria** occurs when the amount of LMWP filtered exceeds the reabsorptive capacity of the tubules. Such a situation may arise when plasma levels of LMWP are increased, e.g. in multiple myeloma, in which large amounts of an abnormal protein called *Bence-Jones* proteins appear in the plasma.
4. **Nephrogenic proteinuria** occurs when tubular enzymes such as N-acetyl β -glucosaminidase (NAG) and γ -glutamyltransferase (γ -GT) are released following damage to the proximal tubular cells.

Renal handling of urea

Glomerular filtration

Urea is freely filtered into the glomerular filtrate. The amount of urea filtered by glomerular capillaries varies with the protein intake. A high protein diet increases the amount of urea filtered, which in turn increases the ability of kidney to concentrate the urine and low protein diet reduces filtration and thus the ability to concentrate the urine.

Tubular transport

- **Proximal tubules** reabsorb 5% of the filtered urea passively.
- **Proximal straight tubule** (PST), **descending thin segment** (DTS) and **ascending thin segment** (ATS) of the nephron receive urea by diffusion (*tubular secretion*) from the interstitium of renal medulla, in which urea is present in high concentration.
- **Thick ascending limb** (TAL), DCT, CNT, CCD and OMCD are all impermeable to urea.
- **Inner medullary collecting duct** (IMCD) reabsorbs large amounts of urea employing a specialized *urea transport protein* (UT-A). There are at

least four isoforms of transport protein UT-A in the kidneys (UT-A1–UT-A4), (UT-B is found in erythrocytes). This protein is stimulated by ADH which consequently increases urea permeability of the IMCD.

Urea recycling.

Urea recycling involves following steps (Fig. 6.2-26):

1. *Concentration of urea in collecting duct* (CCD and OMCD), as mentioned above, the nephron segment distal to ATS (i.e. TAL, DCT, CNT, CCD and OMCD) are all impermeable to urea. Therefore, as water is reabsorbed from the CCD, OMCD and the initial part of IMCD, urea gets more and more concentrated within the collecting duct.
2. *Rapid and massive reabsorption of urea by IMCD*, as described above, increases the concentration of urea in medullary interstitium. Urea transport in collecting duct is mediated by UT-A₁.
3. *Carriage of urea by vasa recta to renal cortex interstitium*. From the medullary interstitium, most of the urea enters the vasa recta and is carried upwards towards the renal cortex by the ascending vasa recta.
4. *Tubular secretion of urea* from the renal cortical interstitium occurs into the PST of cortical nephrons. Some of the urea also enters the thin segment of the long loops of the juxtamedullary nephrons. In this way, the urea is again carried back to the IMCD from where it diffuses out again resulting in a constant recycling.

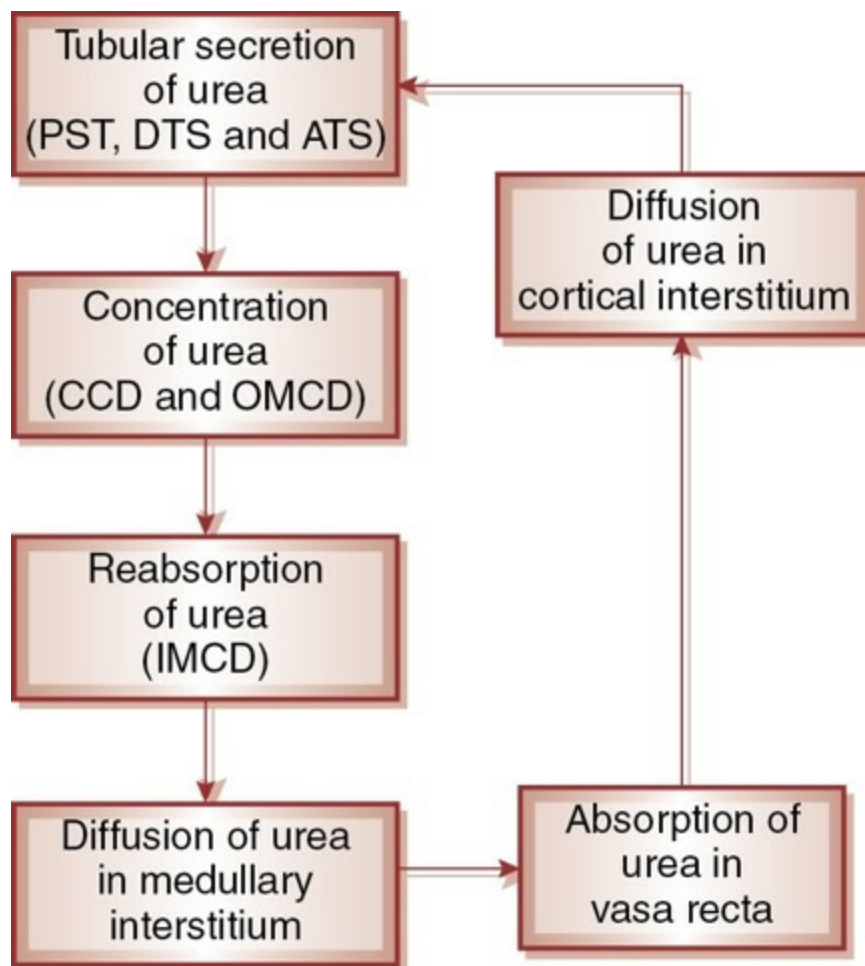

FIGURE 6.2-26 Steps involved in urea recycling.

Urea recycling plays an important role in the countercurrent system (see page 517).

Renal handling of uric acid

Glomerular filtration

Urate is freely filtered by the glomerular capillaries.

Tubular transport

Tubular transport of uric acid is limited almost exclusively to the proximal tubule (Fig. 6.2-27):

- Early proximal tubule (S1 segment) reabsorbs 95% of the filtered uric acid.
- Mid-proximal tubule (S2 segment) secretes a moderate amount of uric acid equivalent to 50% of glomerular filtrate).

- Late proximal tubule (S3 segment) reabsorbs moderate amount of uric acid (equivalent to 40% of glomerular filtrate). This is called postsecretory reabsorption.

FIGURE 6.2-27 Tubular transport of uric acid: reabsorption, secretion and postsecretory reabsorption.

Mechanism of uric acid reabsorption.

The uric acid is reabsorbed by two mechanisms:

- *Passive reabsorption* occurs through *paracellular* pathway.
- *Secondary active transport*, which occurs through transcellular pathways, involves the following steps ([Fig. 6.2-28](#)).

- Across apical membrane, the uric acid enters the cell by countertransport with intracellular anions like Cl^- , HCO_3^- and also organic anions like lactate. The carrier protein involved is called *urate transport protein*.
- Across the basolateral membrane, the urate moves out using another anion-exchanger. The same anion-exchangers are employed for urate secretion also.

FIGURE 6.2-28 Mechanism of urate reabsorption in proximal tubule cell.

Summary of effects of renal handling of common solutes and water

Effects of renal handling (glomerular filtration and tubular transport) of common solutes and water are summarized in [Table 6.2-5](#).

TABLE 6.2-5**Effects of Glomerular and Tubular Function on Water, Electrolytes and Solutes in a Normal Human Adult on an Average Diet**

Substance	Measure	Filtered	Reabsorbed	Secreted	Excreted	Percentage reabsorption	Location
Na ⁺	mEq	26,000	25,850	–	150	99.4	P, L, D, C
K ⁺	mEq	720	620		100	86.1	P, L, D, C
Cl ⁻	mEq	18,000	17,850	–	150	99.2	P, L, D, C
HCO ₃ ⁻	mEq	4900	4900	–	–	100	P, D
Ca ²⁺	mEq	540	530	–	10	98.2	P, L, D, C
Glucose	mmol	800	800	–	0	100	P
Urea	mmol	870	435	–	435	50	P, L, D, C
Creatinine	mmol	12	1	1	12	–	–
Uric acid	mmol	50	49	4	5	98	P
Total solutes	mosm	54,000	53,400	100	700	98.9	P, L, D, C
Water	L	180	178.5	–	1.5	99.2	P, L, D, C

P, proximal tubule; L, loop of Henle; D, distal tubule; and C, collecting duct.

Concentration, dilution and acidification of urine

CONCENTRATION AND DILUTION OF URINE: A MECHANISM TO REGULATE URINE VOLUME AND OSMOLALITY

- Introduction
 - Purpose of concentration and dilution of urine
 - Principal factors involved
- Medullary hyperosmolality and medullary gradient
 - Countercurrent system
 - Countercurrent multipliers
 - Countercurrent exchanger
- Mechanism of urine dilution and concentration
 - Production of diluted urine
 - Production of concentrated urine
 - Urine volume and osmolality changes in response to water intake and water deprivation
 - Factors affecting urinary concentration and dilution mechanisms
 - Assessment of renal diluting and concentrating

ability

- Clinical disorders related to the concentration and dilution of urine

ACIDIFICATION OF URINE

- Hydrogen ion secretion
- Reabsorption of filtered HCO_3^-
- Generation of new HCO_3^-
- Excretion of H^+ as titrable acid
- Excretion of H^+ as ammonium ion

Concentration and dilution of urine: A mechanism to regulate urine volume and osmolality

Introduction

The kidneys possess a unique property of regulating the volume and osmolality of the urine formed by the mechanism of concentrating and diluting the urine as per the need of the body.

Purpose of concentration and dilution of urine. The main purpose is to maintain the osmolality and volume of the body fluids within a narrow range, which is accomplished by kidneys in concert with other systems by regulating the excretion of water and NaCl, respectively. The present discussion pertains to urine concentration and dilution, the mechanism which controls the amount of water excreted relative to the amount of solute excreted and thus regulates the plasma osmolality by varying urine osmolality.

The kidney can produce urine with osmolality as low as 30 mOsm/kg H_2O to as high as 1400 mOsm/kg H_2O by changing the water excretion as high as 23.3 L/day to as low as 0.5 L/day, respectively (Table 6.3-1). From the figures shown in Table 6.3-1, two important facts which need to be noted are:

- First, at least 87% of the filtered water is reabsorbed even when urine

volume is 23.3 L/day; and

- Second, that the reabsorption of the remainder of the filtered water be varied without affecting the total solute excretion, i.e. when the urine is concentrated, water is retained in excess of solutes, and when it is dilute, water is lost from the body in excess of solutes.

TABLE 6.3-1

Effects of Concentration and Dilution Mechanism on Volume and Osmolality of Urine. In Each Case, the Osmotic Load Excreted is Same (700 mOsm /Day)

Character of urine formed	GFR (ml/min)	Percentage of filtered water reabsorbed	Urine volume (L/day)	Urine concentration (mOsm/kg H ₂ O)	Gain or loss of urine formed of water in excess of solute (L/day)
Urine isotonic to plasma	125	98.7	2.4	290	–
Concentrated urine (vasopressin: maximal antidiuresis)	125	99.7	0.5	1400	1.9 gain
Dilute urine (no vasopressin: complete diuresis diabetes insipidus)	125	87.1	23.3	30	20.9 loss

Principal factors.

Principal factors responsible for mechanism of concentration and dilution of urine are:

- Antidiuretic hormone and
- Hyperosmolality and osmolality gradient in medullary interstitium of kidneys.

The details about antidiuretic hormone (ADH) are described on page 691. It will be useful to go through these pages before proceeding further. After an overview of hyperosmolality and osmolality gradient of medullary interstitium, the role of these two principal factors is concentration and dilution of the urine, which is discussed separately.

Medullary hyperosmolality and medullary gradient

Interstitial fluid of the medulla is critically important in concentrating the urine, because the osmotic pressure of this fluid provides the driving

force for reabsorbing water from both the descending thin segment (DTS) and the collecting duct.

Normal osmolality of plasma and other body fluids is about 300 mOsm/kg H₂O. The interstitial fluid of the renal cortex has the same osmolality as that of plasma, i.e. 300 mOsm/kg H₂O with virtually all osmoles attributable to NaCl. The osmolality of the renal medulla is higher than the plasma (i.e. *hyperosmolar*) and that it goes on increasing progressively from about 300 mOsm/kg H₂O at corticomedullary junction to about 1200 mOsm/kg H₂O at papilla (medullary gradient) where a maximally concentrated urine is excreted (Fig. 6.3-1). This hyperosmolality and medullary gradient is generated and maintained by the so-called countercurrent system.

FIGURE 6.3-1 Osmolality gradient of renal medullary interstitium (values are in mOsm/kg H₂O).

Counter current system

A countercurrent system refers to a system in which the inflow runs parallel to, counter to, and in close proximity to the outflow for some distance. The countercurrent flow system is formed by U-shaped tubules. The effect of countercurrent system can be best understood by studying the effect of a heater on a straight water pipe and a pipe bent in U shape (Fig. 6.3-2). Let us suppose, the heater raises the temperature of flowing fluid through the straight tube at a constant flow rate by 10°C from 30 to 40°C (Fig. 6.3-2A). Now, if the pipe is bent in a U shape and the two limbs are brought in close proximity, the temperature at the outlet is again 40°C, but a gradient of temperature is set up along the pipe in such a way that at the bend of the pipe the temperature is not raised from 30 to 40°C but from 30 to 100°C (Fig. 6.3-2B). This is because the outgoing fluid warms the incoming fluid and sets up the countercurrent system.

In the kidney, the structures which form the countercurrent system are loop of Henle and the vasa recta. In both, the direction of flow of fluid in the descending limb is just the opposite to that of the ascending limb. Thus, the countercurrent system of the kidney consists of two components:

- *Countercurrent multiplier*, which is formed by the operation of loop of Henle and is responsible for the production of hyperosmolality and a gradient in renal medulla and
- *Countercurrent exchanger*, which is formed by the operation of vasa recta and is responsible for maintenance of the medullary gradient and hyperosmolality.

FIGURE 6.3-2 Understanding the principle of countercurrent system. Effect of heating on water flowing at a constant rate: **A**, from a straight pipe; and **B**, from a U-shaped bent pipe (countercurrent effect).

Counter current multipliers

The working of countercurrent multiplier, that operates in the loop of Henle and generates hyperosmolarity and medullary gradient, can be best understood by describing it as two processes:

- Origin of single effect and
- Multiplication of the single effect.

Origin of single effect.

The single effect is the main driving force behind the countercurrent multiplier. It is the name given to the osmotic gradient of approximately 200 mOsm that exists between the ascending limb of loop of Henle and the surrounding interstitial fluid. These are the juxtamedullary nephrons which are more important for the production of medullary hyperosmolarity. The cortical nephrons contribute to production of hyperosmolarity in the outer medulla mainly. The mechanism of origin of single effect in outer medulla is different from that of the inner medulla.

Mechanism of origin of single effect in outer medulla.

As shown in Fig. 6.3-3, the thick ascending limb (TAL) of loop of Henle is located in the outer medulla, and not in the inner medulla. TAL is impermeable to water. So NaCl and other solutes are actively absorbed in this segment without water, as a result, the tubular fluid osmolality decreases to less than plasma. This is why; this segment is called the diluting segment. The NaCl reabsorbed in this segment raises the osmolality of outer medullary interstitium by about 200 mOsm. This separation of solute and water by the TAL leading to osmolality difference between that tubular fluid and interstitial fluid is called single effect and is the main driving force behind the countercurrent multiplier.

FIGURE 6.3-3 Location of different components of cortical nephron and juxta cortical nephron with particular reference to origin of single effect in outer versus inner medulla.

Origin of single effect in inner medulla.

Three different mechanisms contribute to the origin of single effect (and thus, ultimately to the development of medullary gradient and hyperosmolality after multiplication) in the inner medullary interstitium. These include:

- Passive transport of sodium ions from ascending thin segment into the interstitium,
- Active transport of sodium from the inner medullary collecting duct and
- Diffusion of urea from the collecting duct into the medullary interstitium (when ADH concentration is high in blood).

1. Passive transport of sodium ions from ascending thin segment

As shown in [Fig. 6.1-2](#), the inner medulla contains ascending thin segment (ATS) of loop of Henle of juxtamedullary nephrons, which is impermeable to water and does not have the property to actively absorb solutes (c.f. TAL). The single effect is, therefore, produced by the passive diffusion of solutes, which occurs because of difference in the composition of tubular fluid and that of interstitium. The tubular fluid in the ATS is relatively rich in NaCl and but has less urea in it compared with the interstitium. Consequently, NaCl moves out from the ATS into the interstitium and urea moves into the ATS from the interstitium. However, the rate at which NaCl diffuses out far exceeds the rate at which urea diffuses into the lumen of ATS. Thus, as a net result, more solute diffuses out in the interstitium, raising the inner medullary osmolality (single effect).

2. Reabsorption of sodium ions from medullary part of collecting duct

In addition to the passive diffusion of Na^+ from ascending thin segment (ATS), smaller quantities of ions are also transported from medullary part of the collecting duct into the medullary interstitium, particularly in the inner part of medulla near renal sinus. As described on page 501, Na^+ is actively transported by the principal cells of the collecting duct, which is followed by electrogenic passive absorption of chloride ions.

3. Role of urea

Urea plays an important role in the development of medullary osmotic gradient, especially when concentration of ADH is high in the blood. Under such circumstances, inner medullary collecting duct (IMCD) absorbs large amount of urea employing a specialized urea transport protein (UT-A) (see page 512). Further, there occurs urea recycling (see page 512), which plays an important role in the countercurrent system.

Multiplication of the single effect.

The hyperosmolality and medullary gradient is in fact generated by the multiplication of the single effect by the countercurrent multiplier. The main characteristics of the components of countercurrent multiplier which play role in multiplication of single effect are ([Table 6.3-2](#)):

- High permeability of a descending thin segment to water.
- Impermeability to water but high permeability to NaCl .
- Impermeability to water and ability to actively absorb solutes by thick ascending limb (TAL).

- In renal medulla, all other tubular structures (except ascending limb) are in osmotic equilibrium. The descending limb, therefore, acquires the increased osmolality of the surrounding fluid. The effect is multiplied as new iso-osmolar filtrate arrives at the descending limb and forces the concentrated tubular contents towards the tip of loop of Henle (hair pin band).

TABLE 6.3-2

Permeability and Transport in Various Segments of the Nephron

Segment of nephron	Permeability and transport of			
	H ₂ O	Urea	NaCl	Na ⁺
<i>Loop of Henle</i>	4+	+	±	0
• Thin descending limb	0	+	4+	0
• Thin ascending limb	0	±	±	4+
• Thick ascending limb	±	±	±	3+
<i>Distal convoluted tubule</i>	±	±	±	3+
<i>Collecting duct</i>				
• Cortical collecting duct (CCD)	*3+	0	±	2+
• Outer medullary collecting duct (OMCD)	*3+	0	±	1+
• Inner medullary collecting duct (IMCD)	*3+	3+	±	1+

*These values are in the presence of ADH. In the absence of ADH, these values are positive.

The process of multiplication of single effect can be best understood by dividing the whole process in hypothetical steps, leading to normal equilibrium condition. These steps are summarized (Fig. 6.3-4):

- *Initially*, let us assume the osmolality of fluid in the descending limb and the ascending limb of loop of Henle and medullary interstitium is 300 mOsm/kg H₂O (Fig. 6.3-4A).
- Further, let us assume that the thick ascending limb (TAL) actively pumps out 100 mOsm/kg H₂O of NaCl into the medullary interstitium. Since the TAL is impermeable to water, this effect will lower the osmolality of fluid in TAL to 200 mOsm/kg H₂O and raise the osmolality of the adjacent interstitium to 400 mOsm/kg H₂O (Fig. 6.3-4B). Establishment of this osmotic gradient of 200 mOsm/kg H₂O, as described earlier, is called single effect.

- The portion of descending thin segment (DTS) which is located in the outer medulla is moderately permeable to Na^+ and highly permeable to water.
- Due to osmotic gradient created, the water moves out and Na^+ from the interstitium (osmolality 400 mOsm/kg H_2O) moves into the DTS (osmolality 300 mOsm/kg H_2O) till equilibrium is reached with osmolality of 350 mOsm/kg H_2O (Fig. 6.3-4C).
- The fresh iso-osmolar filtrate at 300 mOsm/kg H_2O trickles down into the descending loop and pushes some of the hyperosmolar fluid (350 mOsm/kg H_2O) into the ascending limb (Fig. 6.3-4D).
- In the meanwhile, hypotonic fluid flows into the distal tubule, and isotonic and subsequently hypertonic fluid (Fig. 6.3-4 E, F) flow into the ascending thick limb.
- As the process with above steps keeps repeating, the final result is a gradient of osmolality from top to bottom of the loop and surrounding interstitium.

FIGURE 6.3-4 Operation of loop of Henle as countercurrent multiplier producing a gradient of hyperosmolality in the medullary interstitium **A, B, C, D, E** and **F** are hypothetical steps involved in the process of generation of the gradient (see text for details).

Counter current exchanger

Vasa recta (the countercurrent exchanger).

If the vasa recta would have been a straight blood vessel, the osmotic gradient in the medullary pyramid would not last long, as the Na^+ and

urea in the interstitial spaces would have been removed by the circulation (Fig. 6.3-5A). However, because of the hair pin (U-shaped) anatomical arrangement, the vasa recta operates as countercurrent exchanger and retains these solutes in the medullary interstitium (Fig. 6.3-5B). Thus, the countercurrent exchanger formed by the vasa recta is responsible for the maintenance of the hyperosmolality medullary gradient generated by the countercurrent multiplier.

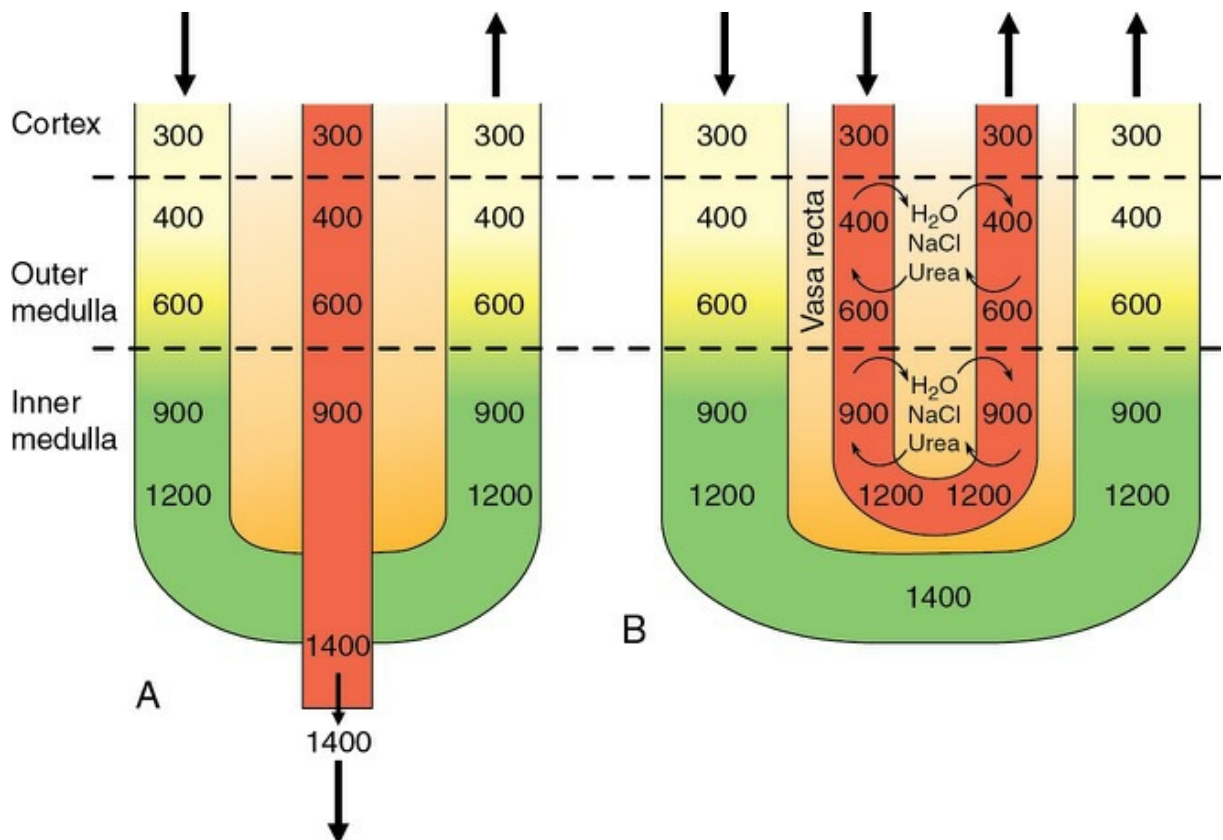

FIGURE 6.3-5 Operation of vasa recta as countercurrent exchangers in the kidney: **A**, effect on medullary osmolality if vasa recta would be a straight vessel without hairpin arrangement; and **B**, as it is a U-shaped vessel.

Operation of countercurrent exchanger.

The vasa recta, the capillary network supplying blood to the medulla, is highly permeable to the solute and water. So, in addition to bringing nutrients and oxygen to tubules within the medulla, these capillaries more importantly remove excess water and solutes, which are continuously added to the medullary interstitium by the nephron segments in this region.

- **Operation at the level of descending vasa recta.** As shown in Fig. 6.3-5B, when the descending vasa recta dips down in the medulla having a progressively increasing osmolality (from 300 to 1200 mOsm/kg H₂O), the solutes diffuse into its lumen and water diffuses out so that the blood flowing in it (with osmolality 300 mOsm/kg H₂O) equilibrates with the medullary interstitium and thus its osmolality also increases progressively.
- **Operation at the level of ascending vasa recta.** The vasa recta then loops around and ascends towards the cortex (Fig. 6.3-5B). As at the beginning of the ascending vasa recta, its blood has attained an osmolality of 1200 mOsm/kg H₂O and when it passes through an interstitium where osmolality is progressively decreasing from 1200 to 300 mOsm/kg H₂O, the solutes move out and water diffuses in, and thus the blood in it once again equilibrates with the interstitium around it.
- **Effect of operation of countercurrent exchanger on the medullary interstitium.** By the above-described operations, the solutes tend to recirculate in the medulla and water tends to bypass it, so that hypertonicity of the medulla is maintained. Since solutes (sodium and urea) are exchanged for water between the ascending and descending limbs of vasa recta, this system has been named countercurrent exchanger.

Another factor which ensures retention of sodium in the medullary interstitium is very slow rate of blood flow through the medullary parenchyma. Some important facts about working of countercurrent exchanger which need elaboration are:

- **The ability of the vasa recta to maintain the medullary interstitial gradient is flow dependent.** A substantial increase in blood flow through the vasa recta will ultimately dissipate the medullary gradient, i.e. wash out the medullary gradient. Alternatively, if blood flow is reduced, the nephron segments within the medulla will receive inadequate oxygen. Under such conditions, the tubular transport, especially by the thick ascending limb (TAL) is impaired. As a result, the medullary interstitial osmotic gradient cannot be maintained.
- Countercurrent exchanger is a passive process, as it depends upon the

diffusion of water and solutes in both directions across the permeable walls of the vasa recta. Therefore, it could not maintain the osmotic gradient along the medullary pyramids if the process of countercurrent multiplier were to cease.

Mechanism of urine dilution and concentration

Production of diluted urine

Conditions in which dilute urine is formed

Dilute urine is called hypo-osmotic urine, in which urine osmolality is less than blood osmolality. It is produced under the following circumstances:

- When the circulating levels of ADH are low (e.g. after water drinking), central diabetes insipidus (see page 696) or
- When ADH is ineffective (e.g. nephrogenic diabetes insipidus (see page 696)).

Principal factors governing formation of dilute urine

As mentioned earlier, the principal factors governing formation of dilute and concentrated urine are hyperosmolality medullary gradient and the presence or absence of ADH. The renal medullary osmotic gradient is smaller in the absence of ADH. This is because ADH stimulates both countercurrent multiplication and urea cycling.

Segmental changes in tubular fluid during formation of dilute urine

Segmental changes occurring in tubular fluid during the formation of dilute urine are summarized ([Fig. 6.3-6A](#)):

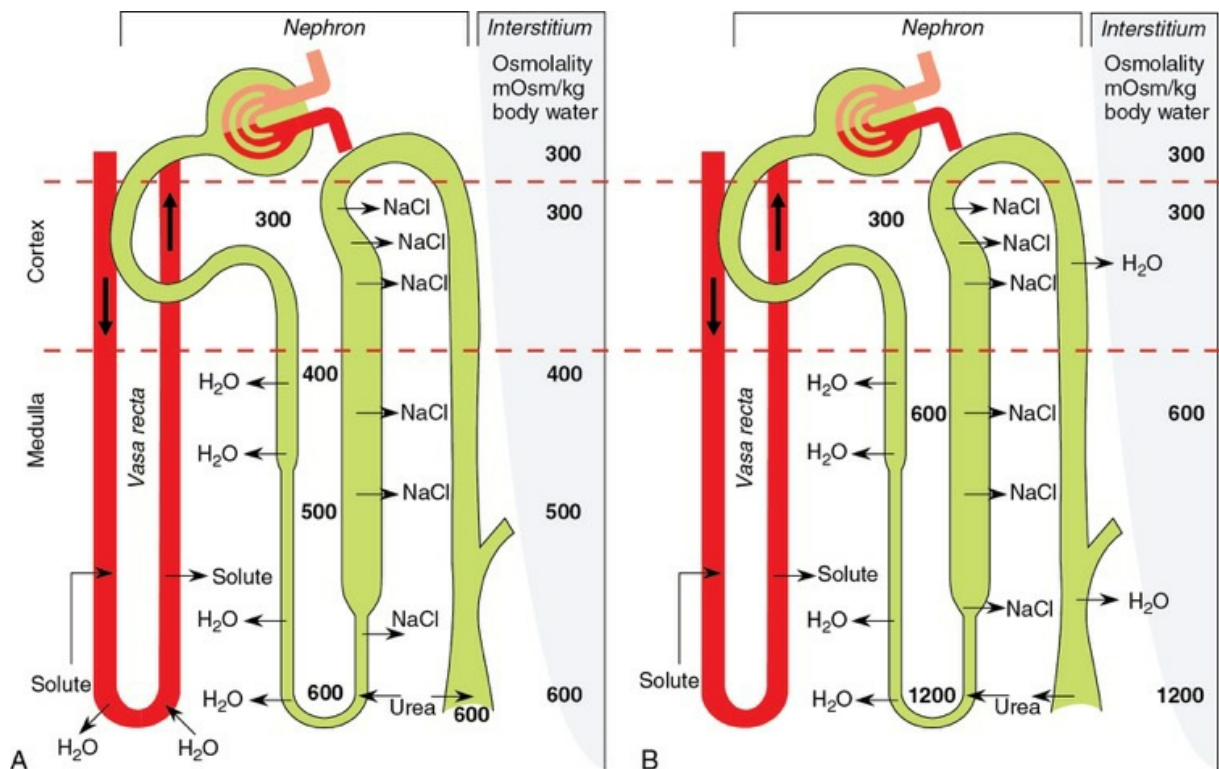

FIGURE 6.3-6 Mechanism of producing: A, dilute urine in the absence of ADH; and B, concentrated urine in the presence of ADH.

- **Proximal tubule.**

The osmolality of glomerular filtrate entering the proximal tubule is identical to that of plasma (300 mOsm/L). About 60–70% of the H₂O is reabsorbed isosmotically (with Na⁺, Cl⁻, HCO₃⁻, glucose, amino acids and so forth). As H₂O is reabsorbed isosmotically, the TF/Posm = 1.0 throughout the proximal tubule.

- **Descending thin segment of loop of henle**

receives isosmotic fluid (i.e. osmolality 300 mOsm/L) from the proximal tubule, because this segment is highly permeable to water but much less to solutes (Table 6.3-2). As thin segment descends deeper in the renal medulla, water is reabsorbed owing to the osmotic gradient set up by the progressive increasing hyperosmolality of the medulla. At the bend of loop of Henle, though the osmolality of tubular fluid and interstitium is equal, but their composition differs. The NaCl concentration is higher and that of urea is lower in the tubular fluid compared with the interstitial fluid.

- **Ascending thin segment of loop of henle**

is impermeable to water but permeable to NaCl and urea (Table 6.3-2). As the tubular fluid moves up in this segment, NaCl moves out and urea moves in. As a net result, the volume remains the same, osmolarity decreases and the concentration of NaCl decreases, but that of urea increases in the tubular fluid.

- **Thick ascending limb (TAL)**

of loop of Henle is impermeable to water and urea. Because of active absorption of NaCl without water, the tubular fluid becomes dilute (although not quite as dilute as in the presence of ADH). In this diluting segment, urine becomes hypo-osmolar for the first time, and the only time. The minimum possible osmolarity of the tubular fluid is 100 mOsm/L (i.e. 200 mOsm less than the surrounding interstitium).

- **Early distal tubule**

behaves like TAL and the tubular fluid is further diluted.

- **Late distal tubule and cortical collecting ducts.**

Cells of these segments actively reabsorb NaCl but are impermeable to urea. In the absence of ADH, the cells of these segments are impermeable to water. So, due to reabsorption of NaCl without the water, the osmolality of the tubular fluid is further reduced.

- **Medullary collecting duct**

actively reabsorbs NaCl. Even in the absence of ADH, this segment is slightly permeable to H₂O and urea. So, some urea enters the collecting duct from the interstitium and about 2% of H₂O is reabsorbed. So, in the absence of ADH, the urine will have an osmolality between 30 and 50 mOsm/L and will contain low NaCl and urea (TF/Posm < 1.0). The volume of urine excreted can be about 18 L/day or approximately 10% of glomerular filtrate: however, in extreme conditions, it may reach to 23–32 L/day (Table 6.3-2).

Production of concentrated urine

Conditions in which concentrated urine is formed

Concentrated urine is also called *hyperosmotic urine*, in which urine osmolality is more than that of blood. It is produced when circulating ADH levels are high, e.g.

- Water deprivation,
- Haemorrhage and
- Syndrome of inappropriate antidiuretic hormone, i.e. SIADH (see page 695).

Principal factors governing formation of concentrated urine

The high level of ADH is the main factor governing the formation of concentrated urine, because it:

- Increases the size of hypersomolality medullary gradient and
- Augments the urea cycling from the inner medullary collecting ducts into the medullary interstitial fluid.

Segmental changes in the tubular fluid during formation of concentrated urine

Segmental changes occurring in the tubular fluid during the formation of concentrated urine are summarized (Fig. 6.3-6B):

- *From proximal tubule to ascending thick limb and even early distal tubule*, the changes occurring in the tubular fluid are the same as during the formation of dilute urine. Only point to be noted here is that the ADH stimulates NaCl reabsorption in the thick ascending limb and therefore increases the size of medullary gradient by *countercurrent multiplier*, which is important for formation of concentrated urine.
- *Late distal tubule*. The tubular fluid entering the late distal tubule is *hypo-osmolar* (osmolality about 150 mOsm/L). In the presence of ADH, H₂O permeability of the principal cells is increased and consequently H₂O is reabsorbed until the osmolality of distal tubular fluid equals that of the surrounding cortical interstitium (300 mOsm/L) (Fig. 6.3-6B). So, at the end of the distal tubule, TF/Posm = 1.0, because osmotic equilibrium occurs in the presence of ADH. It is important to note that though the osmolality of the fluid in this segment is similar to that of the fluid, which entered the descending thin segment from the proximal tubule, its composition has altered dramatically. Because of NaCl reabsorption by the preceding nephron segments (NaCl accounts for a much smaller portion of the total tubular fluid osmolality), urea, filtered and that added in descending thin and ascending thin limb of

loop of Henle, mainly accounts for the osmolality at this juncture.

Note. ADH increases the H₂O permeability of the principal cells of late distal tubule and collecting duct through aquaporin-2 (For details about mechanism of action see page 602).
